down in medical practice at Brixham, a fishing village in the south of Devon. "My patients at Brixham," he says, "were nearly all fishing people, speaking a racy dialect. Their life is the subject of the novel, *Deep Sea*, which distantly resembles Pierre Loti's *Pêcheurs d'Islande* and is dedicated to him." *Deep Sea* was not Dr. Young's first novel. The first, called *Undergrowth*, was written in collaboration with his brother, Eric Brett Young, and published in 1913. This was followed by a long critical study of the poetry of Robert Bridges, poet laureate, and in 1914 came *The Dark Tower*, which the author describes as "an exalted love story following the lines of the old tale of Pelleas and Melisande, with the mountain country of the Welsh border for its setting." He was writing *The Iron Age*, a story of the Black Country near Birmingham, when the World War broke out, and he finished it abruptly by packing his hero off to the war and then following suit himself. Young, having offered his services to the War Office as soon as they could find a substitute for him in civil practice, joined the Royal Artillery Medical Corps early in 1915 and spent the first two years of his service in East Africa. At the end of that period he had to return because of ill health, but continued to serve the colors until after the armistice, ending with the rank of major.

As a result of his experiences in East Africa he has given us two novels, the first, *Marching on Tanga*, and later, *The Crescent Moon*, perhaps the author's best known work. It was *Marching on Tanga* which brought his name into real prominence for the first time. "Written under a stress of emotion and exaltation in a rhythmical prose that too frequently breaks into blank verse," says Compton Mackenzie; "it is a remarkable record of a remarkable experience, and it already beautifully fills in the immense library of war books a space which is assuredly a permanent one."

There are two other novels and two volumes of poetry from his pen. The novels are *The Tragic Bride* and *The Young Physician*, the latter being admittedly autobiographical; the record of a youth's development, during the last half of which period the hero is seen at a medical school. Both volumes of poetry are largely expressions of the author's emotions in East Africa. They are *Poems 1916-1918* and *Five Degrees South*. The author describes *Five Degrees South* as "a sort of lyrical commentary on *Marching on Tanga*. The poems were slender, intimate things, written to my wife and one or two of them published in the *London Times* and the *New Statesman*, but since they have been published I am always coming upon people who prefer them to all my other work."

If we are to accept the verdict of the critics, the

fiction of Dr. Francis Brett Young is extraordinary fiction and the poems are extraordinary poems. Already his work has given him an international reputation that is growing rapidly. His poetry has met with universal acclaim. Reviewers have said that as a poet his work has a distinction and merit that is rare among the unending flood of jingling rhymes, blatant nonsense, and mediocre workmanship that is constantly being poured out. His novels, the critics say, show steady progress toward a high place in the literature of the next decade. No less a critic than Hugh Walpole says of him that "among the more romantic younger English novelists he is easily the first." A fine eye for landscape, plenty of exciting action, unhackneyed scenes and situations and a finely polished style, these are characteristics of Dr. Young's fiction. His output has been heavy, considering his medical practice, his war service and his age—he is only thirty-six, having been born in 1884, the son of a country doctor, near Birmingham. More than mere byproduct is this heavy output of literature, and it would seem to indicate that before long, if not already, Dr. Francis Brett Young and the practice of medicine will part company.

THE ETIOLOGY OF CUTANEOUS PIGMENTATION.

The pathogenesis and etiology of cutaneous pigmentation are unquestionably interesting but little known, and the divers notions we possess are, to say the least, hypothetical. The appearance of dyschromias appears to be related to external and internal causes, the former being the best understood. It is known that any irritation when somewhat intense and prolonged can give rise to pigmentation of the skin, but as Darier has pointed out, these fragmentary disturbances have for the most part the character of vital reactions against an irritant, and consequently their manifestations and intensity depend less frequently on the nature of the causal agent than on the reactionary tendency of the subject. Among the irritating causes, physical agents play an important part. For example, the production of sunburn is principally due to light and in particular to the chemical rays of the spectrum. Heat may be a factor in some cases and Neisser incriminates the caloric action of furnaces in cases of syphilitic dyschromia occurring in blacksmiths and bakers. In the same way non-chemical agents can give rise to pigmentation or at least can play a secondary part as localizing agents. Vitiligo and the so-called primary pigmentary syphilitide are frequently localized in areas chronically irritated, as has been shown by Thibierge and Finger. Finally, to conclude with the external causes, beside the parasitic dyschromias whose etiology seems to

be complex, it may seem logical to include those which are secondary to the dermatoses, such as the bullæ of pemphigus, herpes zoster, boils, papulonecrotic tuberculides, etc., as well as syphilitic lesions. The macula of roseola, secondary papules, and ulcerating lesions are the starting points of pigmentary change in which either a melanoderma or a more or less atrophic leucoderma are observed.

Still other causes of dyschromia have been invoked, both general and internal, whose mechanism has been diversely interpreted. Among them hyperemia should first be mentioned; it unquestionably intervenes in pigmentations having a local or external cause, for example, the melanoderma occurring on varicose limbs. Lesions of the suprarenal capsules have for some time been recognized as a cause of the melanoderma of Addison's disease, but space forbids a discussion as to what extent renal insufficiency or lesions of the pericapsular nervous plexus act as factors. If suprarenal insufficiency is incriminated, it should be pointed out that normally the suprarenals destroy pigment or a pigmentogenous substance and that when diseased they cannot do so. Or if a sympathetic theory is maintained, it will be said that when irritated a hyperactivity of the cells secreting pigment occurs. The sympathetic and cerebrospinal systems undoubtedly play a part in many dyschromias, as in leprosy, vitiligo, and the so-called primary pigmentation of syphilis. The latter does not belong exclusively to lues because it has been observed in tuberculosis and chlorosis. On the other hand, in many ways it is similar to the chloasma of pregnancy and Addison's disease, and it may well be asked if the syphilitic dyschromia is not also consequent upon some disturbance of the pericapsular nerves resulting from the *Spirochæta pallida*.

Other dyschromias have been regarded as due to hematic changes such as malarial melanoderma and perhaps bronze diabetes. According to Diday the blood of syphilitics undergoes a peculiar change in its coloring matter which allows it to become deposited in the tissues. If for any reason congestion arises, with a consequent increase of the blood in the skin, it will progressively infiltrate the integuments and finally the coloring matter will come near enough to the surface to produce a perceptible change in hue. Petresco likens the mechanism of the pigmentary syphilide to that observed in paludism; there is an exaggerated deposit of hemoglobin coming from the destroyed red blood corpuscles, hence melanin and its deposit in the tissues. Other observers have thought that the presence of bile pigments in the blood might be the origin of a good number of dyschromias, and perhaps syphilis, which does not spare the liver, produces pigments in this way. Finally certain disturbances of pigmentation have a toxic

origin, such as arsenical melanoderma and argyria. Although the etiology of dyschromia is poorly understood, this process can be divided into primary and secondary types. The first or spontaneous type is not preceded by an eruptive element. Secondary pigmentations are those succeeding an eruptive element, which was seated at the spot where the dyschromia, melanoderma, or achromia, according to the case, ultimately arises. In the first group can be placed the melanoderma of Addison's disease, lentigo and chloasma of pregnancy. In the second group of secondary dyschromias are the melanodermias or achromias following some local dermatosis, such as pemphigus, lichen planus and varicose ulcer.

MUSIC WITH WORK.

Transplanting rice in the Philippines costs about forty centavos a day, with two meals, cigarettes and betel nut, but when music is provided the output of work is increased thirty per cent. It is often a blind man who plays. He sits on the low rice dyke and sings the old folk songs to his guitar, and frequently the workers join in the chorus. Some of the large stores in the States also tried the effect of music, with good results. We have not heard much lately concerning music in hospitals and operating rooms; perhaps the patients were of the same opinion as the Socialist press, which says that all this welfare work is enlightened selfinterest. It proceeds without taking the trouble to find out whether such patronizing efforts are desired or appreciated.

News Items.

American Dietetic Association.—This organization will meet in annual session in New York October 25th to 27th, with headquarters at the Hotel McAlpin.

Mississippi Valley Medical Association.—This organization will meet in annual session in Chicago, October 26th, 27th and 28th, under the presidency of Dr. Frank B. Wynn, of Indianapolis, Ind.

Harvey Lecture.—The second Harvey Society Lecture will be given at the New York Academy of Medicine, Saturday evening, October 30th, by Professor Jules Bordet, director of the Pasteur Institute of Brussels. His subject will be Coagulation of the Blood.

Coroner's Physician for Monroe County.—The Civil Service Commission announces an examination for the position of coroner's physician for Monroe County, N. Y. Candidates must be licensed physicians and a residence of three months in the county is required; salary \$200 a year.

Cutter Lectures on Preventive Medicine.—Dr. Theobald Smith, of the Rockefeller Institute for Medical Research, delivered the Cutter Lectures on Preventive Medicine at the Harvard Medical School on October 19th and 20th, his subject being Medical Research and the Conservation of Food Producing Animals.

Yellow Fever in Mexico.—Quarantine measures against Tampico, Mexico, on account of yellow fever, were ordered on September 27th, to be enforced at Gulf and South Atlantic ports of the United States. During the four weeks from July 19th to September 18th, fifty-two cases were reported in Vera Cruz, with twenty-eight deaths, and on September 26th Dr. Hedrick, of the United States Public Health Service, died from the disease. In Tuxpan, during the month of September, there were twenty-one deaths.

American Association of Railway Surgeons.—At the seventeenth annual meeting of this society, held in Chicago, October 6th to 8th, Dr. Clarence W. Hopkins, of Chicago, was elected president and other officers were elected as follows: First vice president, Dr. Edwin B. Shaw, of Las Vegas, N. M.; second vice president, Dr. Joseph B. Wharton, of Eldorado, Ark.; third vice president, Dr. George W. Pirtle, of Carlisle, Ind.; treasurer, Dr. Henry B. Jennings, of Council Bluffs, Ia. (reelected); secretary, De Louis J. Mitchell, of Chicago (reelected).

Assistant Medical Officer Wanted at the Port of New York.—The Civil Service Commission of the State of New York announces an examination on October 30th for the position of assistant medical officer, office of Health Officer, Port of New York; salary \$1800. Candidates must be licensed physicians. The appointee must reside at City Island and give part of his time to the inspection of vessels from foreign ports and the examination of passengers and crews for the detection of quarantinable diseases, such as cholera, plague, typhus fever, yellow fever, smallpox, and leprosy.

Pharmacologist in the Bureau of Internal Revenue.—The United States Civil Service Commission announces an examination for pharmacologist to fill a vacancy in the Bureau of Internal Revenue, Treasury Department; salary \$2,500 to \$3,000 a year. Applicants must have an M. D. degree from an institution of recognized standing, and at least an A. B. or a B. S. degree from a college or university of recognized standing, and have had at least two years' postgraduate experience in experimental pharmacology or physiology, such experience to have included study of the physiological action of drugs. Additional credit will be given to applicants who show that they have a reading knowledge of French and German.

Lectures on Industrial Health and Preventive Medicine.—The Long Island College Hospital College of Medicine announces a series of lectures and practical demonstrations on industrial health and preventive medicine to be held during the collegiate year of 1920-21. The course on industrial health will be given in the form of twelve lectures and four demonstrations by Dr. Alfred Edward Shipley, director of the New York Industrial Health Bureau, who has recently been added to the staff of the college. Preventive medicine will be discussed in a course of fifteen lectures by Dr. Edward H. Marsh, assistant professor of preventive medicine and hygiene. These lectures will be free to licensed physicians. For full particulars write the head of the department, Dr. H. Sheridan Baketel, 350 Henry Street, Brooklyn.

Flower Hospital Asks Aid.—Flower Hospital has asked for subscriptions in order that the institution may be properly maintained and its ambulance service continued. It also desires to add sixty-five beds to the 200 now in use and to provide better quarters for the nurses. An expansion of the free work of the hospital is also contemplated. The ambulance service of Flower Hospital covers a territory of 275 city blocks in the heart of Manhattan.

Far Eastern Association of Tropical Medicine.—The fourth congress of this association will be held in Batavia, Java, in August, 1921, under the presidency of Dr. W. T. de Vogel, of the Civil Medical Service. Dr. Neeb, of Batavia, is secretary of the society. Among the countries which will be represented at the congress are the Philippine Islands, Australia, New Zealand, British India, Straits Settlements, Ceylon, the French and Portuguese colonies, China, Japan, and Siam.

Meetings of Local Medical Societies.—The following local medical societies will meet in New York during the coming week:

TUESDAY, October 26th.—New York Academy of Medicine (Section in Obstetrics and Gynecology); New York Dermatological Society; New York Medical Union; Metropolitan Medical Society; New York Psychoanalytical Society; Riverside Physicians' Association; Therapeutic Club; Valentine Mott Society; Washington Heights Medical Society; Woman's Hospital Society; Clinical Society of the Hospital and Dispensary for Deformities and Joint Diseases.

WEDNESDAY, October 27th.—New York Academy of Medicine (Section in Laryngology and Rhinology); New York Society of Internal Medicine; New York Surgical Society; Brooklyn Pediatric Society.

THURSDAY, October 28th.—Hospital Graduates' Club, New York; New York Physicians' Association; Ex-Intern Society of the Methodist Episcopal Hospital, Brooklyn.

FRIDAY, October 29th.—Hospital Graduates' Club, Brooklyn.

Personal.—Sir Berkeley Moynihan, C.B., M.S., F. R. C. S., of Leeds, England, read a paper on Gastric Ulcer and Its Treatment at a stated meeting of the New York Academy of Medicine, Thursday evening, October 21st.

Dr. James Francis Brady, of Boston, has been placed in charge of the Dermatological Department of Carney Hospital.

Dr. Byron G. Clark announces the removal of his office to 163 West Ninety-second Street, New York.

Mr. Ralph Mosteller, formerly assistant bacteriologist to the Board of Health of Atlanta, Ga., returned recently from Siberia, where for two years he had been in charge of the clinical laboratory of the Red Cross Russian Island Hospital at Vladivostok.

Dr. William W. Keen, of Philadelphia, was decorated recently with the Belgian order by the King of Belgium.

Dr. A. B. MacCallum, of Toronto, administrative chairman of the Research Council of Canada, has been appointed to the new chair of biochemistry in McGill University, Montreal.

Dr. W. D. Witherbee has resigned from the staff of the Rockefeller Institute for Medical Research and has opened an office at 116 East 53d Street, where his practice will be limited to x ray therapy. He will also have charge of the x ray work at the Presbyterian Hospital.

Conference on Venereal Diseases.—The All-America Conference on Venereal Diseases will be held in Washington, D. C., December 6th to 11th, under the auspices of the United States Interdepartmental Social Hygiene Board of the United States Public Health Service, the American Red Cross Society, and the American Social Hygiene Association. The administrative committee consists of Dr. Thomas A. Storey, Dr. C. C. Pierce, Dr. Livingston Farrand, and Dr. William F. Snow. The aim of the conference is to bring together recognized authorities and to make possible a comparison and evaluation of the methods now employed in various parts of the world for the control of venereal diseases. All correspondence should be addressed to the Executive Secretary, 411 Eighteenth Street, N. W., Washington, D. C.

Public Health Service Institute on Venereal Disease Control.—The United States Public Health Service has organized an institute on venereal disease control and social hygiene to be held in Washington, November 22d to December 4th. The faculty of the institute will consist of Dr. J. H. Stokes, of the Mayo Clinic, Rochester, Minn.; Dr. Hugh Young, of Baltimore; Dr. John A. Fordyce, of New York; Dr. E. L. Keyes, Jr., of New York; Dr. Thomas M. Balliet, Dr. William A. White, Prof. M. A. Bigelow, Dr. Katherine B. Davis, Mrs. Martha P. Falconer, and some thirty or forty other leading specialists.

During the ten days of the Institute four full courses and eleven half courses will be given. The first three full courses will consist of lectures on the diagnosis and treatment of the venereal diseases, and the fourth will be on delinquent women and their relation to the law. The half courses will be on the diagnosis of the mental condition of delinquent women; on protective work for girls; the work of the venereal disease nurse; heredity and eugenics; sociology and social hygiene; public education in venereal diseases; law enforcement; sex psychology; clinic management; and clinic social work.

Officers of State and city boards of health, clinicians, nurses, social workers, judges, and probation officers of courts of domestic relations and juvenile courts, police matrons, police women, superintendents of eleemosynary institutions, chiefs of police, medical officers of commercial institutions, urologists, dermatologists, gynecologists, neurologists, psychologists, and officers of medical and sociological organizations are all eligible for admission to the Institute. Others who wish to attend will be expected to present credentials from State or city health officers.

Application for admission should be made as soon as possible in order to enable those in charge of the institute to make arrangements for the educational facilities, comfort, and pleasure of the guests. No applications will be accepted after November 15th except by special direction of the Surgeon General. Applications that have been sent in may, however, be withdrawn, if circumstances make attendance impossible. No tuition is charged the generous cooperation of the faculty making this unnecessary. Hotel accommodations will be reserved if instructions therefor are sent to the U. S. Public Health Service, Washington, D. C.

Medical Society of the County of New York.—A stated meeting of this society will be held in Hosack Hall, New York Academy of Medicine, Monday evening, October 25th. The scientific program will consist of a symposium on blood transfusion, as follows: A General Introduction, by Dr. R. Ottenberg; Indications for Blood Transfusion, by Dr. R. E. Stetson; Selection of Donor, by Dr. L. J. Unger; Technic, by Dr. R. E. Brennan and Dr. Richard Lewisohn. Among those who will take part in the discussion are: Dr. Harold Hays, Dr. C. C. Heyd, Dr. E. Libman, and Dr. E. W. Peterson.

Medical Society of Pennsylvania.—At the twentieth annual meeting of this society, held in Pittsburgh, October 4th to 7th, under the presidency of Dr. Cyrus L. Stevens, of Athens, the following officers were elected: President, Dr. Henry R. Jump, of Philadelphia; president elect, Dr. Frank G. Hartman, of Lancaster; first vice president, Dr. Harold A. Miller, of Pittsburgh; second vice president, Dr. Spencer M. Free, of Duboise; third vice president, Dr. David Funk, of Harrisburg; fourth vice president, Dr. Anthony F. Myers, of Blooming Glen; secretary, Dr. Walter F. Donaldson, of Pittsburgh (reelected); assistant secretary, Dr. Christian B. Longenecker, of Philadelphia; treasurer, Dr. John B. Lowman, of Johnstown.

Died.

COMEAU.—In Norwich, Conn., on Friday, October 1st, Dr. George A. Comeau.

DYER.—In New Orleans, La., on Tuesday, October 12th, Dr. Isadore Dyer, aged fifty-four years.

GILSON.—In Boston, Mass., on Wednesday, October, 13th, Dr. Alfred H. Gilson, aged sixty-seven years.

KRAFT.—In Weehawken, N. J., on Thursday, October 14th, Dr. Charles Kraft.

MCCLANE.—In Clarksburg, W. Va., on Saturday, October 9th, Dr. William McClane, aged seventy-five years.

MORSE.—In New York City, on Sunday, October 10th, Dr. C. F. Morse, aged fifty-nine years.

NOBLE.—In Brooklyn, N. Y., on October 10th, Dr. Harriet I. Noble, aged sixty-one years.

RUPPEL.—In Lynn, Mass., on Sunday, October 10th, Dr. Emil F. Ruppel, aged sixty-one years.

SCHLEMM.—In Union Hill, N. J., on Sunday, October 3rd, Dr. Richard Schlemm, aged fifty-five years.

SIMMONS.—In Bangor, Me., on Monday, October 4th, Dr. William Hammatt Simmons, aged seventy-two years.

STEWART.—In Canandaigua, N. Y., on Tuesday, October 5th, Dr. Henry Stewart, aged seventy-three years.

STIRES.—In Columbus, Neb., on Thursday, September 30th, Dr. Ferd Taylor Stires, aged thirty-eight years.

SPAULDING.—In Clifton Springs, N. Y., on Thursday, October 7th, Dr. Frank W. Spaulding, aged seventy-six years.

STUTSMAN.—In Seattle, Wash., on Wednesday, September 22nd, Dr. William Harold Stutsman, of Chicago, aged thirty-four years.

THOMSON.—In Summit Point, W. Va., on Monday, October 4th, Dr. Augustus Pembroke Thomson, aged seventy-three years.

Book Reviews

PSYCHIATRY IN GERMANY

Arbeiten aus der Deutschen Forschungsanstalt für Psychiatrie in München. Edited in December, 1919. JULIUS SPRINGER, Berlin, 1920.

This first report of the new German Institute for Psychiatric Research is richly suggestive of the literary and scientific character to be expected of the contributions which will be made through its work. Kraepelin's review of the history of psychiatry through the hundred years preceding, with which the report opens, gives an instructive outline of the facts of such history presented with a stimulating appreciation of the evolutionary relation of such facts to one another. This becomes evident in a progressive field like that of psychiatry, which contains the promise for wider developments for the future as they gleam through the slow growth of the past. The somewhat familiar story of the abuses which arose through ignorance and superstition, and, we might add, through the fear of mental facts which these nourish, receives new light from Kraepelin's treatment. The story is set forth in clearly related detail, and thus, illustrated as it is also by pictures, it gathers together in striking summary the delays and yet the progress in theoretical and experimental approach to problems of the insane made simultaneously in the several lands of Christendom. It reveals the similarity and the cooperation which are in line with the definite progress of enlightenment and with the growing conception of a mental reality even in the insane which must be accepted and dealt with in a scientifically reasonable manner.

The promise for wider understanding of mental diseases in all phases of approach to them as well as for the possibilities of active development of the science of psychiatry is more than intimated in the writer's words. This prospective work is still more definitely outlined in his following article on the goals and the paths of psychiatric research. Further stimulus is given in his presentation of the needs of research into the various forms of mental disease. His article on epilepsy gives a brief glance also in one of these special directions. It does not lessen the force of his appeal for the various types of research, of which this report gives encouraging examples, if it is objected that too little attention is given to the general background of all mental disease and too little definite emphasis laid upon the weight of psychic factors which work much more deeply in the causation and development of mental disturbances than even this experienced observer makes clear. It is true as he says that there is not one mental disease but that research should proceed upon the admission of most devious paths for research. This is unquestionably true in the field of anatomical investigation; it cannot be disputed from the viewpoint of many psychic factors and countless deviations in the psychic expression of mental disease. Yet there is danger of too much distinction which tends to separate too sharply any disease manifestation from the whole background of personal character and of energy striving. The fuller acceptance of such unified background does

not confusedly merge different pathways of research but would obliterate falsely distinctive boundaries which too often shut out the more vital interpretation.

Such criticism would in no way detract from the high character of the special research reports which are published here. These fully indicate the scientific thoroughness and exactitude of the work that may be expected from the investigators working under this institute. The various subjects are treated with a completeness of detail, a fulness of description, and a wealth of illustration worthy of note.

A last word from Nissl appears in regard to the histological implications of the spirochete. He has also contributed an extended notice of Brodmann's work, whose death preceded Nissl's own. Spielmeyer has contributed a paper on the histopathology of the cortex in typhus, as well as a study of the relations between ganglion cell changes and gliosis phenomena. Plaut reports upon the Sachs-Georgi reaction in syphilis and together with Steiner upon recurrent infection in general paresis. Spatz has a study of a special manner of reaction of the immature central nervous tissue. There are also briefer reports of papers presented at meetings of the institute. Most of the articles of the collection have appeared in the *Zeitschrift für die gesammelte Neurologie und Psychiatrie* but all are here presented in convenient book form.

THE PROBLEMS OF PARENTHOOD

Problems of Population and Parenthood. Being the Second Report of and the chief evidence taken by the NATIONAL BIRTH RATE COMMISSION, 1918-1920. New York: E. P. Dutton & Co., 1920. Pp. v-423.

It was like a nightmare of immigration with no officers to control, no Ellis Island. All day, every day, there was a swift incoming of white babies, brown babies, black babies, crying, smiling, with well rounded limbs, with limbs distorted, splendidly healthy, woefully diseased, babies eagerly welcomed, babies unloved, unwanted. Some so spent with the journey that they soon fluttered back into the great silence, with no power of speech to tell their amazement at so blank a world. Those who stayed on grew to earn the name of "a problem" for though pocketless the rogues had brought in large stores of original sin and unoriginal disease, so that flurried philanthropists had to enlarge the reformatories and idiot asylums and devise means for only better babies to land in the world.

It was sad to learn at their last big meeting in London that men like Professor Leonard Hill and Dr. Saleeby had each a family of six and no means of bringing them up healthily; that Sir Rider Haggard and Professor Arthur Keith had only a two roomed lodging and no playground near for their children. That Miss Maude Royden and Dr. Marie Stopes, though warned of the social disabilities and the immorality, had children called children of shame, and the Bishop of Birmingham and Dr. Sims Woodhead had married at the early age of sixteen and preferred to live in a slum with their children rather than accept a fifty acre tract of land

the other end of nowhere with free air and water. Principal Garvie and Major Leonard Dawson were found incorrigible in preferring a glass of beer at the saloon every night to staying at home in their kitchen-parlor-bedroom while their wives washed up the supper things and the baby. Lady Selborne and Mrs. Bramwell Booth, though repeatedly warned, had trusted their three weeks' old babies to minders only ten years old, while they themselves went out to work when debts were many and pennies few. Mr. Sidney Webb and Sir Conan Doyle spent their evenings going to vaudeville and movies, though they both had a luxurious unwarmed, unventilated attic at two dollars a week and could have had pleasant evenings with books on racial degeneration and social hygiene from the free libraries. The accumulation of records during six years' work showed sixty thousand aristocratic lunatics to have married with an income of only nine thousand dollars a year. The daughters of the rich, though aware of the kind, winning treatment which the world would give, persisted in going wrong and wickedly refused to be restrained in a beautiful, cheerful home and do washing in order to go right. It was also found that Judge Henry Neil and Dr. Eric Pritchard, subway laborers, refused to take a bath each night at the public baths when work wearied, but unwholesomely ate unwholesome food unwashed.

But the reviewer had evidently become a little distracted with the appalling contents of the national cesspool. It was the people who were weak and foolish. The big people mentioned were met to discuss their reformation. But what had kept them decent citizens? Not leisure; they often worked harder than the workmen. Not education; that was free to all.

Well, the commission of rich and learned men and women discussed the prenatal, the postnatal baby; the care of the pregnant mother, the unmarried mother, the illegitimate father; whether help in avoiding venereal disease and care for love babies would increase vice. (Many thought it would). Who should emigrate and to what land? Is it wrong to arrest pregnancy? Decided—No nation can acquiesce in the destruction of children. It was found that the defensive and industrial powers of the empire are in danger if the increasing diminution of the birth rate continues, especially as the decrease is chiefly among those most capable of having healthy children. The questions of alcoholism, gonorrhoea, syphilis, tuberculosis, restriction of children earning wages, good housing, recreation centres, food, endowment of motherhood, were fully gone into, in fact, there was a mass of evidence from well known men and women which showed thorough and exhaustive, even sympathetic study. A special warning was given by Sir Rider Haggard to train the tide of emigration from England to her own colonies, and to combat the growing socialism which would like to keep emigrants out in case of having to share.

The choice of the commission was wonderfully wide: the evidence was fully reported and six years of it should bear weight, but it would be helpful to know why the commissioners were not being

judged as well as the people, or, if you prefer—masses, lower classes, submerged tenth. What has the rich man that the working man lacks, that he requires no investigation? The latter has free parks, education, medical care, libraries, museums, baths, assisted emigration, disablement pensions, clubs, music, everything save the certainty of wages, a suitable home and that home his own. He would rather have a small, healthy house, a little garden all his own, than live in a workman's model dwelling and have all Central Park free for his children to play in. Work as he will, a few weeks of involuntary idleness will exhaust his savings and risk his being turned out of his home. He has nothing he can call his own, and is humiliatingly forced to take anything a generous or a depraved municipality will offer. This is the greatest obstacle to reform: Uncertainty of labor and no sure dwelling place. Meanwhile it would advance progress if a commission were chosen to inquire why the rich needed no such agency.

BEYOND LAW.

The Rescue. By JOSEPH CONRAD. Garden City: Doubleday, Page & Co., 1920. Pp. iii-404.

Mr. Conrad's latest book is not entirely his latest conception. It embodies a theme which he bore around with him for many years, returning to it again and again until it took the form of the present novel. *The Rescue* is one of those marvelous Conrad works, all shimmering with color, filled with the mystery of strange seas and the high handed deeds of adventurers who were beyond law. In it the author tells of the attempt to rescue a kingdom of the South Seas, of a Malay princess and a British yacht, of a woman who was too civilized, and of a man who was "undone by a glimpse of paradise"—Captain Lingard or King Tom.

It would be futile to outline the story, for no mere indication of theme could give an idea of its penetrating analysis of human motives, of the richness of its setting, and of the exquisite prose. Mr. Conrad has chosen as his main character a figure of extraordinary interest. "Whatever he (Lingard) might have been he was not mediocre. The glamour of a lawless life stretched over him like the sky over the sea down on all sides to an unbroken horizon. Within, he moved very lonely, dangerous and romantic. There was in him crime, sacrifice, tenderness, devotion, and the madness of a fixed idea."

Lingard, the owner of a brig, has pledged himself to help Hassim and his sister, Immada, regain their kingdom of Wajo. Something of "the madness of a fixed idea" is in his determination. And then into his horizon comes the yacht of Mr. Travers, bearing with it all the decorum and dulness of British officialdom—and Mr. Travers' wife. "It seemed to him that till Mrs. Travers came to stand by his side he had never known what truth and courage and wisdom were."

The story does not seem to be told as much as to unfold itself, so absorbing are the persons concerned and so inevitable the denouement. Mr. Conrad is a master at this sort of thing. His characters seem to reveal themselves almost with-

out external aid, so deftly does the author encourage them. There are no undigested lumps of psychology; instead there is illumination in almost every gesture. With Mrs. Travers, Mr. Conrad is slightly less successful than in the depiction of King Tom. She remains something of a mystery, a woman whose disenchantment with life is hinted at but not fully revealed. We never really catch her off her guard. In the case of many writers who care as much about the setting as Mr. Conrad, the internal struggle of the characters might as well take place somewhere else. This is not so with *The Rescue*. One cannot imagine the drama of King Tom and Hassim and Edith Travers having been played out in another environment. King Tom himself is too representative of that life beyond law.

And yet real as this book is, compelling and beautiful as it is, it may easily leave the reader unsatisfied. Mr. Conrad is far too sympathetic with his characters to regard them as puppets, and yet in effect they are just that, in the sense that human beings everywhere are puppets. These people move in a setting that dwarfs them by its gorgeousness, small and helpless and terribly alone amid a sea and sky that have no concern with them, in a terrible, impersonal beauty that only emphasizes their isolation. One feels in the author's attitude that same detachment, the absence of a word of hope.

A NEW DISSECTOR.

The Anatomy of Society. By GILBERT CANNAN. New York: E. P. Dutton & Co., 1919. Pp. v-216.

Gilbert Cannan, who wields one of the most trenchant pens among the younger English novelists, has written a book which is part treatise, part sermon and part prophecy, which is vehement and incoherent and at times splendid. It is a rather young book. Dissecting society is a large order. Mr. Cannan keeps up a verbal barrage against capital, restrictions on divorce, tyranny, institutionalism, and every sort of exploitation. He believes in freeing parents from their children and from each other when desirable, in reclaiming the school, in socializing industry—in freeing the human spirit. Interesting, but difficult. Dissection is an operation which should be attended with calmness, and Mr. Cannan is not calm. He hits society on the head with an axe and considers the job done.

INTERRUPTED LAUGHTER.

The Broken Laugh. By MEG VILLARS. New York: Robert McBride & Co., 1920. Pp. vii-343.

If one were given two guesses as to Miss Villars's favorite reading matter, the first would be the novels of Compton McKenzie and the second the *Ladies' Home Journal*. She has not achieved the blend of farce comedy and metaphysics of the Sylvia Scarlett novels; in place of the metaphysics are bits calling for an emotional tear or two if one is that sort of person. But the foundation is McKenzie—snappy narrative built around an obscure little person who is no better than she should be, complications interwoven with what the newspapers call human interest, a dash of sentiment—the whole designed to keep the reader up all night if he is unfortunate enough to start it in the evening.

The heroine is named Kissy, and as a result of gullibility and ignorance she has a baby the father of which she does not even know. Her journey to Paris after she has identified the man by a newspaper clipping and the subsequent adventures that befall her when she learns her mistake form the theme of the story. Miss Villars is not quite as snappy as Mr. McKenzie and the narrative drags in spots, particularly toward the end. The conclusion is a nicely tempered bit of justice. Miss Villars does not want to be too hard on Kissy, neither can she exonerate her after the baby and her ending is nicely calculated to obviate both of these courses.

TALKS.

Ten Minute Talks With Workers, from *The Times* (London) Trade Supplement. Pp. 208. New York: Doubleday, Page & Co., 1920.

There are many shoutful, aggressive arguers who delight to get an audience and choke them with phrases. Many such use terms of which they know not the exact meaning themselves or as little as those they talk to. Now if the bullied will carefully study these *Ten Minute Talks* they will understand the terms used in labor and capital, profits and wages, banks and markets, and be able to use staggering arguments to discomfit the windbag of words next time he comes along, for the book is clearly written.

New Publications Received.

[We publish full lists of books received, but we acknowledge no obligation to review them all. Nevertheless, so far as space permits, we review those in which we think our readers are likely to be interested.]

PEARLS ASTRAY. A Romantic Episode of the Last Democracy. By CONSTANCE M. WARREN. Illustrated. Boston: Small, Maynard & Co., 1920. Pp. 158.

PATHOLOGISCHE BIOLOGIE. (Immunitätswissenschaft.) Dritte Auflage. Von Prof. Dr. HANS MUCH. Leipzig: Verlag von Curt Kabitzsch, 1920. Seiten 323.

AMERICAN MEDICAL BIOGRAPHIES. By HOWARD A. KELLY, M. D., LL. D., F. A. C. S., Hon. F. R. C. S. (Edin.), and WALTER L. BURRAGE, A. M., M. D. Baltimore: The Norman Remington Company, 1920. Pp. xix-1320.

DIE THERAPIE AN DEN BONNER UNIVERSITÄTSKLINIKEN. Herausgegeben von Prof. Dr. RUDOLF FINKELNBURG, in Bonn, Dritte, vermehrte Auflage. Bonn: A. Marcus & E. Webers Verlag (Dr. Jur. Albert Ahn), 1920. Seiten xii-745.

THE VICTORY AT SEA. By Rear Admiral WILLIAM SOWDEN SIMS, U. S. Navy, Commander of the American Naval Forces Operating in European Waters During the Great War, in Collaboration with BURTON J. HENDRICK. Garden City-New York: Doubleday, Page & Co., 1920. Pp. xi-410.

DIAGNOSTIK UND THERAPIE DER KINDERKRANKHEITEN. Mit speziellen Arzneiverordnungen für das Kindesalter. Ein Taschenbuch für den praktischen Arzt. Von Prof. Dr. F. LUST, Oberarzt der Universitäts-Kinderklinik in Heidelberg. Zweite neubearbeitete Auflage. Berlin N-Wien I: Urban & Schwarzenberg, 1920. Seiten vi-471.

PATHOGENIC MICROORGANISMS. A Textbook of Microbiology for Physicians and Students of Medicine. By WARD J. MACNEAL, Ph. D., M. D., Professor of Pathology and Bacteriology and Director of the Laboratories in the New York Post-Graduate Medical School and Hospital, New York. Second Edition, Revised and Enlarged. Illustrated. Philadelphia: P. Blakiston's Son & Co. Pp. xx-488.

Practical Therapeutics and Preventive Medicine

A Compendium of Treatment and Prophylaxis, Original and Adapted

Radium Puncture in the Treatment of Cancer.

—C. Regaud (*Paris médical*, February 7, 1920) notes that radium puncture consists in introducing, into a tumor for example, needles charged with radium. By suitable implantation of the needles a high degree of evenness in the exposure of the tumor tissues to the radium can be obtained. The treatment is very economical in the sense that, for equal effects, it requires much less radioactive energy than does the external application of radium. In a thick tumor mass, a few millicuries introduced with the needles yield greater effects than would several hundreds of millicuries used externally. In the last eight months the author and his coworkers have used radium puncture in about fifty miscellaneous malignant tumors. Too little time has as yet elapsed to speak of cures, but there have occurred at least temporary remissions in the cases, all inoperable, so far treated. The method undoubtedly marks a great step forward in the treatment of malignant growths, both because it affords new possibilities in the treatment of certain rather inaccessible forms of cancer and because it procures an increase of therapeutic efficiency in the treatment of relatively insensitive and bulky tumors. While highly efficacious, radium puncture is harmless only when radiation of healthy tissues is avoided. An illustrated description of the armamentarium and technique is presented.

Treatment of Congenital Dislocation of the Hip.—Calot (*Bulletin de l'Académie de médecine*, April 20, 1920), from extensive anatomical and pathological studies, as well as from x ray, clinical, and therapeutic observation in several thousand children treated for congenital dislocation, found that hitherto x ray specialists and surgeons have nearly always misjudged the location of the upper margin of the primitive cotyloid fossa, into which the head of the femur must be finally adjusted if true anatomical cure is to be obtained. This upper limit is not situated at the uppermost and outermost point of the diagrammatic V representing the cotyloid region in x ray textbooks, but at the apex of the V, i. e., at the upper part of the Y cartilage. Because of this anatomical error, incomplete and false reductions, rather than true reductions, have been obtained. The primitive cotyloid fossa corresponds in small children to the ischial and not the ilial portion of the coxal bone. A mistake has also been made in placing the axis of the head and neck of the femur in an oblique direction. Instead, this axis should, on x ray observation, be found horizontal. The head should be opposite the ischial portion; the neck should appear in its greatest length, and contact, or better, insertion of the head and cotyloid fossa should be obtained. If this is not possible at first, it may be gradually secured by pressure with cotton upon the great trochanter through an opening for it in the plaster apparatus opposite the trochanter. A broad, horizontal vault for the head must be created at the proper point.

This is accomplished both by keeping the axis of the head and neck transverse throughout the period of immobilization and by flexing the thigh to an angle of 135° in the first apparatus used. This overflexion also serves to correct the frequently existing anteversion and antetorsion of the head and neck. Autopsies and radiographs showed that a roof for the cotyloid fossa as horizontal, strong, and extensive as on the normal side can thus be created in from eight to twelve months. The newly formed roof or vault appears in the x ray picture as stalactites and islets of bone which later become confluent. Equivalent changes take place even in the very small children, in whom ossification is normally less advanced. To avoid undue encroachment upon the femoral head by the bony proliferations above it, the head is not left in a fixed position throughout the eight to twelve months, but is moved through the use of three successive plaster dressings, the first holding the thigh flexed at 135°, the second at 90°, and the third at 45°.

Chemotherapy of Chronic Tuberculous Infections.—H. Grenet and H. Drouin (*Bulletin de l'Académie de médecine*, March 9, 1920) refer to the experiments of A. Frouin which showed that intravenous injections of the sulphates of samarium, lanthanum, neodymium, and praseodymium induce an intense, progressive, and lasting mononuclear leucocytosis, and that *in vitro* the same salts cause definite alterations in the vitality, morphology, and chemical constitution of the tubercle bacillus, the fat content of which is reduced from thirty-five or forty per cent. to twenty-two or even sixteen per cent. Clinically, intravenous injections of a two per cent. solution of one of the above mentioned compounds—usually neodymium sulphate—were given in series of twenty or twenty-five, daily or on alternate days, repeated after intervals of fifteen or twenty days. The dose was gradually increased from two to five mils of the two per cent. solution. The injections were well borne in cases of local tuberculosis or with small pulmonary lesions and in fair general health. In more severe pulmonary cases the treatment caused temporarily slight lassitude and loss of weight. In hectic cases and those with extensive cavities the treatment was not tried. In eight cases of tuberculous lymphadenitis marked improvement followed one or two series of injections, the glands becoming smaller, movable, hard, and fibrotic, and long standing sinuses closing in fifteen to twenty days. In eleven cases of lupus erythematosus and two cases of indurated erythema rapid improvement usually occurred, the lupus cases sometimes being cured in a few days, or, where of longer standing, after one or two series of injections. Among twenty-four cases of true skin tuberculosis, weeping and suppurating lesions were soon dried up, and later healing took place, in some instances with scarifications or the cautery as auxiliary measures. Lupoid tubercles of the nasal mucosa were cured without local treatment. The pulmonary cases

treated included three in which, in spite of manifest physical signs, no tubercle bacilli had been found before the beginning of treatment, and twenty-one with tubercle bacilli, subcrepitant or crackling râles at the apexes, rough breathing, prolonged expiration, etc. In the first group, all physical signs disappeared and apparent recovery was secured in from two to six months. In the second group, expectoration ceased in four after two to seven months of treatment; the bacilli apparently disappeared in eight; râles disappeared in all but one of these twelve cases. In the remaining nine cases of the second group tubercle bacilli were still present after treatment, but always showed morphological changes, becoming narrow, branched, and agglutinated, or stout, short, and irregular in outline, invariably with poor staining properties. X ray examinations showed improvement corresponding to that noted in the physical signs. In brief, all patients were benefited by the treatment.

Colloidal Arsenic and Silver in the Treatment of Influenza.—Capitan (*Bulletin de l'Académie de médecine*, March 9, 1920) reports recent cases illustrating the value of intravenous or intramuscular injections of colloid arsenic and silver in grave influenza cases. In a case seen with Tertois, the patient was a man aged ninety years with double basal bronchopneumonia, subnormal temperature, and delirium. In addition to the ordinary measures, such as cupping, camphor in oil, strychnine, and sparteine, intramuscular injections of two mils of colloidal arsenic into the buttocks, morning and evening, were administered. Progressive improvement followed, and after four days the dose was reduced. Complete recovery took place. In the same patient's wife, aged seventy-seven, and likewise gravely ill, injection of two one mil doses of colloidal arsenic and two three mil doses of colloidal silver was followed by defervescence in twenty-four hours and eventual recovery. Similar results were obtained in other cases. The colloidal preparations employed are advantageous in being nontoxic and in acting rapidly.

Iodine Absorption from the Human Skin.—Norman C. Wetzel and Torald Sollmann (*Journal of Pharmacology and Experimental Therapeutics*, April, 1920) report experiments in which iodine tincture was painted on the palmar surface of the forearm and other iodine preparations rubbed thoroughly into the skin of the chest and abdomen. Contrary to the widely prevalent impression that free iodine is absorbed quite readily through the skin, the urine did not contain demonstrable quantities of iodine compounds. Failure to excrete iodine does not necessarily mean that none is absorbed, for if only very small amounts have been absorbed it is conceivable that they may be retained completely in the body. Yet the experiments are held to have shown that the absorption of iodine through the skin is not nearly as extensive as is commonly supposed. The results obtained referred only to single applications to normal skin. Probably if the skin is injured, as by repeated applications of strong iodine solution, its permeability may be increased. This would doubtless occur if there were actual vesication, or probably even if the epidermis had been desquamated.

Treatment of Enterocolitis in Infancy.—W. W. Harper (*Southern Medical Journal*, June, 1920) says that to treat enterocolitis successfully, one must make a distinction between the cases due to the gas bacillus and those due to the dysentery bacillus. The former thrives best on a carbohydrate diet, so this infection is best combated by withholding carbohydrates and giving proteins, while carbohydrates furnish media not favorable to the growth of the dysenteric group of organisms and is the food of preference in the early stages of such infection, although there are subjects who do better on a protein diet. Again, the infection may be principally in the lower ileum, or in the lower colon; in the former case there is early and profound toxemia, rapid desiccation of the tissues, a marked tendency to acidosis, and often a severe nephritis. Absence of lactic acid bacilli indicates that the intestinal canal has surrendered to the invading bacteria. The treatment is as follows: 1. Prompt cleaning of the intestinal canal by catharsis and enema; 2, withdrawal of all food for twenty-four to forty-eight hours; 3, sowing the intestinal canal with virile strains of lactic acid bacilli; 4, an abundance of water by mouth, rectum, and hypodermoclysis; 5, free administration of alkalis and, if acidosis threatens, the use of carbohydrates; 6, adopting measures to prevent urinary suppression; 7, early return to breast or bottle.

As an initial purge the writer prefers castor oil. If the first dose is vomited, a second is given at once, and if this is vomited a third. From the three doses enough will be retained to act. An enema of two teaspoonfuls of sodium bicarbonate to a quart of warm water is given every six hours for the first day or two. All food is withdrawn and water forced. To encourage the drinking of water, it may be given as iced tea, lemonade or orangeade, sweetened with saccharine. If the baby refuses to take the fluids, or if there is marked nausea or emesis, sterile tap water should be supplied by hypodermoclysis, six to eight ounces every six to eight hours to an infant six months old. Should acetone appear in the urine, the solution should contain one per cent. citrate and two per cent. glucose. A less preferable method of introducing fluid is through the stomach or duodenal tube. The least satisfactory method is by proctoclysis. As soon as the castor oil is out of the stomach, give a lactic acid bacillus tablet in sweetened water every two hours; these to be continued until the stools are normal. As acidosis is the great danger, the urine should be kept alkaline with bicarbonate of soda, or sodium citrate, five to ten grains every two hours to a child six months old; it is rarely necessary to continue this longer than forty-eight hours. If the baby is breast fed nursing is resumed at the end of twenty-four to forty-eight hours, the baby to nurse one minute from each breast every four hours, to be preceded with lime and plain water. If the infection is due to the gas bacillus, the baby is given lactic acid milk, or protein milk, before each nursing; this replaces the lime and plain water. If the infection is due to the dysentery bacillus, the nursing is preceded by a

lactose barley solution, varying in strength from two teaspoonfuls each to two tablespoonfuls each to the pint of water. If the baby is bottle fed, the same treatment is carried out except as to the nursing. Although carbohydrates are contraindicated in gas bacillus infections, they must be given in threatened acidosis. Toxic nephritis with impending anuria is best combated with hot baths, hot packs, and warm soda flushes of the colon. For restlessness give chloral by enema, or morphine by injection. As a stimulant, atropine in fairly large doses gives good results. Now and then one will meet with a case of vasomotor paralysis which can be benefited by an intravenous injection of adrenalin. When the stools are large, frequent and watery, opium is often a life saver; paregoric by mouth or morphine by hypodermic injection. For tenesmus the writer likes an enema of silver nitrate solution, one half to one per cent., in distilled water. Intestinal antiseptics and astringents are mentioned only to be condemned.

The Therapeutic Use of Oxygen.—R. D. Rudolf (*American Journal of the Medical Sciences*, July, 1920) says that oxygen is of value whenever a state of anoxemia exists, as in cases of mountain sickness, sickness from high flying, in poisoning by carbon monoxide, nitrites, and arseniuretted hydrogen, and in the effects of enemy gas. It should be tried in all cases of cyanosis, and in such acute respiratory conditions as pneumonia when anoxemia threatens. The ordinary method of giving oxygen by holding a funnel connected with the oxygen cylinder near the face of the patient is practically useless; a better method is to give the gas through a rubber tube inserted into one nostril, and this may be made more effectual if the opposite nostril is rhythmically compressed during inspiration, the mouth being kept closed. The oxygen chamber is a very effectual way of giving oxygen, but it involves much expense and care. A very useful and effectual appliance for the administration of oxygen is Meltzer's apparatus for oral insufflation.

Vaccine Therapy in the Acute Osteomyelitis of Adolescents.—Raymond Grégoire (*Journal de médecine de Paris*, April 5, 1920) states that in certain selected cases of this disorder vaccine treatment gives excellent results. In the septic form of osteomyelitis prompt surgical treatment is, of course, indicated, though vaccine treatment might prove of some value as an auxiliary measure. In the acute or subacute cases, in which the general condition is less seriously impaired, the advisability of vaccine treatment depends entirely upon the state of the involved bone. Where a more or less extensive portion of bone has become transformed into a sequestrum, vaccine treatment is inappropriate and the foreign substance must be surgically removed. Such a condition is detected by x ray examination. In all other cases, however, irrespective of the duration of the case, extent of local inflammatory reaction, and condition of neighboring joints, vaccine therapy may yield surprising results. Cases were thus cured after several weeks of suppuration and fever. Where purulent accumulation about the bone is excessive and threatens to open

into a joint or cause marked separation of tissues, it is well to puncture the abscesses, repeatedly if necessary, until the pus becomes clear and finally ceases to form. Joint involvement would at first sight seem to demand incision. Yet in several cases distended joints went on to recovery without it and even recovered their mobility, wholly or in part. To avoid persisting with vaccine treatment for more than a reasonable and safe period, reliance should be placed on the temperature curve. The vaccine tends to subdue the temperature very rapidly. In some cases it drops quickly from 39° or 40° C. to about 37°, though frequently several days are required for it to reach normal. Whenever the vaccine acts, there is noted a distinct depression in the temperature. If by the third day no remission has occurred, the vaccine may be considered insufficient in the case under treatment, and open surgery should be resorted to at once.

Pituitary Syndrome Coexisting with Spinal Deformities.—Apert and Cambessédès (*Presse médicale*, January 31, 1920) report the case of a boy of twelve who for some years had been exhibiting general torpor, somnolence, headache, and increasing obesity. The hips and breasts enlarged so as to resemble the feminine type and the pubes began to show a premature growth of hair. The extremities were cold and cyanotic. The sella turcica was found broadened. In addition, the child had presented at birth an upper dorsal meningocele, which had been subjected to operative treatment. X ray study of the back showed multiple malformations of the vertebræ. It is supposed that the same condition of dysembryoplasia involved simultaneously the spinal and pituitary regions, the latter constituting, as a matter of fact, the upper extremity of the spinal tissues.

X Ray Treatment in Primary Neuralgia.—A. Zimmern (*Paris médical*, February 7, 1920) reports marked benefit in cases of occipital, trigeminal, and lumbar neuralgia and in meralgia paresthetica from radicular x ray treatment. With the exception of the cases of facial neuralgia, particularly those of the tic douloureux type, the results obtained were remarkably constant. They were especially rapid and complete in neuralgia of the brachial plexus. Only rather small doses of the rays need be used. One or two applications averaging three H units, with filtration through two or three millimetres of aluminium, proved sufficient to bring about complete cure or at least to allay the pain very greatly. In the brachial cases the irradiation should be practised over an area extending from the fourth cervical to the first dorsal, and be directed obliquely from behind forward and from without inward. The patient should be warned that a few hours after the first treatment there may occur a painful, though never severe, reaction preceding the ultimate sedative effect. This reaction seemed, however, to occur less frequently in the brachial cases than in cases of sciatica similarly treated. With the doses mentioned, one remains below that required to produce erythema even if it becomes necessary to repeat the treatment every week. Furthermore, with a sufficient degree of filtration no trace of pigmentation can occur.

Proceedings of National and Local Societies

AMERICAN GYNECOLOGICAL SOCIETY.

Forty-fifth Annual Meeting, Held in Chicago, May 24, 25, 26, 1920.

Dr. ROBERT L. DICKINSON, of New York, in the Chair.
(Concluded from page 608.)

Operation or Radium for Operable Cancer of the Cervix.—Dr. WILLIAM P. GRAVES, of Boston, stated that his paper was an inquiry, based on personal experience, into the question of the treatment of choice in operable cases of cancer of the cervix. The subject was opportune because of the recent severe criticisms that some of the radium enthusiasts had cast on the modern operative methods of treating cervical cancer, and because a few excellent surgeons had of late practically discarded surgery for radiation in this field.

Dr. Graves reviewed the cases of cervical cancer which had come under his observation and that of his associate Dr. F. A. Pemberton. During a period of eleven years 181 cases were seen, of which 114, or sixty-four per cent., received radical operation (deducting three cases in which operation was refused.) Of the 114 operations ninety-nine were performed by the Wertheim technic. In fifteen the Wertheim method was considered too dangerous, and a complete hysterectomy was performed in the usual manner. There were six operative deaths in the series, making an immediate mortality of 5.2 per cent. Of postoperative disabilities due to the operation there was one vesical fistula and one rectal fistula. The five year curability percentage at the time of writing was 27.6 per cent.—34.2 per cent. according to the particular method used in computation. These figures seemed to refute in some degree, at least, the criticisms of operative treatment on the ground of "low percentage of operability, shockingly high immediate mortality, and a large majority of distressing and desperate sequela."

Dr. Graves then reviewed his personal experience with radium in the treatment of cervical cancer. Radium in his hands had proved to be an invaluable agent in the palliation of inoperable cases. Many brilliant primary results had been achieved but, as a rule, the ultimate results had been disappointing, there being only one case which he could at present confidently pronounce cured.

On account of the danger of fistula formation from burns, radium had been discarded in frankly operable cases, either before or after the operation. If the operation had been unsatisfactory so far as a complete extirpation of the disease was concerned, radium was used as a prophylactic against recurrence. In numerous borderline cases, difficult of operation, the patients were treated first with radium and then operated upon. In most of these cases there were recurrences ultimately.

Dr. Graves concluded that there was as yet nothing in his personal experience with radium to justify giving up the radical operation in operable cases. He, however, called attention to the fact that the results of radium treatment observed at the Memorial Hospital, New York, were superior to his own

and ascribed this superiority to a greater knowledge and experience in radium, to the possession of larger quantities of the radium element, and to a more elaborate and efficient technic of application. He stated therefore, that the conclusions from his own personal results should not be generalized at present.

A New Method of Covering Raw Surfaces Upon the Uterus.—Dr. GEORGE GELLHORN, of St. Louis, stated that the practitioner started to do a Gilliam operation or one of its numerous modifications or substitutes in a case of fixed retroflexion. The adhesions that held the uterus glued to depth of the cul de sac or the rectum were broken up, the round ligaments were shortened and the uterus was now lying in a more normal position, but with a more or less extensive area of denudation on its fundus which invited the speedy formation of new adhesions. The difficulty was easily solved by a procedure the various steps of which were given by the author in the following words: "The fundus is grasped by a volsellum and pulled backward and upward in the direction of the promontory. The reflection of the bladder peritoneum upon the cervix which now becomes plainly visible is incised transversely as in a hysterectomy and pushed off from the uterus. If this blunt dissection with the finger is gentle enough and does not extend into the broad ligaments, the bleeding is usually insignificant and is quickly checked by the pressure of a sponge. The uterus is then tilted forward, the bladder peritoneum is pulled over the uterus and stitched to the posterior aspect of the fundus, where an intact peritoneal surface presents itself. In small uteri, the bladder peritoneum may be fastened as far back as the insertion of the sacrouterine ligaments, if necessary. After the first or second turn of this continuous catgut stitch the volsellum is removed and the stitching is continued until the entire fundus with its denuded area has disappeared beneath its new peritoneal covering. By using an inverting stitch, even the catgut knots become visible. The newly formed covering consists only of the bladder peritoneum which, in many cases, is so thin and transparent that the raw uterine surface and even the volsellum holes may be distinguished."

The method just outlined not only supplied the raw fundus with a new serous coat, but it also safeguarded a normal position and mobility of the uterus, and the late results had remained most satisfactory. It was, however, not to be relied upon exclusively in a case of fixed retroflexion. In such a case the order of the operative steps were these, viz., first, loosening of the bladder peritoneum as described above; second, shortening of the round ligaments; third, fastening of the bladder peritoneum to the back of the uterus beyond the area of denudation. He anticipated two pertinent questions. Was the function of the bladder disturbed after this procedure, and what happened to the bladder in a subsequent pregnancy? In the six or seven years that he employed the method, he had never observed an instance of vesical disturbance other than those that might follow any laparotomy.

Lutein Cysts Accompanying Hydatiform Mole.

—Dr. W. A. COVENTRY, of Duluth, Minn., said that the cases which he reported presented several very interesting features: 1. The appearance of the ovarian tumors in one case appeared with the mole (in fact, clouding somewhat the history of mole), and in the other case seemed to arise and start to grow rapidly after the mole had been removed. 2. The gross and microscopical appearances of these cysts were in marked contrast to those of the ordinary type of ovarian cyst. 3. These multiple lutein cysts were beyond a doubt different from those normally appearing during pregnancy. 4. These lutein cysts undoubtedly accompanied only the formation of chorioepithelioma and mole and were probably not to be found in any associated condition. There were many references in the literature to the occurrence of cysts of the ovaries accompanying pregnancy, mole or chorioma, but he was sure that many of these references were only to small cysts, which disappeared spontaneously after expulsion of the mole or the fetus.

As regards prognosis and treatment, Eden and Lockyear asserted that some of these cysts receded following the expulsion of the mole, and some such cases had been recorded by Russell, Andrews and Albert, but this literature was not available. Findley stated that occasionally cystic ovaries became greatly reduced in size following delivery of the mole, and reported in the fifty-eight cases collected by him that in only four was there any retrogressive change following the expulsion of the mole. Still, he did not specifically state that these were large lutein cysts such as described in this condition. In view of the fact that the literature in the large majority of cases connected this condition with the presence of chorioepithelioma, and also in view of the fact that the condition was undoubtedly a retrograde metamorphosis from the normal cystic conditions found in the ovary, he believed that we were perfectly justified in not waiting for the recession of these tumors but that we should operate and remove them when found.

MEDICAL SOCIETY OF THE STATE OF
NEW YORK.

*One Hundred and Fourteenth Annual Meeting,
Held in New York, March 23 to 25, 1920*

The President, Dr. CLAUDE C. LYTLE, of Geneva, in the
Chair.

(Continued from page 344.)

The Abduction Treatment of Fracture of the Neck of the Femur.—Dr. ROYAL WHITMAN, of New York, stated that he had presented this method before but that the results obtained by it had been so highly satisfactory that there was no reason for abandoning it. For the restoration of function it was essential that deformity be reduced and that the fractured surfaces be fixed in contact. Contact could be assured only by adapting the outward fracture to the inward. To accomplish this the patient must be anesthetized, and the shortening was then reduced by direct traction. The thigh, having been lifted to the proper plane, was abducted to the normal limit, and abduction was effected

with the perineum against a perineal support. Abduction turned the fractured surface down to meet the head of the femur; it made the capsule tense and aligned fragments; it relaxed muscles whose contraction tended to displace the fragments; it apposed the trochanter to the side of the pelvis, or, if the fracture was near the head, engaged the neck beneath the rim of the acetabulum and provided a mechanical check to displacement. What was known as impacted fracture was usually a complete fracture. After reduction the body and limb were covered with sheet wadding and cotton flannel bandages, all bony points being carefully protected, and a long plaster spica support was applied. With the fracture thus dressed the patient could be turned completely over on the abdomen, avoiding bed sores and also the danger of hypostatic pneumonia. The head of the bed was elevated at an angle of twenty-five degrees, providing a semi-reclining position which favored the nutrition of the injured parts. The neck of the femur in young, vigorous persons might be broken by slight violence and the fracture might not cause complete disability. The bad prognosis usually given for fractures of the femur was not warranted, and was largely due to incorrect technic. He had treated many elderly persons by the abduction method with gratifying results. His oldest patient was a woman eighty-nine years of age who lived to be ninety-three.

Urological Diagnosis in the Practice of the General Surgeon.—Dr. LEO BUEGER stated that modern urological investigation with highly developed urological instruments and practice in their use made available to the urologist many special procedures not ordinarily employed by the general surgeon. The general surgeon could cooperate with the urologist to his own advantage and to that of his patient. There was great need for educating young men in the field of urological diagnosis, for here many mistakes were made. For instance, calculus of the ureter might give symptoms simulating intestinal obstruction and even peritonitis, and operation might be performed when it would have been possible to remove the calculus through the urinary tract. Urinary calculus in the lumbar region might be taken for retrocecal appendicitis. When there were signs of urinary retention, calculus should be suspected. In some cases of supposed subacute or chronic appendicitis vaginal examination revealed the presence of ureteral calculus low down. Tuberculous nodules in the ureter might be mistaken for calculi. Ovarian disorders had been diagnosed in cases in which a cystoscopic examination would have revealed intraureteral debris. The indications for and method of employing the retention catheter were discussed and lantern slide demonstration showed what the urologist could discover by means of the shadow graf catheter, the pyelograph, which though its use was restricted, was important in certain cases; the baby cystoscope, which had aided in the diagnosis and treatment of pyelitis in children; the Bueger opera cystoscope, which carried a scissors-like instrument which made possible certain operative procedures on the bladder, and the direct, indirect and retrograde cystoscopes.

Surgical and Nonsurgical Treatment of the Prostate and Seminal Vesicles in Arthritis.—Dr. OSWALD S. LOWSLEY, of New York, stated that the teeth, tonsils, sinuses, and various other focal infections had received attention in their relation to arthritis and he wished to call attention to the part played by the prostate gland and the seminal vesicles in the production of this condition. His observations were based on a study of 100 cases of arthritis in the urological department of Bellevue Hospital. The ages of these patients ranged from seventeen to fifty-one years, the average being twenty-nine and one third. The season of the year did not seem to make any difference except that there were not quite so many cases during the summer months. The joints affected, in the order of frequency, were the knee in fifty-three, the ankle in forty-four, the wrist in thirty, and the foot in twenty-six. The infection was traced to the teeth in thirty-one cases and to the tonsils in ten. Twenty-three per cent. of the patients denied having had gonorrhoea. The impression that infection arising from the prostate and seminal vesicles was usually gonorrhoeal was incorrect. An analysis of these cases showed other organisms predominating in this locality such as the *Staphylococcus aureus*, *Streptococcus viridans*, and other forms of streptococci. In three of the cases brilliant results were obtained with vaccines. In a number of cases treatment by steaming was very satisfactory. Ten cases were treated surgically with good result. Where there was chronic seminal vesiculitis, seminal vesiculectomy was preferable to vesiculotomy. Of fifty cases of polyarthritis in which infection from other sources was eliminated, examination of the prostate and seminal vesicles showed these to be the source of the infection. In searching for the source of infection in any case of arthritis the prostate and seminal vesicles should not be overlooked. Autonomous vaccines were extremely valuable in same cases used in conjunction with other methods of treatment.

The Rôle of the Colon Bacillus in Infections of the Kidney.—Dr. HUGH CABOT, of Ann Arbor, Mich., said that, excluding tuberculosis, the colon bacillus was found to be the infecting organism in a large proportion of kidney infections. The number of these infections did not seem to be decreasing. The most common and perhaps the most important kidney lesion was pyelitis. Of this condition there were two groups of cases: In the first there was no demonstrable reason for the infection in the urinary tract, while the second group was dependent upon urinary outflow. The second class presented the least difficulty. These cases were dependent upon stricture, stone in the bladder, or other obstruction to the urinary outflow in the urinary tract itself. Such obstruction, however, was not the only factor, but was merely instrumental in preparing for infection. He did not believe instrumentation of the urinary tract was frequently the cause of infection. Where there was residual urine associated with lowered resistance the soil was prepared for infection. The so-called catheter system following operation was open to criticism. It was too much the custom to delay catheterization and trust

that retention would not occur, and it was too frequently assumed that catheterization was responsible for infection. So long as patients were catheterized by the clock, just so long would infections continue to be a reproach to the physician. All these patients should be regarded as likely to have retention. The bladder should never be allowed to become distended above twelve ounces. If early catheterization was carried out, postoperative cystitis would become a rarity. The first group of cases was that in which kidney function might be below normal and the cause lay outside the urinary tract. In this group pressure from the outside produced interference with the urinary outflow, leading to congestion, which prepared the soil for the infecting organism. In this group came the pyelitis of pregnancy as well as the so-called spontaneous cases associated with disease of the large intestine, such as mucous colitis and ulcerative colitis. There was also a group of cases occurring in adult life, particularly in women suffering from constipation and visceroptosis, and another group, in female children in which we had been accustomed to blame the condition on the anatomical conformation. If these infections in female children were due to the introduction of the colon bacillus by way of the urethra, it was strange that they were not more common. Experiment had shown that introduction of the colon bacillus into the bladder did not produce pyelitis, and clinical experience was against this view. It might well be that the colon bacilli affected the kidneys of those who had little resistance. The use of formaldehyde in local irrigation of the kidneys had been much in vogue, but it had failed to live up to its temporary reputation. It was quite strange that patients with a stormy onset and severe symptoms were most likely to go on to complete recovery, while chronic cases often resisted treatment. Attempts with autogenous vaccines might at times relieve the symptoms but failed to remove the infection. He was not sure they had pushed the use of autogenous vaccines to their logical conclusion. There was need of further study of bacilluria, and perhaps conditions in the large intestine might give a clue to the treatment of pyelitis.

Dr. EDWARD L. KEYES, JR., of New York, asked Dr. Cabot concerning the relation of the passage of instruments into the ureter to pyelitis. Attempts to wash out the pelvis of the kidney had not proved satisfactory. It was possible that a certain amount of benefit might be due to the straightening out of the ureter by the passage of the instrument employed in giving the irrigation.

Dr. A. W. BRASCH, of North Germantown, questioned whether the large intestine was the etiological factor in pyelitis. It was his impression that the connection between the colon and the kidney was limited. In treating pyelitis he removed the foci of infection in the teeth or tonsils if any were present and then employed lavage of the kidney pelvis with silver nitrate, placing the patient in the Trendelenberg position. He passed good sized bulbs that straightened out any stricture which might be present, and he believed this cured pyelitis in a large proportion of cases.

A SERIES OF FOREIGN BODIES IN THE BRONCHI AND ESOPHAGUS.*

By HENRY LOWNDES LYNNAH, M. D.
New York

In the presentation of this series of foreign bodies in the food and air passages, I wish to call attention to the difficulties often encountered in the removal of some of the intruders, the mechanical method of removal, and also the comparative ease in which many of the uncomplicated foreign bodies may be removed.

In the removal of all sharply pointed objects, such as pins and tacks, great care should be taken to see that the point is disengaged from the bronchial wall before removal is attempted. Faulty manipulation of a sharply pointed foreign body may place it in such a position in the bronchial wall as to render its removal extremely difficult, if not impossible. The prolonged sojourn of a foreign body in the bronchus makes the removal much more difficult than one that has been recently aspirated. Long standing foreign bodies in the bronchus are usually surrounded by granulation tissue. There is also a stricture of the bronchial wall, with a resultant bronchiectasis or pulmonary abscess below the foreign body or stricture, due to the retention of pulmonary secretion of long duration. Patients with bronchiectasis and pulmonary abscess usually improve, and even get entirely well, after the removal of the obstructing foreign body and pumping out of the sponge soaked lung and establishment of proper lung drainage. Bronchoscopic dilatation of the remaining stricture and evacuation of the bronchiectatic cavity may be necessary several times before the cavity is finally obliterated. These are only a few of the complications which may arise in bronchoscopic foreign body extraction; the difficulties and dangers however are numerous, and perforation of the bronchial wall and sudden death of the patient from pneumothorax has been known to occur in the attempted removal of sharply pointed foreign bodies, and one case is recorded where the bronchus was ruptured accidentally on the introduction of the bronchoscope. Therefore, extreme care on the introduction of the bronchoscopic tube, and gentle manipulation of the foreign body should be constantly before the operator who wishes to successfully remove foreign bodies from the bron-

chi and esophagus with a minimum amount of damage being caused.

The difficult removals encountered in this series were the sharply pointed objects, one of which was transfixed, and the impacted foreign bodies, at times completely covered with edema. As a rule smooth objects are extremely difficult to grasp with forceps, and are therefore difficult to extract. The esophageally lodged foreign bodies, such as coins, are as a rule easy of removal, especially when the operator sees the patient before several unsuccessful attempts and much traumatism have been made.

At times the foreign body is buried in a dense ring of edema, which renders its exact localization problematical, and its removal in these instances is extremely difficult. The irritation and inflammation produced by the lodgement of metallic foreign bodies in the bronchi are not nearly as pronounced as the result of inspired nuts and food of any sort. The longer the lodgement of a bronchial or esophageal foreign body the greater the danger to the patient and the more difficult the removal. At times the very innocently lodged penny in the esophagus may slough through into the trachea and the patient succumb to pneumonia.

The most extremely irritating substances bronchially lodged in this series were found to be raw carrot, parched peanut kernel, masticated toilet paper pulp, cheesy infectious material from the tonsil, meat and casts of diphtheritic membrane. All of them were looked upon with extreme suspicion as diphtheria, for the symptomatology and physical signs are much the same. In bronchial diphtheria asthmatic respiration is usually present and this is also an accompaniment of all irritating substances inhaled into the lung. The onset in the fulminating types of bronchopulmonary or asthmatic types of influenza simulate these types of foreign body. closely, both in characteristic symptoms and physical signs, where there is no history of foreign body inspiration. Given a case with such symptoms, negative radiographic findings mean nothing, and the only means of one being able to arrive at a definite diagnosis is by a bronchoscopic examination. When such substances are inhaled by young children, which is frequently the case, they wheeze and rasp and are profoundly prostrated. There is often a marked pulmonary emphysema on the side of the obstruction, for air is much more easily inspired by the foreign body than expired. Therefore, the lung necessarily compensates in turn by

*Read before the Southern Section of the American Laryngological, Rhinological and Otological Society, Richmond, Va., March 1, 1919.

a marked ballooning. The x ray may show a depressed diaphragm in such cases, on the affected side. If the effort at inspiration by a tight obstruction is kept up for many hours the child soon becomes exhausted and death may rapidly follow. In one of these cases there was such an enormous

FIG. 2.

FIG. 2.—(Case II.) Shawl pin removed from left upper lobe bronchus.

amount of pulmonary emphysema that the lung ruptured, and there was a generalized tissue emphysema just prior to death. There is always extreme cyanosis when pulmonary or tissue emphysema appears.

CASE REPORTS

CASE I. Shawl pin in right superior lobe bronchus of a woman thirty years of age, referred by Dr. Ard, of Plainfield, N. J. In bronchus twenty-five hours. By radiographic and bronchoscopic examination the point was deeply imbedded in the opposite bronchial wall. The head of the pin had entered the upper lobe orifice as far as it could go, while the point was transfixed in the opposite bronchial wall. The shaft of the pin presented across the mouth of the bronchoscopic tube and neither head nor point was visible. The head of the pin could not be pushed farther into the upper lobe orifice to release the point and a very difficult mechanical problem presented. The point of the pin by lateral radiographic measurement had penetrated deeply into the opposite bronchial wall. To attempt to remove the pin in the position presenting would only court failure and attempting to pull it out would prove disastrous by causing a rupture of the bronchial wall.

With a nine mm. bronchoscope *in situ*, the head and neck of the patient were rotated well to the right, for the transfixed and buried point had to be attacked in the bronchial wall on the opposite side. The long slanting tip of the bronchoscopic tube was used to press out the bronchial wall just above the imbedded point while the side curved forceps partly open covered the shaft of the pin and gradually followed it up towards the point while pressure was made with the bronchoscopic tube lip. By keeping the blades of the forceps in such position they acted by gentle counter pressure on the bronchial wall and at the same time were in a position to grasp the pin point as soon as it was released. After seventeen minutes the point was released and as the forceps were in position it was grasped. Now the head of the patient was moved to the left and the

pin easily extracted in the normal manner. Had the head not been rotated well to the right it would have been next to impossible to disengage the point.

The patient had been a sufferer for a long time from a substernal goitre and the x ray revealed an enormous thymus gland. While the patient had received a dose of morphine and cocaine, the cough reflex was not affected locally, and an extremely irritating cough from which she had suffered for a long time persisted during the entire operation.

CASE II. A girl aged sixteen referred by Dr. William Dougherty of New York. The girl gave a history of having swallowed a shawl pin some five days before and had no cough or discomfort after it had disappeared. A radiographic picture taken by Dr. George S. Dixon showed the pin to be located in the upper cervical region. There was considerable swelling of the neck of the patient and she complained of pain in her throat from an attempted removal before admission. The patient had some difficulty in swallowing. The patient was prepared for an esophagoscopic examination and the spatula esophagoscope was introduced without anesthesia. There was no pin in the larynx. There was a long rip in the cricopharyngeous constrictor and esophageal wall and the swelling we had noted in the neck was due to subcutaneous emphysema, no foreign body was visible. As the pin had disappeared the patient was sent again to the radiographic room and another picture taken of the entire chest and abdomen.

The chest plate showed the pin to be lodged in the left bronchus with the point in the upper lobe orifice. As the patient was in a very poor condition from the esophageal rupture no anesthetic was

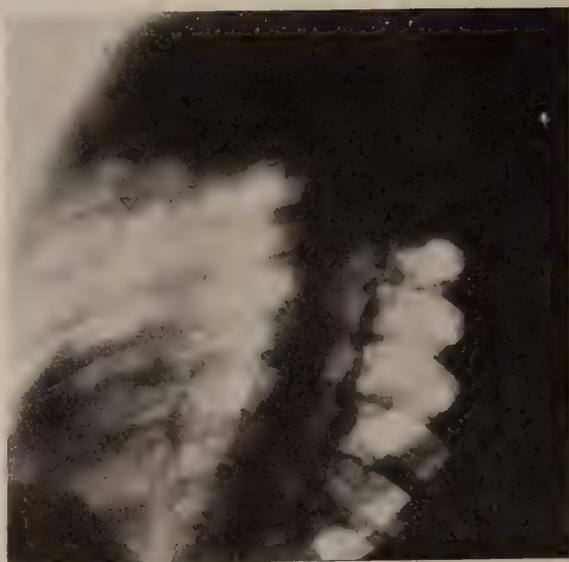

FIG. 3.—(Case I.) X ray picture showing shadow of shawl pin.

used. A dose of morphine was administered and the pin was rapidly removed through a seven mm. tube. The point of the pin was in the left upper lobe bronchus, but it was easily pushed downward after grasping the shaft with forceps and disengaged. The removal of the pin from the bronchus taking three minutes. After the removal of the pin the esophagus was inspected.

There was a long slit in the esophagus, the edges of the wound were covered with a thick slough. A suction tube was introduced into the wound and with a twenty inch vacuum some foul smelling material was removed. The wound was then swabbed with tincture of iodine. As the patient

FIG. 4.—Shawl pin in the larynx supposed to be in the upper esophagus. Radiographic plate taken before attempted removal from the esophagus. (Case II.)

had been unable to swallow for the past twenty-four hours and was suffering from water hunger, milk and water were injected by syringe into the stomach through the esophagoscope. A soft rubber stomach tube was then introduced and the patient fed by the syringe method through the proximal end of the tube which extended out of her mouth. The tube was attached to the neck by tape to prevent its becoming dislodged and swallowed. By this time there was marked emphysema of the neck and face and the temperature had risen to 103.2° F. The pulse was weak and rapid. The patient was at all times conscious, and her chief complaint was a severe stabbing pain in the region of the sternum on inspiration. There was a booming systolic heart sound over the entire precordial region. The second sound could not be elicited. Scattered râles were elicited over the anterior aspect of the chest, but these were probably due to the crackles of the subcutaneous emphysema in this area. The following day after a thorough dose of the water cure treatment, the patient requested that the tube be removed. This was done and the wound in the esophagus was again swabbed with iodine after thorough evacuation of the pocket. The feeding tube was then replaced. This treatment was continued from day to day and by the end of the first week the patient showed signs of improvement. The temperature was 101.4°, pulse 110 and regular and respirations 32. There was a pleuritic rub over the region of the sternum but the heart sounds could be distinctly heard. By the tenth day the patient continued to show improvement but strenuously objected to the method of feeding. The esophagoscope was passed and the wound inspected. The wound had almost completely healed but there was still an inflammatory

exudate about it. This was probably protective for there was no foul odor. The patient was given a swallowing trial with a glass of milk and did fairly well. The reintroduction of the feeding tube was discontinued. By the end of the second week the girl was able to be up and about and by the end of the fourth week she was able to leave the hospital. She could swallow without difficulty at this time and the esophageal wound had completely healed. The patient was seen a year later and there was no stricture of the esophagus and no difficulty in swallowing. A radiographic plate taken at this time showed the lungs and precordial region to be normal. It is extremely interesting to note the difference in the two radiographic plates. The one taken just after the accident before an attempt was made to remove the pin from the cervical esophagus and the other after the attempted esophageal removal and rupture of the esophagus. Air entered the mediastinum and it can be definitely made out in the radiographic plate taken after the esophageal rupture.

CASE III. A boy aged seven was admitted to the Kingston Avenue Hospital suffering from measles and croup. There was a large perilaryngeal abscess present which Dr. Cannon, the resident physician, recognized as the probable cause of the croupy symptoms. As the abscess was opened there was a blast of air through the wound and much pus was sucked in with inspiration. The child was immediately inverted and a quantity of foul smelling pus was drained from the abscess cavity. Then the wound was examined and found to communicate with the trachea. On examination of the tracheal fistula Dr. Cannon saw an object in the wound and as he opened the tracheal fistula the object dropped into the lung. The following day a radiographic

FIG. 5.—Radiographic plate taken on admission after an attempted removal of pin from the esophagus. Note that the pin was dislodged from the larynx and was found in the left bronchus. The white area over the base of the heart is due to mediastinal pneumothorax. Compare this plate with the one taken before the esophagus was ruptured. (Case II.)

plate was made which showed a closed safety pin in the right main bronchus. By peroral bronchoscopy through a five mm. tube the pin was located and easily extracted in four minutes. The

larynx looked not unlike a larynx following prolonged intubational tubage, but it readily returned to normal. The tracheal fistula healed in the usual manner. The child had been treated for diphtheria and croup for six weeks, and it was only after he was admitted to the hospital for measles that the

first trial. Neither of us was able to grasp the head of the screw at the first trial with the forceps at hand, for there was a firm ring of edema above the head of the screw which almost completely hid it from view. It was evident from the radiographic plate that the screw was a large one and the head

FIG. 9.

true nature of the cause of the croup was recognized. The boy made a complete recovery and there was no stenosis after a year.

CASE IV. Dental root brooch in left superior lobe bronchus. The patient was a young lady aged seventeen who inhaled the tooth canal reamer which slipped from the fingers of the dentist. Dr. Fidler saw the patient and after having taken some excellent radiographic plates referred the patient to me for removal of the foreign body. The brooch was in the left superior lobe bronchus for thirty hours. Under local anesthesia the brooch was readily extracted through a seven mm. bronchoscope in two minutes. No sign of the presenting hair like point could be seen in the mouth of the left upper lobe bronchus until the patient's body was rotated well to the right. In this position a small hair like point

must have been considerably larger than the diameter of the bronchus into which it had entered; nevertheless it had worked its way downward by its ratchet movement as far as it was possible to go.

After fifteen minutes' trial further attempts at removal were discontinued and a second trial was to be made a week later. In the interval I had a special pair of alligator forceps made which would dilate the stricture above the head of the screw and at the same time grasp it firmly. A week later a second attempt was made to extract the screw by upper bronchoscopy, and after Dr. Arrowsmith had worked for a few minutes he decided that it would be advisable to remove the screw by tracheotomic bronchoscopy owing to the massive head of the screw which was bound to cause much traumatism if removed through the glottis, and the resultant secondary sub-

was visible lying on the floor of the bronchus. It was gently grasped by straight forceps and removed. The patient recovered.

CASE V. Carpenter screw in the lung of a boy of two years. I had the good fortune to see this case with Dr. Arrowsmith whom I assisted at the

glottic edema would necessitate tracheotomy later. Dr. Arrowsmith performed a low tracheotomy with the five mm. bronchoscope *in situ*. After working for a short time Dr. Arrowsmith's eyes became very tired and he gave me a second trial at removal. I had the good fortune to have the blades of the for-

ceps dilate the edematous stricture above the foreign body and engage it and the screw, forceps and bronchoscope were removed through the tracheal fistula. Had not Dr. Arrowsmith's eyes become tired I would never have had a chance to remove the foreign body as he would have worked a few

FIG. 14.—X ray shadow of dental brooch removed (Case IV).

minutes longer and removed it himself. The cannula was successfully removed and the child made a complete recovery.

CASE VI. Metal intubation tube removed from the right main bronchus of a child of two years. The child was admitted to the Kingston Avenue Hospital suffering from laryngeal diphtheria for which she was intubated. A large dose of antitoxin was administered and as the general condition of the child was good on the fourth day an attempt was made to remove the tube. The tube was lost during the attempt and was thought at first to have been coughed up and swallowed, for the child had little discomfort and breathed well through the larynx. During the afternoon the child had some difficulty in breathing but intubation was not considered necessary. The case was referred to me for bronchoscopic examination, and on the introduction of a five mm. tube the head of the tube was seen to be in the right bronchus. The lumen in the head of the tube was entered with the extracting forceps and it was removed through the mouth. As the head of the tube was much larger than the glottis there was some traumatic subglottic edema which followed and the child again became croupy, but reintubation was not necessary. The child made a complete recovery.

CASE VII. A special O'Dwyer tube with large retaining swell and head was accidentally shoved down during the act of digital extubation. The tube, a three year size, was introduced into one of the coughup cases owing to the great diameter of the retention swell. The tube gravitated downward

owing to the absence of the cricoid cartilage which would have ordinarily held it in place, had not the cartilage sloughed out as a result of perichondritis which is the chief factor in all cases of coughing up of the tube. As the head of tube had gravitated downward, there being no cricoid cartilage to hold it in position, the added attempt to remove it shoved it down into the bronchus below. The child immediately became cyanotic and an emergency tracheotomy was performed. The tube was removed through the tracheotomic fistula. The child recovered but became one of the postdiphtheritic retained tracheal canula cases. He was eventually decannulated and made a complete recovery.

CASE VIII. A two year intubation tube removed from the right bronchus in a child aged two and a half at Riverside Hospital. The usual thing occurred at attempted extubation by the digital method that the tube head was pushed through the glottic opening and fell into the bronchus. A second tube was introduced after the first tube fell into the bronchus but as this gave no relief tracheotomy was performed and the tube was extracted by tracheotomic bronchoscopy, a five mm. tube being used. The child was greatly improved following the removal of the tube but as she had a bronchopneumonia before the accident which continued to spread she succumbed two weeks later.

CASE IX. A two year intubation tube removed from the left bronchus in a boy of two years and nine months. The boy was admitted to the Willard Parker Hospital and intubated for laryngeal diphtheria. A large dose of antitoxin was administered and as the general condition was good on the fifth day a digital detubatory trial was made. The at-

FIG. 15.—X ray showing location of carpenter screw removed from the lung (Case V).

tempt to remove the tube was unsuccessful at the first trial and several attempts were made. Finally the operator said that he could not feel the tube. An attempt was made by the resident physician to locate the tube but this was unsuccessful. The writer was notified of the condition and removed the tube the same afternoon with some difficulty

through the mouth. The child became stenotic a few hours after the removal of the tube and reintubation was necessary to relieve subglottic edema. The tube was worn for one week and removed by the direct method. The child remained without the tube and made a complete recovery.

CASE X. A one year noncoughup tube removed

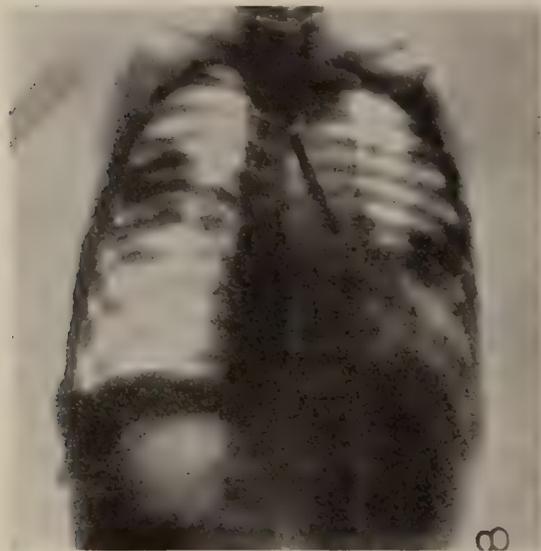

FIG. 16.—Intubation tube shown by x ray removed from right bronchus. (Case VIII).

from the right bronchus of a child aged a year and half. The child was admitted to the Kingston Avenue Hospital and intubated with a one year O'Dwyer tube. After a large dose of antitoxin the child improved but was unable to remain without the tube at the first trial. During the second week the child started to cough up the tube, and one of my noncoughup tubes was introduced. This tube was retained and put a stop to further trouble. One week later one of the staff while attempting to remove the tube shoved it down into the bronchus. At first the tube was thought to have been extracted and swallowed, for there was little discomfort following the lodgement in the bronchus. A radiograph showed the tube to be in the right bronchus. The child had so little discomfort from the tube in the bronchus that at first it was thought impossible, until the child became stenotic five days after the accident, the afternoon of the same day that the x ray was taken. I attempted to remove the tube after the introduction of a five mm. bronchoscope and while the tube could be brought up to the glottis it could not be extracted. A tracheotomy was performed with the bronchoscope as a guide and the tube removed by the straight extractor through the tracheotomic fistula. The child wore the tracheal cannula for a long period after the removal of the tube but was eventually decannulated and made a complete recovery.

CASE XI. A small piece of toilet paper in the right lower lobe bronchus in an infant of eight months. The case was referred by Dr. Angelo Smith, of Yonkers, N. Y. The infant was in the habit of putting paper in her mouth and the nurse who had been left in charge of the baby probably

paid little attention to her during the absence of the parents. When the nurse returned to the room she found the child choking. She immediately put her finger in the mouth of the infant and removed several pieces of toilet paper. The child was in *extremis* and Dr. Smith was notified. When I saw the child a few hours later she was in poor condition. The lungs were ballooned, and there was a marked asthmatic wheeze on expiration. Little air entered the right lower lobe of the lung. The radiographic plate was negative. The infant was bronchoscoped, a four mm. tube being used. In the right bronchus, as far downward as it could go, was seen a whitish mass which looked like a plaque of diphtheritic membrane. This was removed by suction, for fear of maceration with forceps. Both bronchi were then explored but no further pulpy masses found. The baby improved after the removal of the piece of paper and much secretion by suction but within a short time the lungs began to fill and there was difficulty in breathing. The four mm. tube was again introduced and much secretion evacuated. Marked subglottic stenosis was seen on the second introduction of the bronchoscope even though we had only worked fifteen minutes. We decided to perform tracheotomy for the subglottic stenosis and drainage of the lung. Tracheotomy was performed with the bronchoscope as a guide.

The tracheotomy temporarily relieved the condition, but pulmonary edema became very bothersome and repeated aspirations were made to remove secretion. This was easily accomplished by the introduction of a small catheter into the tracheotomy tube. Repeated aspirations continued each time that there was difficulty with respiration, but this was all to no purpose, for thirty-four hours after bronchoscopy the unfortunate infant succumbed to pulmonary edema.

CASE XII. This is a bronchoscopic gauze sponge which became detached from a sponge holder which was not fixed properly and became lodged in the right upper lobe bronchus. This accident occurred in an adult suffering from tracheobronchial diph-

FIG. 17.

FIG. 19.—Upholsterer's tack removed from right stem bronchus (Case XIII).

theria after the removal of a diphtheritic cast. It was during the process of swabbing the tracheobronchi with antitoxin that the sponge was lost. The nurse, in applying the sponge, did not tighten the collar over the grasping blades of the sponge

holder and it was easily detached and lost. The sponge, readily absorbing the bloody secretion in the bronchus after the removal of the membrane, was difficult to locate. However, after a few minutes' search, it was located in the upper lobe orifice and was easily removed. The patient made a complete

FIG. 20.—Upholsterer's tack seen in right stem bronchus opposite the middle lobe orifice (Case XIII).

recovery from the diphtheritic foreign body and sponge.

CASE XIII. An upholsterer's tack removed from the right stem bronchus opposite the middle lobe orifice after a sojourn of two and a half years. I had the pleasure of seeing this patient, a boy of eight years, with Dr. Forbes. The tack was in a difficult location in the right stem bronchus, and the head was anchored at the middle lobe bronchus, imbedded in a firm stricture of long duration. The point of the tack could be easily seen through the seven mm. tube pointing well to the left. The head of the tack was not visible. Dr. Forbes had dilated the stricture several times but the tack could not be budged. I had the good fortune to be of assistance at two sittings and it was at the last trial that I was given the opportunity to remove the tack. The difficult problem presenting was, that the shaft and point of the tack were pointing well to the left, and that the head of the tack would be reanchored in the lip of the middle lobe bronchus each time an attempt was made to remove it against the axis of the presenting point. Therefore, the boy's body was rotated well to the left and the bronchoscope and forceps were brought into a line with the presenting shaft and point of the tack. Now axis traction was applied with considerable pull, and in one minute the bronchoscope, forceps and tack were all removed together. There was a lung abscess which ruptured into the pleura, and a rib was resected to drain the cavity. It was a long time after the removal of the foreign body before the drainage tube could be removed from the pleura. The boy recovered.

CASE XIV. Four pieces of raw carrot inhaled into the right and left bronchi in a child aged three. The

child had a croupy cough and violent asthmatic wheezing for five days, and had been treated as a case of diphtheria. As the asthmatic dyspnea did not improve after antitoxin, and as Dr. Raymond Laub had obtained a history from the mother that the child had a choking spell five days prior while eating raw carrot, the child was referred to me for bronchoscopic examination. On admission, the child was in *extremis* and made no effort to cough. There was a marked asthmatic wheezing expiration audible at some distance. Dr. Laub had made a physical examination of the chest, and stated that little air was entering either lung, and that the percussion note was tympanitic. There was a general subcutaneous emphysema present which involved the face, chest and trunk. The larynx was emphysematous and shiny. The trachea and bronchi were not involved. With a five mm. tube a piece of carrot was removed from the right main bronchus. The child was moribund and died shortly after the removal of the large piece of carrot. An autopsy was permitted by the parents and three smaller pieces of carrot were removed from the lung. One piece was found in the right superior lobe bronchus; the third piece in the left main bronchus, and the fourth piece in the dorsal branch of the left lower lobe bronchus, at which location there was a well defined abscess containing foul smelling pus. The lungs were beefily congested and ballooned with air. The visceral pleura was covered with air blebs from the size of a pea to a half dollar. The rupture of the blebs probably caused a leaking of air into the mediastinum, which followed the cervical fasciæ

FIG. 21.—Lateral view of upholsterer's tack in right stem bronchus (Case XIII).

and produced tissue emphysema. The heart was increased in size. This case illustrates the valve-like action of loosely placed foreign bodies in the air passages. It also illustrates that the irritating effect of raw carrot in the air passages is equally as irritating and fatal as the inhalation of peanut kernels, and was rapidly productive of food inhalation bronchitis and lung abscess within five days of the accident.

CASE XV. Peanut pulp of a parched nut removed from the right bronchus of a child two and a half years of age. The child had been given several pieces of peanut which had been partly broken up by the mother. The child aspirated it into her lung shortly after taking it into her mouth and had a

been a fatal peanut bronchitis and pulmonary abscess.

CASE XVI. Peanut kernel and several small pieces removed from the right bronchus of a child of three years and eight months. The child was admitted to the hospital five days after the accident. A

FIG. 22.

FIG. 22.—Four pieces of raw carrot removed from the bronchi of a child (Case XIV):

FIG. 23.

FIG. 23.—Peanut pulp removed from right bronchus (Case XV).

violent choking spell. The child was brought to the hospital six hours after the accident. The physical examination showed that little air was entering the right lung. There was an asthmatic expiratory wheeze. An x ray plate revealed a shadow over the right upper and middle lobes, but the radiographer thought there was also a shadow in the right lower bronchus. Bronchoscopy was performed without anesthesia and a small piece of peanut was removed from the right stem bronchus opposite the middle lobe orifice, a five mm. tube being used. As the piece removed by forceps seemed to be the largest piece, the remaining fragments were removed by suction through a two millimetre tube. The small pieces of pulp were readily removed by this method, care being taken not to wad the pulp in the lower lobe bronchus.

All of the peanut pulp was apparently removed for air entered the whole of the right lung. There was a high rise in temperature to 105.2°, following the removal, but gradually fell to normal within two days. The child was kept under observation for two weeks and then discharged after repeated stethoscopic examinations of the chest. The child made a complete recovery and was in perfect health six months after the extraction. This case illus-

FIG. 24.

FIG. 24.—Peanut kernel removed from right bronchus (Case XVI).

splendid radiograph taken showed a dense shadow over the right lobe. Bronchoscopic examination was made and a fragment removed from the right stem bronchus. By suction several small fragments were removed and about a dram of foul smelling pus evacuated from the lower lobe bronchus. After having worked for fifteen minutes the procedure was discontinued. There was considerable reaction following the bronchoscopic examination and the temperature rose to 104.2°. The pulse and respiration were rapid. A physical examination made at this time showed that there was a diffuse bronchitis and pneumonia over the lower lobe of the right lung. Posteriorly there was no air entering. Three days later a second bronchoscopic examination was made with a four mm. tube and the dorsal branch of the lower lobe bronchus explored. No fragments of peanut were removed, but some pus was evacuated. From this time on the child began to run a septic temperature. The left lower lobe was aspirated with a long needle and the abscess cavity located. Unfortunately a pulmonary abscess developed, owing to the failure to remove a small fragment which had entered a small dorsal branch bronchus. Later the abscess increased in size and a rib was resected. This drained the abscess but the child did not improve. She continued to linger

FIG. 25.—Fragments of meat removed from right bronchus (Case XVII).

trates the value of suction in removing small pieces of peanut from the lung. Had an attempt been made to remove all of the small fragments with forceps there would have been great danger of macerating them, and some of the tiny fragments would have been lost, and the result would have

FIG. 26.—Pieces of infectious material removed from right upper lobe bronchus (Case XVIII).

in this septic condition and succumbed six weeks later.

CASE XVII. Some fragments of meat removed from the right bronchus of a boy aged four. The boy was admitted to the Kingston Avenue Hospital for laryngeal diphtheria, for a dose of antitoxin

given by the family physician did not relieve the dyspnea. On admission, Dr. Adam Eberle, by a very careful physical examination, ruled out tracheo-bronchial diphtheria, and notified me of the possibility of a foreign body on account of the mother's statement that the child choked while at the table

FIG. 27.—X ray of peanut pulp in right bronchus (Case XV).

and developed croup the same night. The onset of the croupy attack was too sudden for diphtheria, and Dr. Eberle suspected that a foreign body in the right lung was the cause of the trouble. A bronchoscopic examination was made with a five mm. tube and a small mass of chewed meat was removed from the right bronchus. The physical signs did not clear up while the bronchoscope was *in situ*, and on a second inspection a small piece was removed from the lower lobe bronchus. The physical signs as elicited by the stethoscope immediately improved after the removal of the fragment, and air readily entered the lung. The boy was kept in the hospital for two weeks and discharged as cured. The interesting points of this case are the diagnosis of a foreign body by Dr. Eberle on a vague history and the stethoscopic signs in the chest. And second, that a stethoscope physical examination with the bronchoscope *in situ* is of the greatest aid in determining whether all of the foreign body has been removed.

CASE XVIII. Some small pieces of cheesy infectious material removed from the right upper lobe bronchus of a child of one year. The child was admitted to Riverside Hospital for supposed diphtheria. After the acute diphtheritic process had subsided there was a severe hacking cough and a peculiar wheeze on expiration. Dr. John Crawford suspected the presence of a foreign body and had an x ray picture made. The x ray showed a very dense shadow over the upper lobe of the right lung. Two days later we bronchoscoped the child and located a foreign body in the orifice of the right upper lobe bronchus. A whitish mass was seen in the orifice of the upper lobe bronchus through a four mm. tube. It was grasped with forceps and re-

moved. On its removal a small piece was seen to fall into the stem bronchus. The child was placed in an exaggerated Trendelenburg position and with a small suction tube this piece was removed. With the first piece removed there was a small sac which seemed to contain the particles. A few hours later subglottic edema developed, even though we had only worked ten minutes. The stenosis required intubation, a oneyear tube being worn for two days. One month later the child was discharged from the hospital cured. The specimen was sent to Dr. Jeffries of the Polyclinic Medical School Laboratory and he reported that the material was enclosed in an epithelial sac. "The material removed from the right bronchus of K. Z. was a mass of pus cells and mixed organisms, no tubercle bacilli were found. The mass is similar to the cheesy infectious material removed from the crypts of tonsils, and no doubt it fell from the tonsil into the lung." The child had hypertrophied tonsils with cheesy material in them when examined after the report from Dr. Jeffries. The small mass in its epithelial covering produced a complete blocking of the right upper lobe of the lung. Later x ray plates showed the lung to be clearing.

CASE XIX. A tracheobronchial diphtheritic cast removed from the right bronchus of a boy eight years of age. The boy had been ill with a mild bronchitis for six days and diphtheria was suspected by Dr. Brendler, who asked me to see the patient with him. A large dose of antitoxin had failed to relieve the croupy attack, which had become gradually worse twenty-four hours later. The child was *in extremis*, and expiration was difficult and accompanied by an asthmatic wheeze. A rapid stethoscopic examination showed that little air was entering the right lung. There were many noisy râles over both lungs. We bronchoscoped the boy and found the larynx congested. The lower tracheal and right bronchus were filled with membrane, which

FIG. 28.—X ray of peanut kernel in right bronchus (Case XVI).

was easily removed by suction. The trachea and bronchi were swabbed with antitoxin and a long intubation tube introduced. There was a very severe reaction following the removal of the membrane and the temperature gradually rose until it was 107° an hour later. It was evident at this time

that the boy was *in extremis* and would probably succumb. He was irritable and craved for water, which he could not swallow on account of the trickling into the tube. A small rubber catheter was introduced through his nose into the esophagus

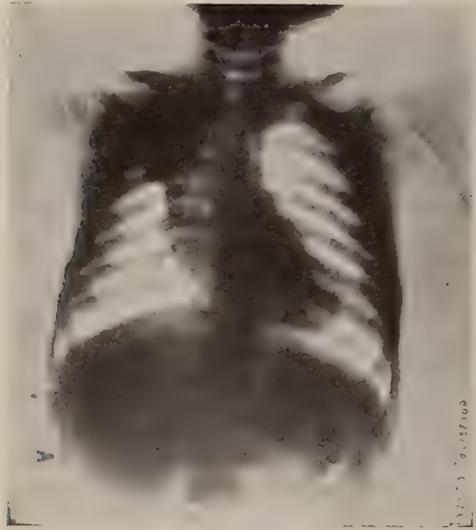

FIG. 29.—X ray showing dense shadow over upper lobe of right lung (Case XVIII).

and a half pint of milk with two drams of whiskey introduced. His thirst having been relieved the boy fell asleep. Within two hours his temperature had fallen to 105° and it continued to range between 105° and 103.2° for the next two days. Feeding was continued by gavage and as he was getting a good amount of nourishment he continued to improve. By the end of the fourth day the general condition of the boy had improved to such a degree that I decided to remove the long bronchial tube. This was done and there was no discomfort after its removal. Reintubation was not necessary. The boy had a protracted convalescence owing to a patchy pneumonia following, but he made a complete recovery after two months.

CASE XX. Membranous diphtheritic plaques removed from the trachea and bronchi. This case

FIG. 30.

FIG. 30.—Diphtheritic cast removed from right bronchus (Case XIX).

FIG. 31.

FIG. 31.—Diphtheritic plaques removed from trachea and bronchi (Case XX).

was seen with Dr. Ginsberg, of Yonkers, N. Y. The child had been intubated by Dr. Pisek who had given a large dose of antitoxin. The child was greatly improved after intubation of the larynx, but the same evening he became dyspneic in spite of the

tube, and I was called to bronchoscope the patient. In the meantime the tube had been coughed up and when I arrived the boy was in much distress. The bronchoscopic examination revealed a loose cast of membrane in the trachea. This was removed and a thin piece was visible in the right bronchus. After this was removed there was no further membrane visible. An intubation tube was introduced. The condition of the boy was much improved the following day and he was in sufficiently good condition to remove the tube on the third day. There was no further trouble after the removal of the tube and the patient made an uneventful recovery. The tube used was a five mm. and the time of operation six minutes.

ESOPHAGEAL FOREIGN BODIES.

CASE I. Codfish bone imbedded in the plicacricopharyngeus with only the small beaded head of the articulating end presenting. Referred by Dr. H. T.

FIG. 34.—Chicken bone removed from esophagus (Case II).

FIG. 35.—Chicken bone from esophagus (Case III).

FIGS. 37 to 41.—Diameters of coins removed (Cases IV to IX).

Galpin. Radiographic plate negative. Great pain from spasmodic contraction of cricopharyngeus, and much gagging and discomfort. Beaded end presenting in area of inflammation. Easily removed through spatula esophagoscope in one minute; no anesthesia; recovery.

CASE II. Clinical case in child of four years. Small piece of the breast bone of a chicken, presenting crosswise and transfixing in upper thoracic esophagus for five days; marked edema. Radiographic plate did not show bone. Easily removed through seven m.m. esophagoscope in a few seconds after turning to avoid cutting esophageal wall.

CASE III. Piece of breast bone of chicken in esophagus of a child of ten years; in esophagus three days; below cricopharyngeus. Easily removed through esophagoscope in two minutes; no anesthesia.

CASE IV. American penny in esophagus of a child of one year. It was lodged in the esophagus below

FIG. 32.—Penny in esophagus (Case IV).

cricopharyngeus for a week. The esophagus was lacerated and swollen from two attempts to remove before admission. A spatula esophagoscope and alligator forceps was used; extraction in eight minutes. It was difficult to locate on account of marked edema and sloughs in esophagus; extraction followed by cure. There was no stricture of esophagus six months later.

CASE V. Coin, penny, in esophagus of child two years; in esophagus fourteen hours; easily extracted in one minute; cure.

CASE VI. Referred by Dr. Angelo Smith. Coin, nickel, in esophagus of child two and a half years, upper thoracic region for eight days; much edema covering coin; extraction, cure. Removed in four minutes. Tube, seven mm. bronchoscope.

CASE VII. Coin, nickel, in esophagus of a child of three years and eight months; in esophagus four weeks; opposite bronchial crossing after having been thought to have been shoved down with a stomach tube; extraction, cure. Esophagoscope. Time, ten minutes.

CASE VIII. Coin, nickel, in esophagus of a child two and a half years; in esophagus twelve days; edema covering whole of presenting edge; extraction through tube spatula with alligator in six minutes.

CASE IX. Coin, nickel, in esophagus of an infant of one and a half years; in upper esophagus two days; difficulty in breathing and swallowing; extraction through laryngeal spatula with alligator forceps in one minute.

CASE X. Coin, quarter of a dollar, in esophagus of a child of three years for fourteen days. There was a marked edema; esophagus covered with thick

exudate; no history of any attempted removal before admission; pharyngeal wall much inflamed; membrane removed was diphtheritic by culture. The foreign body was completely hidden from view in membrane and edema. The extraction was difficult owing to edema, which was difficult to push aside to see coin. The esophagoscope and long alligator forceps were used after the edema over the coin was separated with blades of forceps. Time of operation, seven minutes. Recovery.

CASE XI. Triangular piece of sternum of chicken in esophagus below plicacricopharyngeus of a young lady of sixteen years for twenty hours. The patient was referred to me by Dr. Ard of Plainfield, N. J. Easy removal in three minutes with spatula esophagoscope and alligator forceps.

CASE XII. Large triangular piece of the sternum of a chicken in esophagus below cricopharyngeus of a woman of thirty years for two days. Good x-ray plate of triangular piece of bone. Referred by Dr. Angelo Smith, of Yonkers, N. Y. Points deeply imbedded in esophagus with some bleeding at fixation of points; spatula esophagoscope; rotated to disengage points to prevent laceration; extraction, cure. Time of operation, four minutes.

CASE XIII. Mother of pearl button in upper thoracic esophagus in a girl of six years for forty-six hours. Easy extraction through seven mm. esophagoscope in two minutes. No anesthesia. Recovery.

CASE XIV. Large mother of pearl button in esophagus of a girl of ten years for five days. Referred by Dr. Angelo Smith. Radiographic plate showed

FIG. 42.—Quarter dollar in esophagus (Case X).

button below bronchial crossing. Patient had been fed by force and efforts had been made to push the button down. There had also been several emetics administered by the parents with the hope of bringing it up or sending it down. No new x ray picture taken just before esophagoscopy. A seven millimetre esophagoscope showed a curdled mass below the bronchial crossing, but no button was seen. X rays were then taken of the stomach and intes-

tines, but no button was located. The curdled mass seen in the esophagus was the remains of the dissolved button, the button having been dissolved by the frequent emesis of hydrochloric acid. At the suggestion of Dr. Goldhorn, a similar button was

FIG. 43.—Chicken bone in esophagus (Case XII).

removed from her coat and immersed in a very dilute solution of hydrochloric acid. The button became a cheesy mass within twenty-four hours. It is interesting to note that these buttons, so often called mother of pearl, are made of compressed casein and are readily dissolved in dilute hydrochloric acid. Had an x ray plate been made just prior to the esophagoscopic examination the opera-

FIG. 44.—Pearl button in esophagus (Case XIII).

tion would never have been attempted, for no foreign body shadow would have been seen. However, on the other hand, failure to find nothing but the cheesy mass of the button taught us what these buttons were made of.

FIG. 50.—Apricot seed removed from esophagus (Case XVI).

CASE XV. A lead skirt weight in esophagus of a boy of six years. In esophagus, below cricopharynx, for four days. Extraction by spatula esophagoscope in two minutes.

CASE XVI. Apricot seed held firmly in crico-

FIG. 51.—Olive bougie in gastrototic stomach (Case XVII).

pharyngeus in a man of sixty-two years. In esophagus five hours. Much pain and gagging and difficulty in breathing. Extraction through spatula esophagoscope with Jackson's safety pin closer in five minutes. The head was held well over end of table for fear that the relaxation of the spasm of the cricopharyngeus would release the foreign body.

CASE XVII. Olive pointed bougie and staff accidentally broken off while a gastroenterologist was attempting to dilate a stricture blindly. Case referred by Dr. Wolff Freudenthal. The patient was an extremely emaciated woman of forty-three years. Bougie in esophagus forty-six hours. Much laceration of upper esophagus from attempted extraction before admission. Olive by x rays in gastrostotic stomach in pelvis. Metal of staff opposite and below bronchial crossing. A ten mm. esophagoscope was used and the presenting metal part of staff grasped by long alligator forceps. Extraction in three minutes. The bulbous end was not held in a stricture on removal.

FAILURES AND DEATHS

Out of this series of foreign body extractions there has been one failure to remove the foreign body at the first trial, and three deaths. The failure was an attempted extraction of a deeply-located shawl pin in the dorsal branch of the right lower lobe bronchus, the point having penetrated through the bronchial wall of the opposite side. The point was disengaged and an attempt was made to remove the intruder, which now seemed to be extremely easy. The point and shaft of the pin were brought outward through the bifurcation, while the head of the pin, which caught on the opposite bronchial wall, held it firmly, and this caused the forceps to slip its hold. The writer had worked only a short time, but as the pin was now placed in an extremely difficult position, further attempts were not made, as it was decided then that new x ray plates were advisable to determine the changed position before another attempt was made. The second trial for me, however, was not forthcoming, as Dr. Jackson was consulted in the meantime, and the pin successfully extracted by him one week later. The patient suffered no discomfort other than the mental anxiety of knowing that the pin was still in the lung. The temperature and pulse remained normal throughout the week before the successful removal.

Of the three deaths, two occurred shortly after bronchoscopy. One was moribund on admission

and would have died shortly with or without examination, and the other, an infant, had pulmonary edema at the time of the bronchoscopic examination, which continued up to the time of her death. The third death was due to the retention of a piece of peanut kernel, which caused septic bronchitis and pulmonary abscess, and death ensued six weeks later. General anesthesia was not used for any of the extractions. Cocaine, ten per cent., was used for the bronchoscopic examinations in adults, and no anesthesia for the esophagoscopic in children.

The patients with the two diphtheritic foreign bodies included in this series recovered, but one of them had a stormy time. In a former series of diphtheritic foreign bodies reported, all of the cases without complications recovered. Pneumothorax occurred in one very difficult extraction after the report of this series and is therefore not included, but will be reported later in another series.

ACUTE INFECTIONS OF THE HAND AND THEIR SURGICAL TREATMENT.

BY WILLIAM T. COUGHLIN, M. D., F. A. C. S.,

St. Louis, Mo.,

Professor of Surgery, St. Louis University.

The general practitioner is seldom called upon to treat a condition which can give him more annoyance than an infected hand, nor one whose treatment is fraught with greater difficulty; and perhaps no subject in the whole field of surgery has been more neglected by the surgeon. Even though the results may be the best obtainable, they are never satisfactory from the viewpoint of the patient, who expects *restitutio ad integrum*, and that in much less time than is always required; while the compensation to the surgeon, for his efforts and skill in preserving through a tedious course of treatment a useful though often a somewhat disabled hand or finger, is always more grudgingly allowed than would be that for the total removal of the same part followed by a quick recovery.

The neglect of this subject by the general surgeon probably arises from the fact that few of these cases are referred to him, and, like other people, surgeons prefer to talk, teach, or write about that which comes most often under their special care. In our schools the teaching of the surgery of the hand consists in *telling* the student how to perform amputations, or reduce fractures or dislocations, while the topic of how to deal with hand infections, which, by the way, are more frequent than all three former conditions put together, is hurriedly passed over, or, if dealt with at all, is wrongly taught. If you doubt it, just ask yourself if you were not taught that through and through drainage was the best way to deal with palmar phlegmon?

A knowledge of the gross anatomy of the hand is a *sine qua non* to the intelligently successful treatment of any infection in finger, hand or forearm, and I would like to call attention to it briefly by means of the diagrams herewith shown.

The most common site for the entry of infection is the distal phalanx, and Fig. 1 shows a diagram sketched from a section through any distal phalanx

FIG. 52.—Olive pointed bougie from esophagus (Case XVII).

close to the proximal end of the nail. In the centre note the bone covered tightly everywhere (except under the nail and over its articular surface), with periosteum. Under the nail, filling up the interval between it and the bone and strongly adherent to both, is a fibrous layer—the matrix of the nail.

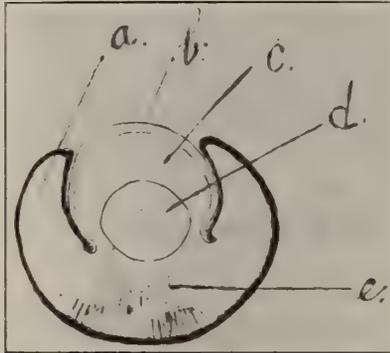

FIG. 1.—Diagram of cross section through distal phalanx; a, fold of nail; b, nail; c, matrix of nail; d, bone covered with periosteum; e, fibrous trabeculae of pulp reaching from periosteum to skin.

This layer has very slight resistance to infection and, once infected, there is no room for the inflammatory exudate to be thrown out. Even very slight inflammatory reaction produces such pressure between bone and nail that the blood supply at the point is cut off or diminished and spread of the infection ensues. This is why infections of the matrix of the nail are so slow in getting well.

I remember a strong, healthy young man, whose thumb nail, partly undermined with pus, had been treated for a period of nine weeks, and then, as he expressed it, "was worse than ever." He had been accused of syphilis but his Wassermann reaction was negative, and his thumb got well without any antiluetic treatment in about eight or ten days when he was treated surgically. The quickest and best way to deal with an infected matrix is to remove that portion of the nail overlying the infected area—wide removal so that there will be no overhanging edges—and apply a moist, mild antiseptic or normal saline dressing. Keep the part at rest and change the dressings often. Never allow a dressing to become dry before healing begins, and thereafter it is better to use an ointment.

In Fig. 1 notice how the soft parts roll up over the sides of the nail; Fig. 2 shows a longitudinal section through the same phalanx. In this figure note the fold of soft parts—skin and subcutaneous tissue carried forward over the back of the nail. This fold over the back and along the sides of the nail is perhaps the most commonly infected part of the finger, this tissue being much exposed to injury. The bacteria get into the injured tissue and suppuration on the deep aspect of the fold ensues, for here they find moisture, warmth and darkness, while injured tissue makes for them a good culture medium. It is but a short distance around the root or side of the nail to the matrix, and if this becomes infected the overlying part of the nail must come off.

For the ordinary slight infections hardly more than a splint and alcohol pack are needed. If, however, the condition does not yield to such measures the fold should be cut through at once. It is worth

doing under anesthesia. It can be properly done only when the patient feels no pain. Cut through the fold backward from its free edge on each side until the incision reaches back as far as the root of the nail extends. That is nearly half way from the edge of the fold to the joint. One must be careful not to open the joint, Fig. 3. The fold thus incised can now be turned back as a flap. The underlying nail root is examined to make sure that the matrix under it is not infected. Pus under the nail looks yellowish white. If there is pus under it remove the nail widely; then lay a thin bit of rubber or lint in the wound and replace the flap. Apply a mild antiseptic wet dressing and put the part on a splint and the arm in a sling. Change the dressing frequently and keep immobilized until well.

In Figs. 1 and 2, notice the so-called pulp of the finger. Observe the lines stretching from periosteum to skin. They represent dense, tough fibrous bands or partitions. These divide the space between skin and bone into innumerable chambers and each chamber is filled with fat. Were it not for these partitions, at every grasp sensitive nerve endings would be painfully pressed between skin and bone, for the fat, being fluid at body temperature, would flow to one side of the point pressed upon. But these same fibres prevent the skin from being pushed away from the bone when exudation occurs between the two. When for any reason, therefore, an inflammation occurs here, it is not long until the pressure against the skin on the one hand and against the periosteum on the other, becomes sufficient to imperil the vitality of one or both, and also that of the parts intervening. In such a circumstance the fat and the fascia are always the first to suffer. Always offering poor resistance to infection, when thus injured they now favor the growth of bacteria and a bad condition becomes worse.

For infection in the pulp the alert physician never waits for the pointing of suppuration. An early and free incision, not only through the skin but down through the pulp, with proper dressing and fixation, will check the spread of the trouble. Incision relieves the tension, and it is the tension which causes death of the periosteum, the skin, the bone, and of all the intervening tissues, for the tension soon shuts off the blood supply.

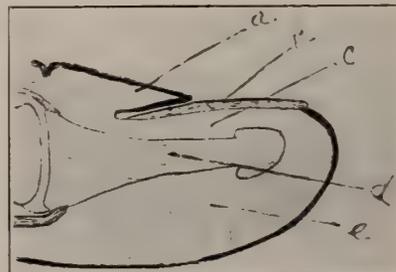

FIG. 2.—Diagram of longitudinal section through middle of distal phalanx; lettering is the same as in Fig. 1.

I have called attention to the periosteum, saying that it was firmly adherent to the bone except over its articular surface. Exposed to trauma as the distal phalanx is, and separated only such a short distance from the surface as its periosteum is, it is not surprising that the periosteum is itself often

injured. When injured, blood or serum collects under it, as all have seen it collect under the nail at the site of trauma, and such small extravasation is often a focus for the development of bacteria lodged here by the blood stream.

When bacteria reach such a site the result will

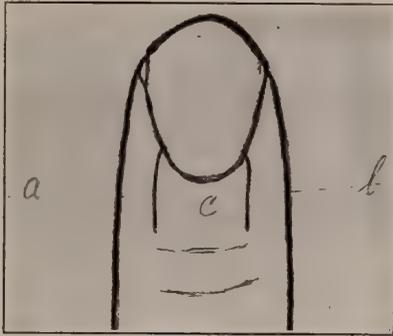

FIG. 3.—a and b, incision through the inflamed fold of nail; c, flap to be turned back to expose root of nail.

most probably be an abscess under the periosteum. The signs are unmistakable. The patient complains of severe pain in the finger, which is constant, throbbing and almost unbearable; pus is about to form, or has already done so, under the periosteum. The periosteum does not readily stretch in any direction, but it yields a little in all directions around the pus and soon the pus has lifted it up from the bone over a considerable area. The pus may pass completely around the bone, and spreading backward when it reaches the end of the periosteum at the edge of the articular cartilage, it may break into the joint. But before it has done this, or afterward, it may break through the periosteum into the subcutaneous space—into the pulp. Whenever the pus escapes from the periosteal covering, then the throbbing pain is instantly relieved. The patient will have pain later on but for a while there is relief, and when the pain recurs, which it does when the subcutaneous tension increases, it is not so severe as it was at first. A strange thing is, that at the onset of any subperiosteal suppuration, while the patient is complaining so bitterly of the pain, there is very little swelling of the part or perhaps none whatever. In fact, there is little swelling before the periosteum bursts.

Careful examination will always reveal a point of maximum tenderness, which is to be found by pressing gently on the skin with a toothpick or some such pointed object. The patient can often locate this spot very accurately. This tender point exists very early in the disease before the infection has spread far or broken through the periosteum. Under the tenderest point between the periosteum and the bone is the seat of the trouble. Over this point is the place to open, and the knife point should reach the bone here only. A large incision is never needed if one can get the patient early. Often only a very small drop of pus is found. The process usually lasts two or three days before the periosteum gives way.

Knowing the pathology, course, and prognosis of infections, no sane man would counsel any other than surgical treatment; yet, those who do not know

advocate poulticing until the felon—for this is a real felon—is "ripe."

The offending organisms in hand infections are usually the staphylococcus and the streptococcus, and the pus is very thick and does not run out easily. Saline in which citrate of soda has been dissolved, two drams to a pint, helps to thin the pus. So does Dakin's solution. Dress with gauze moistened in such a solution, change often, and keep the part at rest. Instead of the moist dressing, constant immersion in a hot bath of saline and citrate is often better. We use the latter during the day and the warm, wet pack at night.

When infection following wounds in the skin or subcutaneous tissue spreads, it does so most often by way of the lymphatics. There are lymphatic vessels passing along the sides of the fingers. Their radicles are in the deeper layers of the skin, the subcutaneous tissue, and in the periosteum and bone. But in addition there are what are known as lymph spaces; for example, what are called perifascial lymph spaces exist between the subcutaneous fat and the deep fascia or tendon sheaths, and there are perivascular lymph spaces around the vessels on each side of the finger. If now, for any reason, a lymph space becomes infected, the pus can easily spread in any direction until the whole space is involved. This explains how it happens that pus may extend completely around a finger and not affect the tendon sheaths or periosteum at all. It is a point to remember in opening phlegmons of the fingers; for if one cut deeper than the plane where he encounters the pus, and if the incision is over a tendon sheath, he may cut through the fibrous tendon sheath and unnecessarily open its synovial lining. This, too, may follow the insertion of a drain or pack, the pressure of the same causing necrosis of the tendon sheath. The ordinary lymphatic vessels passing down the sides of the fingers converge in the web, unite, and crossing the web, enter the palm or pass to the back of the hand. Great numbers of them eventually reach the back of the hand. This, as well as the loose nature of the subcutaneous tissue there, explains why it is

FIG. 4.—Shows the web in first space cut across to open a web abscess.

that the back of a hand undergoes such great swelling in all these infections. It is simple, lymphatic edema. Very seldom does pus so spread, but the web between the fingers is the place to look for the first metastatic abscess in finger infections. Bacteria—not pus—get into the lymph channels and

flowing back reach the web. The web is filled with fat. Fat is poorly supplied with blood, its resistance being low. This fat is no exception to the rule and the bacteria find a good place to grow, just as they do when crossing the ischio-rectal fossa through the lymphatics there. An abscess develops in the

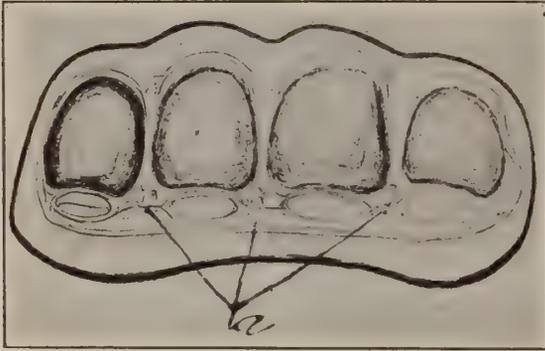

FIG. 5.—Diagram of cross section of hand through web of finger; a, tendons of lumbricals and interossei.

web. Treated in time, nothing serious will happen; but delay is dangerous, for this little abscess in the web can, in a few days, extend directly into the palm, and while recovery is to be expected, the hand will never be as good as it formerly was, once it has suffered from a deep palmar abscess.

At the beginning, metastatic abscess in the web is not very painful. There is plenty of room for the exudate; therefore the pressure is not great at first. At the same time, the pain at the original site of infection is great and distracts the patient's attention. If the diagnosis of metastatic abscess is not made before the patient directs attention to it, it is too late to prevent him from having a deep palmar abscess. How then shall we make the diagnosis? First, by being aware of the fact that here is the first site for the development of a metastatic abscess, and that metastatic abscesses may develop here in any kind of finger infection, but most often in those of the skin and subcutaneous tissues; and secondly, by looking for the abscess in the web. Pain on pressure over the web is a sign that infection is present. One may elicit tenderness deep in the web within a few hours after the infection begins there, and when first the diagnosis is made is the time to treat the condition. Never wait for that sign which even fools may read—fluctuation. Remember that to delay, means to provoke a palmar abscess.

Fig. 4 illustrates the proper way to open a web. Cut straight through it for at least half an inch from its free edge, and if pus is not found, open bluntly through the fat in the middle of the incision still further toward the palm. If one cuts back farther than the point where the pus is, he will carry the infection into the palm. Insert a thin bit of rubber to keep the wound edges from agglutinating and dress the fingers wide apart. Immobilize the whole hand and forearm and immerse all in a hot bath as before. Do not practise changing the drains daily and never pack a wound in which there is virulent or viscid pus. The web abscess in any of the three inner spaces spreads by direct continuity into the fat of the palmar pad and thus an infection

of any one web may lead to infection of all the others. I have often seen this happen.

Now how does the web abscess become a palmar abscess? The lumbrical muscles are found deep in the palm. Springing from the tendons of the deep finger flexors, they run downward and pass to the radial side of the base of the corresponding finger; going through the base of the web, they insert into the tendon found lying on the back of the first phalanx—the common extensor of the fingers. The tendons of the interossei do almost the same. Thus the fat of the web comes into actual contact with these tendons. Each tendon is surrounded with loose areolar tissue—a lymph space—and so it is easy for pus, having once come into direct contact with a tendon to dissect its way along it.

Infection (metastatic) of the web of the first space is in a class by itself, inasmuch as it is nearly always intermuscular from the beginning. It follows infection of either thumb or index finger and can occur by direct extension of pus along perifascial lymph spaces, or by the ordinary lymphatic route to the base of thumb or index, and then along muscle tendons into the intermuscular space between the first dorsal interosseus muscle and the adductors of the thumb. As before, tenderness on deep pressure is the sign to watch for, and the space should be opened as soon as that sign appears. Fig. 4 shows the incision directly across the web. It continues through the superficial and deep fasciæ until the edges of the muscles are seen. The lines of their fibres cross each other *x* wise. The space between the two is found and opened by blunt dissection. The pus is there. A drain is inserted to the bottom of the abscess cavity and fastened there. The whole hand and forearm are immobilized with thumb and index slightly separated.

An abscess in this web can readily become a palmar abscess by dissecting its way around the edge of the adductors of the thumb, or along the palmar arch, or it can spread easily to the wrist along the synovial sheath of the flexor longus pollicis. In dealing with abscess in this web, no muscle

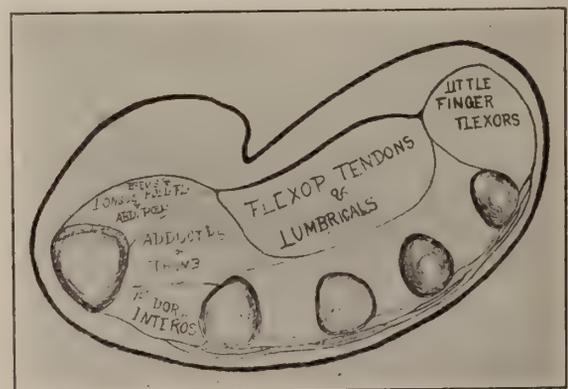

FIG. 6.—Diagram of cross section of hand through proximal half of palm to show compartments.

is cut. Through and through drainage is never used.

We shall briefly consider abscess in the palm. You are told of three compartments. The partitions between the compartments are none of them strong, and pus may pass from any one compart-

ment to any other, for the partitions fail as the bases of the phalanges are approached. The partitions are of fascia and are backward extensions of the deep palmar fascia. The outer compartment lodges the thumb muscles, the inner one the flexor tendons and short muscles of the little finger, while in the middle we have the flexor tendons and lumbricals of the middle fingers, together with vessels and nerves. Tendons and muscles must be surrounded with loose areolar tissue, or they will work but stiffly, and infective material spreads readily through loose areolar tissue. The deep palmar fascia is strongest over the middle compartment, and over all compartments the deep palmar fascia thins out, becomes cribriform, and finally fails entirely as we proceed distally. It disappears first in the interdigital spaces, leaving the digital vessels

FIG. 7. Palmar fascia. (Gray's Anatomy, p. 488.)

and nerves uncovered by it as they enter the webs of the fingers.

Here the superficial fat of palm and web becomes continuous with fat and areolar tissue under the deep palmar fascia. One can thus see how readily a primary superficial abscess can become a deep palmar abscess by direct extension, because the fascia forming the roofs of the palmar compartments is so strong and unyielding, and abscess in any of the compartments may spread well up into the wrist or forearm along the tendons or into its neighboring compartment long before it points on the surface of the palm. The swelling in the palm is for the same reason never marked until the abscess is well advanced.

Swelling on the back of the hand is always marked, but this swelling alone should not induce one to incise the dorsum. It is nearly always lymphedema, because as before mentioned the lymphatics drain toward the dorsum, but pus does sometimes collect here in the perifascial lymph space, and here as elsewhere localized deep tenderness is an early and never failing sign. The tender spot should be opened as soon as found. To "squeeze out" the pus is the most primitive surgery.

How to open a palmar abscess is a real problem

and whether to incise vertically or transversely is a moot question. A transverse incision will remain open better while the fingers are extended, and the fingers should always be dressed in extension, but a transverse incision in the lower part of the palm exposes the digital vessels and nerves to danger, while a vertical one higher up imperils the palmar arch. The patient should be anesthetized and an Esmarch bandage applied. One cannot use an Esmarch bandage to advantage unless the patient is anesthetized; hence the need for a general anesthetic and, besides, a local anesthetic in an inflamed area is not often successful. We use the ether rausch or ethyl chloride for such operations.¹ Use whichever incision you prefer, but identify the structures before you cut them. Cut down to the deep fascia and proceed with caution. Divide the deep fascia and then lay down the knife. If you have opened over the spot most tender on deep pressure, go straight on with blunt dissection until the pus appears. Do not pack, but insert soft rubber and fasten it in the wound. Any drainage material that presses on a tendon with any force for even a few hours, may cause local death of the latter. If a tendon or part of one dies, it takes four to six weeks to separate and come away. Immobilize fingers, hand and wrist, keep fingers in extension, and use the hot bath or moist dressing.

Every student remembers the synovial sheaths of the flexor tendons. He knows that there is around each set of flexor tendons, as they lie on the phalanges, a strong fibrous tunnel through which they run and which holds them to the bones. But inside this fibrous tunnel is a synovial bursa, as it were, which surrounds each set of tendons. These synovial investments extend farther up into the palm than do the fibrous sheaths: those for the index, medius, and annularis extending up to the middle of the palm, while those for the thumb and little finger reach right up to join the bursa under the anterior annular ligament. When pus is found in any of these synovial sheaths, that sheath is to be laid wide open over the place where the pus is, and for at least one to two centimetres above and below this. When the tendon sheath is involved, any attempt to move the tendon causes pain, and there is local tenderness over it.

When pus has invaded the great bursa at the wrist, the anterior annular ligament is cut through and the hand and fingers dressed in hyperextension and left so until healing is well advanced.

When the hot bath is used, the part must be kept on the splint while in the bath, and the solution should be as hot as can be borne without blistering. On no account should the temperature of the bath fall below 110° F. In weak patients it is not well to continue the bath day and night, because of fatiguing the patient; therefore during sleeping hours the part, still on the splint, is placed in large, hot packs wrung out of the solution and wrapped in waterproof cover, and the whole surrounded with hot water bags which are frequently renewed.

If an infection of the palm is properly opened and treated as outlined above, the progress of the

¹In my service ethyl chloride has been much used as a general anesthetic for short operations since 1915.

disease is quickly checked. The drains are removed in from three to ten days and the wound kept open so that pus cannot be retained and burrow. Active motion is encouraged for a few minutes at a time two or three times daily as soon as the drains are removed and gradually these periods of activity are increased and lengthened. Only those too long immobilized or improperly handled fail to regain useful function.

405-413 UNIVERSITY CLUB BUILDING.

THE X RAY AS AN ESSENTIAL GUIDE FOR PRODUCING ARTIFICIAL PNEUMOTHORAX IN ADVANCED CASES OF PULMONARY TUBERCULOSIS *

BY DAVID DUDLEY KRUPP, M. D.,
Brooklyn, N. Y.,

First Lieutenant, Medical Corps, U. S. A.; Röntgenologist to the U. S. Army General Hospital, Fort Bayard, New Mexico.

The purpose of this article is to show the advantages of the use of the x ray in the control of the production of an artificial pneumothorax in advanced cases of pulmonary tuberculosis; and to demonstrate the necessity of a careful study of such cases before attempt is made to produce this condition.

In advanced cases of pulmonary tuberculosis, the almost constant harassing cough and frequent hemorrhages are the most difficult symptoms to treat.

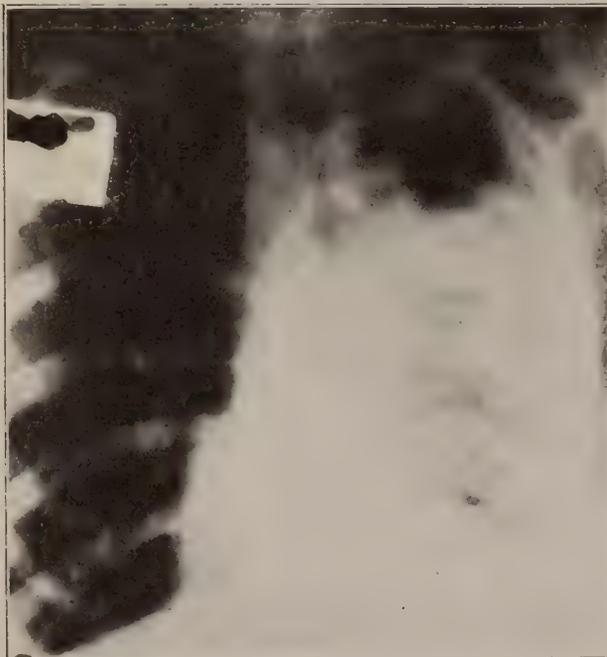

FIG. 1.—Condition of lungs prior to injections of air (Case I).

Narcotics and other methods are used to give relief, which is only temporary. With the production of an artificial pneumothorax, the affected lung is collapsed and the annoying symptoms are more or less permanently relieved; certainly to a more marked

extent than by the use of narcotics, and without their undesirable depressing effects. The purpose of the pneumothorax in these cases is not to produce a cure, primarily, but to render the patient's life more comfortable and possibly increase his chances for recovery. This relief from the harassing cough

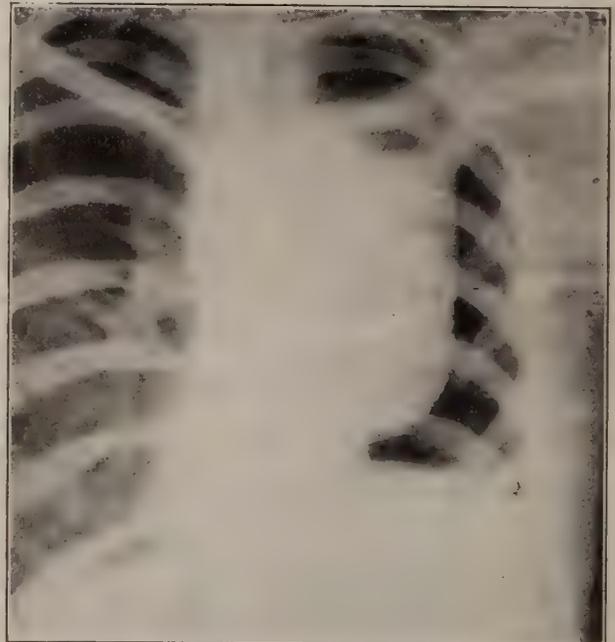

FIG. 2.—Condition of lung after injections of air (Case I).

and pain will also have a favorable effect upon the morale of the patient, which is a matter of great importance in the treatment of pulmonary tuberculosis. The relief of his sufferings is what we strive for. In certain seemingly hopeless cases, this treatment has caused an apparent arrestment of the disease in three selected cases cited in this article. Two of the advanced cases became ambulatory, after the patients had been bedridden for almost a year. They have shown a great amount of improvement.

There are several important factors to be considered before a pneumothorax is tried, and the x ray stands out as the essential guide to the clinician. I must not omit the aid of the fluoroscope, which is also part of the guide. With the bedside unit, the hand fluoroscope is used to great advantage. The x ray plates give the pathological findings as a permanent record, while the fluoroscope gives a clue as to the mobility of the chest and the excursion of the diaphragm of the affected side. The following points were studied before pneumothorax was produced: 1. The extent of the pathology, especially as to cavities. 2. Will the opposite lung be able to furnish sufficient pulmonary tissue after the affected lung has been collapsed without throwing additional risk to the patient? 3. Pleurisy and adhesions.

1. In the extent of the pathological involvement of the lungs, the x ray stands out as the positive guide. Cavities will always show on the x ray plate, whereas they may be missed by the most thorough physical examination (without entering into a discussion of the relative merits of the physical examination); and in deciding the extent of the

*Published by permission of the Surgeon General of the U. S. Army. Now on duty at U. S. A. General Hospital No. 19, Oteen, N. C., June, 1920.

involvement, I think it has been found that the röntgenological studies are the final and deciding factor.

2. The question of the opposite lung being able to furnish sufficient pulmonary tissue to functionate after the affected lung has been collapsed, is a serious problem to determine. In a case where one

FIG. 3.—X ray of lung prior to injection of air (Case II).

lung is involved and the other lung normal, there is no question, of course, that this is the ideal treatment. But it is in those cases where both lungs are heavily involved, and perhaps one somewhat less than the other, that the difficulty arises. A careful study of such cases is necessary, before any attempt is made to collapse the lung. Now, what is the course to follow when such is the case and the patient needs relief from his sufferings? In all probability this patient is going to die. Therefore we must be governed by the following factors, namely: the cessation of the cough, with a less copious expectoration; control of the hemorrhages and lessening the toxemia, which outweighs the risk we take in throwing additional burden on the small amount of uninvolved lung tissue remaining.

3. Adhesions and fibrinous pleurisy associated with a pulmonary tuberculosis, as seen by the x ray plate, is another factor to be thoroughly considered, for one cannot attempt to collapse a lung that is firmly plastered to the parietal pleura.

Of the 453 x ray examinations made in the last three months, forty-six were bedside examinations. I also made use of the hand fluoroscope. The remaining cases were examined stereoscopically. With this large number of cases to choose from for the production of an artificial pneumothorax, the problem was less difficult. Of the three selected cases, which I have followed by a series study of x ray plates, the results obtained are here noted and illustrations given. The cases were given up as hopeless. Two of the patients were bedridden for almost a year and now they are walking about the hospital

grounds to a limited extent. The third patient was the worst of the three, because both lungs were heavily involved in addition to the cavities in both upper lobes. By a study of these cases, with the x ray plates and the fluoroscope, an excellent guide is given to the clinician for the procedure of an artificial pneumothorax.

CASE I. Cadet H., admitted to the hospital on December 18, 1918, with a diagnosis of pulmonary tuberculosis, chronic, active, of the entire right lung; sputum positive; the left lung was apparently healthy. On October 20, 1919, the first introduction of air was begun. Fig. 1 shows the lung condition prior, and Fig. 2 shows the lung after numerous injections of air. This lung shows a few bands of fibrous tissue holding the upper part of the lung from complete collapse. On January 8, 1920, this patient had 200 C. C. of fluid removed from the base of the affected chest. He is now able to walk around after being in bed for about a year. The number of hemorrhages have been markedly reduced; the cough and expectoration have moderated greatly. In this case a tuberculous laryngitis seems to be developing, which may account for the patient in Case II being in a better physical condition although the lung is collapsed to a lesser extent.

CASE II. Colonel M.—, admitted to the hospital on June 18, 1918, with a diagnosis of pulmonary tuberculosis, chronic, active, of the entire left lung. He had been in bed for over a year and had numerous hemorrhages. In September, 1919, the first injection was given. Since that time the

FIG. 4.—Condition of lung after injection of air (Case II).

injections of air have been very frequent. Fig. 3 shows the lung prior to, and Fig. 4 shows the lung after the production of pneumothorax. For the last set of x ray plates, this patient was able to walk to the laboratory unaided, a distance of 600 feet, and also able to walk up and down a flight of stairs.

He has shown remarkable physical improvement, and has not had a hemorrhage in the last three months. Sputum is still positive.

CASE III. Private B.—, admitted to the hospital on September 22, 1919, with a diagnosis of pulmonary tuberculosis, chronic, active, all lobes, both lungs; sputum positive. On December 22,

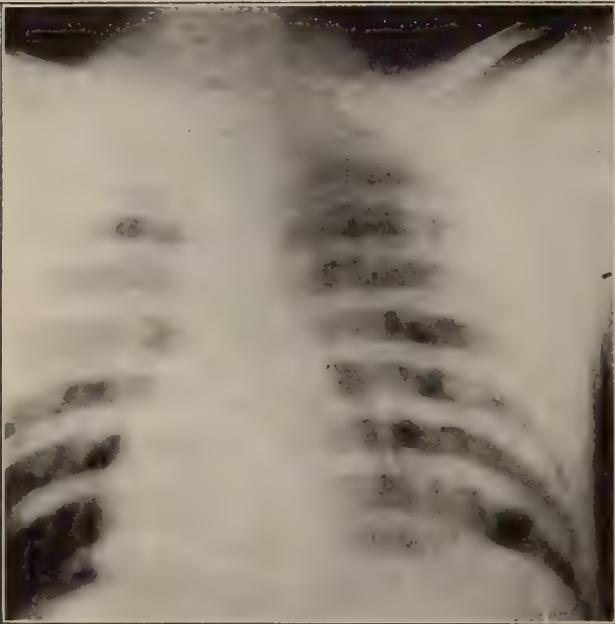

FIG. 5.—Lung prior to injection of air (Case III).

1919, he went on a furlough and had several severe hemorrhages. He returned to the hospital in a serious condition. On March 15, 1920, the following general report was made of his condition: Patient in bed with a temperature of 100.6°; general condition, unfavorable; cough, severe; expectoration, copious. He had several hemorrhages in the week prior to this report and it was then that the first injection of air was made to stop the hemorrhages. The right chest received 400 c.c. of air when a positive pressure was reached. It was seen by the first injection of air that the hemorrhages were stopped and he received further injections of air about once a week to keep the pressure on the inside of the right chest positive. The amount necessary would vary from two to four hundred c.c. The result of the pneumothorax was successful, as the hemorrhage ceased and the expectoration was less copious and coughing controlled to a great extent. The x ray findings were as follows: All lobes, both lungs, show a heavy flocculent infiltration with multilocular cavities in both upper lobes. Fig. 5 shows the lung prior to the injection of air and Fig. 6 shows the lung at the last examination. This patient, although bedridden, has been made more comfortable, and weakness is the only bad symptom he complains of.

As to the future of these patients, there is a possibility of the complication of a hydropneumothorax, as illustrated in Fig. 7, in the following case. This patient (a beneficiary of the Soldiers' Home) was discharged from the hospital in 1914, with an artificial pneumothorax on one side and an inactive tuberculosis in the other lung. He returned to this

hospital a month ago with a hydropneumothorax containing about two thousand c.c. of fluid. Under the fluoroscope, the first examination was made and the waves of the fluid were clearly demonstrated on slightly shaking the patient. During his stay away from the hospital he had been working constantly and without any other bad result than the collection of fluid in the chest. The fluid is gradually being removed and air injected to replace it.

DISCUSSION.

Since it is in the hemorrhage cases that the most satisfactory results are obtained, it should nevertheless be borne in mind that it is in this class of cases that the greatest risk is also taken; for, while it is usually possible to presume that the hemorrhage is from the side showing the greatest involvement, still it is possible to collapse a lung showing considerable involvement when the hemorrhage might occasionally be from the lung showing the minor lesion. In these cases, the x ray plates have been showing small cavities in the region of the hilum of the lung that appears to be least involved. A few patients have come to the autopsy table and on sectioning the lung, the apex of the lower lobes and the middle lobe on the right side revealed very small cavities.

The condition of the chests of the tuberculous patients, found at the autopsy table, brings out the statements made in the paragraph on adhesions and pleurisy. The pathologist found great difficulty in trying to remove the lungs in such cases without tearing part of the lung tissue. If these conditions are present, it would then be useless to try to force air into such a chest. In a few cases, fibrous bands of adhesions can be released by persistent frequent injections of air. If these bands are not too strong, the chances for collapsing the lungs are very good. The gradual tearing loose of these bandlike adhesions can be beautifully studied by the radiographic

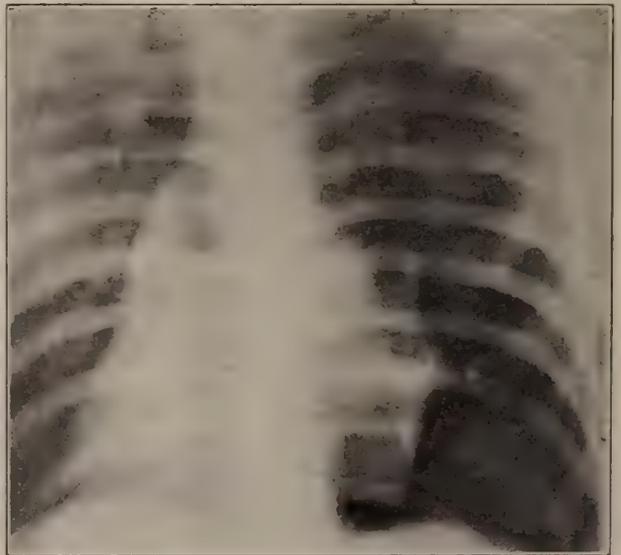

FIG. 6.—Final examination of patient (Case III).

examinations, as the treatments are continued. In the beginning, one sees air pockets formed about the adhesions with gradual thinning out; finally the desired result, the complete separation and the col-

lapse of the lung. We always find these bands attached to the upper lobes, where the greater percentage of cavities occur, and which may communicate with the periphery of the lung.

CONCLUSION.

In compressing the affected lung, the walls of the cavities are put in opposition and become fixed

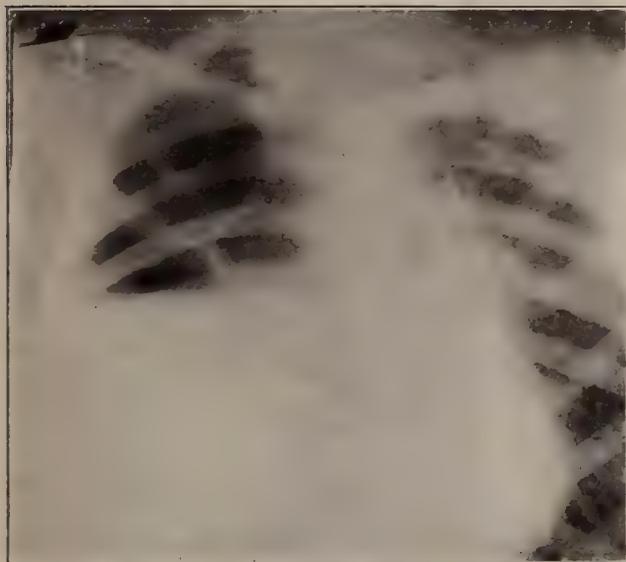

FIG. 7.—Hydro-pneumothorax as a complication.

together and the desired results are obtained, namely, giving the patient the feeling of wellbeing and comfort. Since the symptoms are lessened and comfort increased, there is no doubt in my mind that an artificial pneumothorax is an excellent adjunct to the other treatments of pulmonary tuberculosis in the advanced cases, in association with the röntgenologist, who gives the clinician the guide to the successive steps taken for collapsing the lungs. We must not forget the possibility of acceleration of the tuberculous process of the opposite lung, when one lung is collapsed and a burden put upon that lung to functionate and take care of the toxemia from the affected lung.

485 STONE AVENUE.

THE KNIFE CAUTERY IN SURGERY OF THE THORAX *

By JOHN F. VAN PAING, M. D.,
Chicago.

In a recent article (1) I called attention to the importance of the knife cautery procedure as an operative technic in decreasing postoperative shock, hemorrhage, and the morbidity incidental to convalescence. It can be used in incising the visceral pleura and the lung proper, in removing foreign bodies, such as bullets, fragments of high explosive shells, and particles of bone or bits of clothing, carried into the lung tissue by the missile, and in operating for hemorrhage, lung abscess, or tumor. Before the advent of the knife cautery, pulmonary operations were the least developed and the least understood from the viewpoint of technic and post-

operative complications of all forms of surgery. The mortality rate was exceedingly high, shock and hemorrhage being the chief contributors, and the postoperative morbidity continued over a period of weeks or months.

Hemorrhage.—Heretofore hemorrhage has been very difficult to control and postoperative oozing has caused a large number of deaths, owing to the facts that suture of lung tissue is unsatisfactory in the control of bleeding and the needle punctures themselves continue to bleed after the wound is closed. Lung tissue in particular must be free from oozing when the wound is closed, or the bleeding may continue for an indefinite period, exsanguinating the patient and being almost impossible to control without a large firm packing. The removal of this packing produces a return of bleeding, and, while it is in position, it causes incessant coughing, which so greatly weakens an already overburdened heart that cardiac dilatation is likely to occur. Furthermore, iodoform or cyanide gauze will in almost every case cause some symptoms of toxemia, the absorption being so rapid that often within twenty-four hours toxic symptoms manifest themselves by rigor, vomiting, high temperature, and delirium.

Shock.—Profound shock followed by delirium accompanies a large percentage of pulmonary operations by the older methods, induced, I believe, by the combined factors of hemorrhage, anesthesia, and packing. Then, too, the class of patients in whom these operations are indicated suffer from low vitality, secondary anemia, and usually present profound toxic phenomena. Blood transfusion is, in my opinion, the ideal treatment in this condition.

Lung abscess, tumors and foreign bodies are indications for surgical intervention, and with all of these dyspnea and cardiac weakness or irregularity are prominently associated. Obviously, therefore, any procedure which decreases the danger of postoperative shock or cardiac dilatation is to be preferred.

Dyspnea.—All cases of pulmonary disease requiring surgical operation are accompanied by dyspnea, its severity depending upon the location of the diseased area, the toxic element, and cardiac compensation. Pleural effusions and hemothorax greatly embarrass respiration, and I believe it is good practice to aspirate or drain these accumulations forty-eight hours before pneumotomy is to be performed. Atropin and digitalis in full doses sometimes will temporarily control dyspnea to a great extent. When it is dependent upon increased intrathoracic pressure it is impossible to control until this pressure is relieved. Postoperatively, strychnine, administered in large doses hypodermically, diminishes respiration and may sustain the circulation through the shock period. Morphine of course is preeminent in decreasing respiration and quieting delirium, as well as controlling cough.

TECHNIC

Location of incision—external marking.—The location of the primary incision on the chest wall should conform to the pulmonary area to be incised as nearly as possible. Preliminary outlining with

*Read before the Chicago Academy of Medicine, May 27, 1920.

iodine or silver nitrate stick is useful in that it remains as a guide after sterilization of the chest wall is complete. The incision may be U shaped or longitudinal, conforming to the contour of the ribs, the primary flap consisting of skin, superficial and deep fascia down to the muscle. The muscles may be separated or incised. The number of ribs chosen is important, three being the usual number. All of them may be fractured, and reflected; or one may be fractured and removed and the one above and below displaced widely with a rib spreader or a Balfour abdominal retractor, which answers the same purpose. At this point I make a practice of tying all bleeding points and removing all forceps.

The parietal pleura is grasped with stomach forceps and the knife cautery at red heat is applied in a line about three inches in length and enlarged if necessary to admit of free access to the underlying structures. This incision in most instances should conform to the direction of the ribs. Four stomach forceps are applied to this parietal incision, and it is retracted well above and below, and stitched to the visceral pleura with single O continuous catgut on a full curved fine needle.

The knife cautery at red heat is applied to the visceral layer, the length corresponding to the parietal incision. The anesthetic is removed as the lung is approached and the cautery is used as one would use a scalpel in penetrating the lung tissue. With this method hemorrhage is practically absent except in the division of the larger blood vessels, and for the sake of safety these should be tied.

The foreign body having been removed, or the abscess drained, as the case may be, the line of incision is permitted to collapse after the insertion of a fanshaped drain of rubber tissue or a small cigarette drain, loosely covered and without gauze projecting from the end. If the wound edges are not apposed at the completion of the operation, one kidney suture of fine catgut may be used on a heated needle. The wound in the pleura may be partially closed over the drainage and a buttonhole incision made through the skin. The rib retractor is removed and the fractured rib replaced, or removed entirely, in the pus cases. The skin is closed with interrupted silk or silkworm gut and adhesive tape tightly applied, the wound is dressed and a pneumonia jacket applied.

LUNG COLLAPSE

When gas-oxygen is used with a rebreathing apparatus the lung does not collapse in a large percentage of cases, and in others only partially so, the entire operation being performed with only a slight change in respiration. The postoperative morbidity is decreased materially if we can circumvent lung collapse and the tedious convalescence of delayed reexpansion is obviated to a great extent.

Postoperative posture.—Posture is important in that it favors drainage and prevents in a great measure the respiratory embarrassment so common in chest surgery. The patient usually rests better in the semi-Fowler position, lying on the affected side. If the incision inclines posteriorly air bags or pillows should be placed to insure rest.

Postoperative attention is of great importance and the smoothness of convalescence will be in

direct proportion to the care the patient receives. Morphine and atropine hypodermically in full doses repeated until respirations are decreased to eight or ten a minute the first twenty-four hours, is, in my opinion, good treatment. A wool pneumonia jacket should be applied in every case and I believe it decreases the incidence of bronchitis or lobular pneumonia, so frequent in these cases and so serious when they occur.

Postoperative delirium.—This may be very violent in character and necessitate constant watching, or it may manifest itself as a low muttering speech and restlessness. I am of the opinion that the toxic element with its attendant fever is first in the production of delirium and secondly cardiac decompensation manifesting itself as a tachycardia, arrhythmia, or cyanosis, and due possibly to dilatation of the right heart. Cool sponging, the hot wet pack, normal salt solution with sodium bicarbonate intravenously, or blood transfusion may be required.

Cyanosis.—Slight cyanosis always is present to some extent, owing to the sudden changes in the pulmonary circulation and the attempt on the part of the heart to maintain circulatory equilibrium. Cyanosis in favorable cases usually disappears in forty-eight to seventy-two hours, but I have seen instances of its persisting for days, and this with a healed wound, regular heart, and low temperature. Strychnine and belladonna are useful in this condition, in that they sustain the patient and tend to equalize circulation.

Temperature.—Postoperative temperature is sometimes quite high for the first twenty-four to seventy-two hours, and may require a warm pack, glucose solution intravenously, or blood transfusion the second or third day following, if the temperature rises again, usually will control temperature in the favorable cases.

Delayed reexpansion.—This condition should be treated by breathing exercises, the two bottle siphon method, and an abundance of fresh air.

Sinus formation.—This sometimes persists for an indefinite period and does not seem to materially affect the general health. Phenol, bismuth, and methyl violet in a petrolatum base usually is sufficient when combined with general measures, such as rigid hygiene, nutritious diet, and hematopoietic drugs such as iron and arsenic. It will be interesting to observe the effect of mercurochrome-220 in an ointment base in these cases of chronic sinus formation.

SUMMARY

I would emphasize the following points:

1. As rapid an operation as is consistent with careful technic.
2. Accurate diagnosis relying upon the physical signs, the history, and the x ray.
3. Avoidance of delay in operation.
4. The knife cautery at red heat, to the exclusion of all other methods when the lung tissue is to be incised.
5. Avoidance of sutures whenever and wherever possible.
6. Rubber tissue in the drainage cases.
7. Strict postoperative attention with a pneumonia jacket and nutritious diet.

8. Morphine to the point of narcosis the first twenty-four to seventy-two hours.

9. Blood transfusion early and repeated if necessary in shock, hemorrhage, delirium and anemia.

10. The importance of breathing exercises and fresh air in delayed reexpansion.

CARCINOMA OF THE MIDDLE EAR.*

Report of a Case.

BY JOHN GUTTMAN, M. D.,
New York.

Malignant new growth of the middle ear are of comparatively rare occurrence, therefore the report of such a case should prove of interest.

CASE.—Ph. L., aged sixty years, consulted me for the first time in July, 1919. Five years ago he suffered from an attack of otitis media purulenta acuta of the left ear. The purulent discharge ceased after a time and the ear remained well until six months ago, when the purulent secretion appeared again and he began to complain of dizziness. Three months ago, some granulations were removed from the same ear. Subsequently a facial paralysis set in, and four weeks later a swelling of the zygoma region appeared, whereupon a mastoidectomy was performed by an attending aurist.

Present state: In the zygoma region in front and above the ear lobule, extending backward to the mastoid bone, there existed a swelling the size of a walnut slightly fluctuating. Back of the ear the mastoid bone showed a groove about half an inch deep,

FIG. 1.—Circumscribed swelling in the zygoma region as shown by the x ray.

caused by a previous mastoidectomy. The wound was fairly clean and its base was covered with healthy granulations. In the tympanic cavity there exists a slight purulent discharge. The left facial

nerve in all its branches and the left abducent nerve were paralyzed. There was total deafness in the left ear. The labyrinth of the left ear did not react to cold water irrigation. The reaction of the right labyrinth was sluggish. The examination of the fundi of the eye, and of the urine and blood, did not

FIG. 2.—Narrowing of the lumen of the esophagus as shown by the x ray.

show any pathological changes. The Wassermann reaction was negative and the x ray showed a circumscribed swelling in the zygoma region, and a considerable narrowing of the lumen of the esophagus. There was dysphagia. The laryngeal examination did not show any pathological change. It was doubtful whether the swelling of the zygoma region was an extension of the preceding mastoiditis into the zygomatic cells, or whether this swelling was a neoplasm. I therefore decided to explore it.

An incision in the skin was made connecting this swelling in the zygoma region with the mastoid wound. A large amount of pus and granulation tissue was evacuated. Thereupon the mastoid bone was attacked with chisel and rongeur. The cortex was found to be sclerosed, and did not show any softening. In entering the antrum large masses of neoplasm were encountered and these were evacuated. The wound was then packed and the patient returned to his bed. The diagnosis of the removed tissue made by the pathologist was squamous cell carcinoma. Six weeks later the patient died showing the symptoms of a purulent meningitis.

In all cases of this kind it is very difficult to ascertain the time and place of the onset. It is difficult to state where the primary seat of the disease was, whether in the tympanic cavity, the antrum

*Read before the Section in Otolaryngology of the New York Academy of Medicine, May 14, 1920.

of the mastoid, the petrous bone, or in the inner ear. Most cases of carcinoma of the ear show an early affection of the facial nerve. In this case the paralysis of the facial nerve was accompanied by a paralysis of the abducens nerve on the same side. The x ray picture seems to indicate that the dysphagia was probably caused by a metastasis in the esophagus, as the larynx did not show any pathological condition.

1261 MADISON AVENUE.

FREQUENT TYPES OF NASAL OBSTRUCTION AND THEIR TREATMENT.

By M. S. ITTELSON, M. D.,
Brooklyn, N. Y.,

Assistant Surgeon, Manhattan Eye, Ear, and Throat Hospital.

The impression is frequent that defective nasal breathing in the adult is due to a mechanical obstruction within the nasal passages and that this symptom requires operation or local treatment. This is true only in some cases. The causes that are responsible for this condition are many. The treatment too is often puzzling, as is evidenced by the variety of opinion that is sometimes expressed in a given case. Difference of opinion is to be expected here as in most other conditions, but to some extent this could be avoided. From the numerous patients who seek relief from this condition certain types can be recognized as occurring very frequently. It is well to consider the pathological conditions, both local and general, that are often found to be present in these types.

Those patients who complain of obstruction when none exists are interesting. Those with atrophy of the nasal mucous membrane, not associated with scab formation or other complications and where an intranasal examination reveals a wide breathing space, will often complain of blocked up noses. This symptom is also noticed in those on whom extensive nasal surgery has been performed. It is difficult to give a satisfactory explanation of this condition and probably several factors are involved. This is most often due to some sensory disturbance, where the patient does not feel the air either because of the involvement of the sensory nerve filaments or because of the wide passage the current of air does not exert sufficient pressure on the mucous membrane. This is well illustrated in those cases where the lumen in one side of the nostril is wider than in the other, in which case the trouble is more often referred to the open side. It is doubtful whether a sinus affection by preventing ventilation and an interchange of air within the sinuses, an interchange which normally occurs, should by itself be responsible for this symptom. In rarer cases the trouble will be found to be general rather than local. Due to a diminished alkalinity of the blood or to some other error in metabolism, there is an increased demand for oxygen, the lack of which may be referred to the nose. Occasionally, too, local and general conditions are both apparently normal and we are obliged to use such terms as nasal neurosis or nasal neurasthenia. Whatever opinion one may have as to the causes of this symptom it is important

to remember that in this type the obstruction complained of is apparent and not real.

A more frequent condition is an obstruction due to the abnormal action of the nasal mucous membrane. To perform its function of warming, moistening, filtering, and perhaps regulating the amount of the inspired air, this membrane expands and contracts, thus varying constantly the lumen of the nose. The causes responsible for this variation in dimension of the mucous membrane are often obscure, and to some extent depend on the function that is to be performed. Changes in the atmosphere, chemical and mechanical irritants, and mental emotions—all affect this highly susceptible membrane and cause it to expand and contract. This expansion is due to an increase in the blood supply, which distends the venous sinuses not unlike the erectile tissue elsewhere in the body and with little or no inflammatory reaction. The term functional obstruction is suggested for this type of cases. There are few individuals who have not occasionally experienced a sudden change from opening to closure and reversely occurring in both nostrils or more often alternating from one nostril to the other without any apparent cause.

Inflammation of the nasal mucous membrane is another condition that is frequently responsible for obstruction. Functional disturbance may occur in a normal mucous membrane: more often it occurs in one that has undergone inflammatory changes. Clinically, a chronically inflamed mucous membrane is either hypertrophied or atrophied or without change in size and it loses its moist pearl pink color which is characteristic of a normal mucous membrane. The hypertrophy or hyperplasia may be a conservative process, one of Nature's efforts to compensate for some loss of function or for some local anatomical irregularity. Thus, large turbinates are found in roomy noses and on the concave side of a deviated septum. No such utilitarian purpose is evident in an atrophic or otherwise chronically inflamed membrane. One cannot but feel that here the underlying cause is some general systemic disturbance, such as syphilis, gout, rheumatism or intestinal intoxication. It may be, too, that a disturbed secretion of the ductless glands has some influence. The relation of the erectile tissue of the nose to the gonadal glands has long been noticed. The facies of those with atrophic rhinitis is not unlike those with a deficiency of the thyroid gland. The broad nose, dry skin, and its frequent occurrence in women all suggest this, as well as the fact that the condition is less often seen in patients with hyperthyroidism. In the acute cases of inflammation the individual immunity is an important element. A virulent Klebs-Loeffler may be innocuous to some, while a bit of innocent dust will in a susceptible person excite the most violent inflammatory paroxysm.

In the treatment of these forms of obstruction much can be accomplished by the correction of any general disturbance, which even a superficial examination will in most cases disclose. Changes in the diet, the prevention of auto-intoxication, the correction of hygienic errors, and the treatment of any indefinite gouty, rheumatic, glandular or syphilitic

conditions do more good as a rule than local applications. In this connection may be mentioned the favorable action of laxatives, potassium iodide, and small doses of thyroid extract carefully administered. If the obstruction is suspected to be of an anaphylactic origin vaccine therapy and protein desensitization might be tried. As for local treatment irrigation is the one most frequently employed. Nichol's nasal syphon is well suited for this purpose, acting as it does more by suction than by pressure. A solution of soda bicarbonate, a teaspoonful to a quart of water, is less irritating than normal saline. There are some nasal membranes on which water in any form acts unfavorably. In these cases an oily preparation may be substituted. Menthol, three grains; ichthyol, thirty grains, and petrolatum, one ounce, is a prescription that can be freely used and often repeated by patients. Intranasal operations are now undertaken reluctantly. Removal of a diseased tonsil by improving the general health relieves local symptoms. Turbinectomy or turbinotomy has largely proved a failure. There are, of course, exceptions to this as to other rules, but the essential validity of this statement is apparent to all who have seen the passing of what was once a popular operation. Among the exceptions may be mentioned the removal of the hypertrophied portion of the inferior turbinate, or of an enlarged posterior tip, which is still done occasionally.

Considerable attention is now paid to the appearance of the septum. Deviation of the septum, particularly if it is of traumatic origin and limited to the anterior portion, does prevent the air from passing through, and there are few operations where the good results are more striking. On the other hand, it must be noticed that some form of septal irregularity is almost a universal condition, and a perfectly straight septum is an anatomical exception. The curves and angles that one sees so frequently on the septum are usually normal and innocent variations occurring coincidentally with some other pathological condition. Patients have a way of disappearing and it is difficult to get accurate data regarding many submucous operations. Many of these subsequently show up again at a different clinic or office with the same complaint. The surgeon thus sees less of his own unsuccessful cases and more of those of his colleagues, unsuccessful as far as the functional result is concerned, although the appearance of the septum following such operation is all that could be desired and shows evidence of surgical skill. Many feel that a submucous resection is always a conservative operation because the original incision is small and the mucous membrane is not sacrificed. In the separation of the periosteum and in the removal of the bone and cartilage considerable trauma is done which with the subsequent fibrosis often affects the mucous membrane unfavorably. Following the removal of the bone and cartilage there remains considerable redundant tissue which assumes somewhat its former position, and a deviation may persist after operation. Diagnosis of a deviated septum is easily made, but to determine its relative importance in the causation of the obstruction requires careful watching and good judgment.

CONGENITAL UNDERDEVELOPMENT OF THE RIGHT SIDE IN AN INFANT THREE MONTHS OLD.*

BY B. K. RACHFORD, M. D.,
Cincinnati, Ohio,

Professor of Pediatrics, University of Cincinnati.

CASE—J. S., infant three months old, brought to my office on December 11, 1919, by his mother because she had noticed a few days before that his left leg was much larger than his right.

Previous history.—Labor was instrumental. Baby was apparently normal at birth. He had been

FIG. 1.—Underdeveloped fibula and tibia.

fed exclusively upon breast milk and had never been ill, and until a few days before his mother had not noticed that the left side of his body, especially the left leg, was larger than the right.

*Read by title before the American Pediatric Society.

Physical examination.—This showed an apparently perfectly nourished male child. He had been all of his life and was at that time perfectly well. His only abnormality was the underdevelopment of the right side of the body, especially the right leg. The right leg was ten inches long, the left leg eleven inches long, measured from the anterior superior spine to the internal malleolus. The right thigh, one inch above the knee, was eight and one quarter inches in circumference, the left thigh was ten inches in circumference. The right foot, plantar surface, measured by placing the foot on a sheet of paper, was three and three quarter inches, the left foot, measured in the same way, was four inches. The right chest, measured from the xyphoid process to the corresponding spinous process of vertebræ, was eight and one quarter inches. The left side of the

the right and the left arm and hand were larger than the right. The most marked difference was in the size of the legs. The whole left leg was much larger than the right. This was especially noticeable in the thighs. The left foot was several sizes larger than the right. It was also apparent that the left side of his chest was larger than the right. The baby was normally developed mentally. In standing the baby on his feet it was evident that he had more strength in the left leg than he had in the right. He apparently also had more strength in his left arm and hand than he had in his right, but this difference between the left and the right side was only comparative, as the baby used his right arm and his right leg in an apparently normal way, and there was not the slightest evidence of paralysis of any kind. In fact, the mother believed that he had quite as good use of his right arm and leg as he had of his left.

Measurements on March 23, 1920, were as follows: Right leg, twelve inches; left leg, thirteen and a quarter inches; circumference of right thigh, nine inches; circumference of left thigh, ten and one half inches. Left foot four and three quarters inches long, right foot, four and one quarter inches long.

The accompanying radiograms show the underdevelopment of the bones of the right leg and the progress of development that has occurred in five months.

SEVENTH AND RACE STREETS.

FIG. 2.—Underdeveloped epiphyseal ossification centre; underdeveloped greater and lesser trochanter, as compared with left side; lesser transverse diameter of right femur, as compared with left.

chest, measured in the same way, was eight and three quarter inches. The right femur was one and four fifths inches shorter than the left. The right tibia was one and one fifth inches shorter than the left.

On March 23, 1920, the baby being then about seven months old, had remained perfectly well and had continued to be nourished exclusively upon breast milk. He weighed twenty pounds. The left side of his body was as well developed as that of any normal breast fed baby of his age, but the whole right side of his body, although there had been a marked increase in development, still remained underdeveloped as compared with the left.

The left side of the baby's face was larger than

THE RECENT INCREASES IN VENEREAL DISEASES.

An International Peril.

BY THOMAS E. SATTERTHWAITE, M. D.,
New York.

Dr. Joseph E. Moore, an American officer, consulting urologist to the district of Paris in France, has told us that following the late armistice seventy thousand prostitutes were for a time thronging the streets of that city, of whom only five thousand were registered as under police surveillance, while two thousand five hundred hotels were used for assignation purposes. He has also stated that at one time he found the incidence of infection in the American Expeditionary forces from some kind of venereal disease about 330 in a thousand, i. e., about one in three; and that there was no special effort made to lower this rate. Eventually, however, it was reduced to ninety-four in a thousand. In August and September, 1917, the incidence among five thousand British troops in Paris was two hundred in a thousand. The ratio alluded to above by Moore was said to be four times greater than elsewhere among our men in zones occupied by them, the inference being that special efforts were capable of reducing the disease, if proper measures were adopted. (1)

Someone was responsible for this wholesale infection. Was there collusion or laxity on the part of the French officials, or our own? In either case

should not the guilty be held morally, if not otherwise, responsible for failure to prevent infections, which must necessarily lead, if they have not already done so, to widespread disease throughout the United States and France. Humanity demands an investigation. Of this there can be no doubt, for public prostitution is capable of being controlled in time of war by military or civil authorities, the first naturally being the more effective. I know this from personal experience in one of the provincial towns of France, where at one time it had assumed the proportions of an epidemic. Civil control by local police, with legal punishment, such as prevails in Denmark, is also a powerful agency in this regard, provided the laws are properly administered. It may not be generally known, but I believe it to be true, from my experience, that French prostitutes are likely to be contaminated with aggravated forms of venereal diseases. We have the authority of the *NEW YORK MEDICAL JOURNAL* (2) that venereal diseases increased greatly during the war, and on the authority of Riddell, (3) there are probably more than half a million syphilitics now in Canada, forty thousand of them being in Toronto. But it is generally agreed that the increase in Europe has been more marked than on this side of the water, pointing to the probability that Europe has been largely responsible for the increase over here. This statement is also borne out by Miss Ettie A. Rout (4). According to Miss Rout the British military rate in 1917 was twenty-seven in a thousand. In 1919 it had risen to eighty in a thousand, while in the present year it is still higher. She also says "probably no European country has less than three or four times the amount of venereal diseases it had in 1913-1914."

We come now to one of the special causes of infection. Writing in the *Daily Herald*, of London, E. D. Morel (5) has stated that he was informed by letters, personal statements, and other data, which he regarded as trustworthy, that eighteen months after the armistice, when the French had from thirty to forty thousand of their colored African troops in the Bavarian Palatinate, these men were raping women and girls, so that in this zone their victims filled the hospitals to overflowing, naturally spreading syphilis, with which they were to a large extent affected, right and left. As is known to many of the medical profession, the colored race is contaminated with syphilis to a much larger degree than the white race. Recently at Fort Riley, Kansas, the incidence of syphilis among the colored troops was set at about twenty-three per cent. against about thirteen per cent. among the white (6). Though statistics on this point are not very numerous, the consensus of medical opinion is that the general incidence among colored people is much greater than among the whites.

In this connection the report of Moron (7) throws some light on the matter. He states that syphilis is not taken seriously by the colored people of Madagascar, a French protectorate. Indeed, with them syphilis in young girls is regarded as an asset, because brides are then immune against subsequent attacks, and their value in the matrimonial market is thereby enhanced. Notwithstanding, if Dr. E. J.

Dillon, the famous war correspondent and author of *The Inside Story of the Peace Conference*, is to be credited, the French military authorities not only compelled local authorities to open public brothels within the occupied zone, for their colored soldiers, but supervised and received the money for the traffic. In one page of his book he publishes a copy, in French, of the military orders in the case of a brothel at Muenchen-Gladbach, under the title: *Exploitations et police de la maison publique de Muenchen-Gladbach*. The notice gives in detail the rules and regulations of the house, both as to the men and women. Dillon publishes it in French without translation, as he infers his readers would prefer to read it in the original!

As no exception has been made, apparently, to such statements, it seems probable that the method is still practised in Muenchen-Gladbach. Indeed, it has come to the writer's notice recently that a similar brothel is being operated at Wiesbaden. The plea in defense of these practices would be that they are military necessities. In Denmark today, under its present laws, if a civilian should undertake to keep a public brothel or rent rooms for immoral purposes, he would be liable to a prison sentence. We are led, therefore, to believe not only that there is a veritable plague emanating from Europe, but that the *fons mali* is still pouring out its deadly poison, to be carried to the four corners of the universe.

I hold that this infamous traffic, as it is regarded by most Americans, can be stopped at any time by a note from Washington, for if only well known sanitary measures, such as come within the scope of police, military or civil authorities, are put in practice, as the laws of Denmark provide, the danger of infection can, I believe, be reduced to a minimum, even without the prophylactic measures that are used in our military and naval services. We cannot, of course, abolish venereal diseases now, for present sources of contagion must necessarily continue for an indefinite time to be a danger to the public, even if no new instances of the disease should occur. Moreover, we can never prevent clandestine relations.

I was present at a meeting at the New York Academy of Medicine on October 7 when a paper on present measures for limiting venereal infection was read by a prominent government official. The paper and the discussion that followed bore on the efforts that have been made by the United States Public Health Service, various boards of health and private or semiprivate associations to combat venereal diseases by public lectures, posters and publicity measures in general. These methods probably have some value. I admit it. They emphasize, however, a popular fallacy that prophylaxis can effectively *prevent*, by bureau work, backed by a liberal use of money. There is always stress laid on the latter word. No mention was made in the paper as to military or civil repression of this traffic. We should not be led astray by visionary views. On the contrary, our opinions should be based on those of practical men who have dealt successfully with such problems. The strong arm of the law is, and always will be, the most deterrent force.

As Moore has said, probably one third of the cases of infection he has described would have oc-

curred in his Paris experience any way, under the license then prevailing. Given the cupidity of the prostitute, the money of the American soldier, the opportunity easily afforded, the recklessness of men and women, and conditions were present for infection, notwithstanding the warnings of humane associations, public service organizations, or the like. In fact, while these various agencies have something of a deterring force, venereal diseases have also increased rather than diminished, as I have shown. We should also remember that in the case of sanitary prophylactic measures, the belief that they will prevent contagion may widen the doorway to immoral relations.

Miss Ettie A. Rout, a New Zealand Government authorized reporter and honorable secretary of the New Zealand Volunteer Sisters, who has already been referred to, says on this point (8): "We found that French and Belgian public women were quite ready to attend a Red Cross dispensary for prophylactic treatment and quite ready to accept prophylactic outfits from the soldiers. (We had the directions printed in French and English.)" In other words, "Employ regulation safeguards and you run little risk." What a satisfactory statement for the inmates and patrons of brothels. Miss Rout's paper is called the *Conquest of Venereal Disease*. Might it not quite as appropriately have been called, *Promiscuous intercourse made comparatively safe by scientific methods?*

Now assuming from Miss Rout's given title in her article that she is a New Zealander, and that the New Zealand troops in the war as a class were clean and healthy men, as they are reputed to have been, would not some of them nevertheless, under the tutelage of Miss Rout's associates who appear to have opened the door for them to comparatively safe promiscuous intercourse, have eventually become infected, provided their experiences were sufficiently large?

Certainly the prophylaxis as practised in military and naval life does not prevent infection so surely as vaccination against smallpox. In fact, Miss Rout asserts that prophylaxis is successful when properly applied in only two thirds of the cases, as shown by the returns of the American, Canadian, and Australian armies, as against the almost complete protection claimed by Moore in his personal experiences.

Why lay so much stress on prophylaxis when all authorities agree that, except in accidental cases, abstinence is the only practice that really prevents; and medical men, in general, say it does no harm to men or women. I do not propose, however, to discuss the moral side of these prophylactic measures; but will say that notwithstanding their use, it is shown that infection will occur sufficiently often to make immoral relations dangerous to one's life and health, and the individuals infected a menace to society.

This statement cannot be confuted successfully. Even from the viewpoint of protection, such measures will not stand the crucial tests of actual conditions. Take life in Europe today, among civilians in the many localities where they are still bearing the burdens and sorrows of the war. Poverty and hun-

ger, produced by embargoes on food for which Americans are to a large extent responsible, lack of work, and the high cost of living, with a currency depreciated by the results of the war, while thousands are kept alive simply by the generosity of a comparatively few philanthropic Americans make women and girls the easy prey of licentious soldiers, especially if they are Africans, armed with brief authority and backed by military officers who have neither fear of God nor man before their eyes. How can such a depraved condition of things be remedied by lectures, posters, or any other form of publiclicity? Intelligent people know it cannot. Or is it to be supposed that where brothels were opened on the outskirts of our camps, during the late war, lectures or literature effectually restrained our youth. We know they did not. I am certain from personal experience at home and abroad that public prostitution, our greatest danger, in this regard can be controlled by the law. Public women, of course, have the greatest opportunities for producing infection and are almost certain to be infected sooner or later. To regulate by military or civil forces this feature of the case, therefore, would be the method most effective in results of any in the prophylaxis of venereal diseases.

Therefore, let us first of all bend our efforts to suppressing the public traffic by the well known methods, which are simple, efficient and economical, and let other methods, such as those I have described which are largely theoretical, expensive and inefficient, if not in some cases immoral, have a secondary consideration. These facts can, however, be brought into a clearer light, if some of these scandalous practices that I have mentioned, whether international or national, are made themes of a Congressional inquiry. Fortunately we have at hand many high in Government circles who have had an opportunity of witnessing some of the orgies I have described, in foreign lands. Their testimony might be most valuable; indeed, we should recognize that Europe is the source of the venereal diseases that just now are threatening civilization.

There are various reasons why an inquiry into this topic should emanate from the Government. The profession of medicine is, as a rule, fearful that under the pressure of outside influence laws will be introduced compelling them, on the witness stand, to violate the tenets of professional secrecy. Fear of it would prevent many of the laity from telling the truth about themselves. Moreover, inasmuch as venereal diseases prevail more or less extensively in the practice of every physician and surgeon, compulsory notification would remove a source of considerable revenue. Indeed the patient might prefer to use nostrums to having his disease exposed on the public records. To be sure, if notification were made compulsory we may be quite certain physicians would not be likely to carry it out and public opinion would sustain them. In fact, compulsory notification could not be carried out successfully in American circles at the present time. But as a result of compulsory notification laws the disease, though perhaps making alarming strides forward, would apparently be diminishing, according to the reports of our public health authorities. Again by

a government inquiry the public should be officially informed of the real dangers of these diseases and the comparative values of prophylactic measures. For example, if the following queries were taken up at such an inquiry, under the subjoined heads, as bearing on the Parisian scandal, they would be productive of the most valuable results to our people at large. The topics to be taken up might be:

1. Could public women in France have been successfully quarantined?

2. Could not the danger of contagion have been prevented by the withholding of passes, by the military or naval authorities?

3. Is abstinence harmful to men or women?

4. Is not the public woman the source of the greatest danger?

5. Is the furnishing of public women by sociological associations with prophylactic packets a safe procedure, or a moral one?

6. What is really the ratio of effectiveness by the prophylactic measures pursued in military and navy circles?

Certainly if we joined the League of Nations as at present constituted, would we not be expected, to at least give tacit consent to the maintenance and regulations of military brothels, such as have been in operation recently, and probably are now, under the guise of military necessities.

Now while the statements I have made in this paper, based on the reports of government officials, will probably be accepted as true by the medical profession at large, we need not expect they will be accepted by all of the sociological workers who have visited the areas referred to. This attitude on their part, which has already been observed by the writer, was to have been expected, and for various reasons. In many instances the men and women sent over to supervise the work of their associations or gather material for home consumption, were either ignorant of foreign languages or of the nature of the diseases, or otherwise unqualified; or they thought it unpatriotic to tell of unpleasant conditions noted in their work. This remark applies to the clergy as well as to the laity employed in such missions.

We may, therefore, expect no help from any of them unless it can be shown that now we require the truth, and it is pseudopatriotic for them to withhold it. But, after all, prophylaxis in venereal diseases is essentially a medical problem and it is, therefore, most fitting that efforts to solve it should emanate from the medical profession.

INSTRUMENT FOR SIMPLIFYING TONSILLECTOMY BY SNARE.

By ISIDOR F. SHAPIRO, M.D.,
New York.

The saving of time at a critical juncture in the course of the snare operation has been effected by the use of the instrument shown in Fig. 1, which I have devised. It consists simply of a Hurd dissector onto which has been brazed part of a Weder tongue depressor. This saves the operator the trouble and extra motions that go with two separate instruments and permits a considerable saving in the time of the operation, which is important for a patient under a general anesthetic. It also reduces the

FIG. 1.—Combination tonsil dissector and tongue depressor.

amount of hemorrhage and sponging which, after all, is traumatic and is to be avoided as far as possible. All these advantages are especially apparent when the operation is done without many assistants or at the patient's home, where there are no suction facilities. The loss of blood is reduced when the suction method is used, on account of the saving of time of operation.

355 EAST 149TH STREET.

Influenza in the Tuberculous.—Maurice Fishberg and Ernst P. Boas (*American Journal of the Medical Sciences*, August, 1920) state that in an outbreak of influenza in the tuberculosis pavilion of the Montefiore Hospital during January and February, 1920, twenty-eight out of 127 patients were affected. The proportion seems to be about the same as might be expected among nontuberculous individuals. The clinical form of tuberculosis and the stage of the disease had no influence on the tendency of the patients to contract influenza. Of the twenty-eight patients who contracted influenza nine died, which is a higher rate of mortality than is generally observed. Of the twenty-eight patients with influenza, twenty-two developed bronchopneumonia, again a rate much higher than is usually seen. It seems that the tendency to complicating bronchopneumonia varies with the epidemic. During the epidemic of 1918 this complication developed in a smaller proportion of patients and the mortality was lower. The clinical course of the influenza resembled that seen in the nontuberculous. The tendency to develop complicating bronchopneumonia bears no relation to the stage, clinical form, or acuteness of the tuberculous process in the lung and pleura. In nearly all of the patients who recovered the complicating disease had no appreciable influence on the tuberculous lung lesion, so far as could be ascertained by physical exploration of the chest or on the subsequent course of the disease. They cannot say that the anergic state brought about by influenza had an influence on the incidence, course and termination of this disease in the tuberculous.

VENEREAL PROPHYLAXIS

The venereal problem is one that has confronted the world for many centuries. Slowly, very slowly, have we gained accurate knowledge regarding the transmission of venereal diseases. First of all our efforts were directed to cure. Then diagnostic methods were perfected and we found that our hospitals and homes were filled with victims of syphilis and gonorrhoea. These victims ranged from the fetus killed in the uterus by a syphilitic virus to the latent manifestations in general paresis. Between these two we found a formidable host of lesions attacking every portion of the body—the eyes, the bones, the nervous system, the skin and viscera—no structure escaped. Blind babies were born. This is not a sentimental plea, but a statement of reality. Textbooks were written and various ways and means devised to combat the results of the twin evils, gonorrhoea and syphilis.

Finally, the more sane realized that this ghastly army of the sick and disabled did not need to exist. Ibsen and Brioux portrayed from the stage the results of venereal infection. The less timid gave support; the reactionaries attempted to suppress. Professional uplifters crusaded and attempted to clean up communities. But the practice of the genitourinary specialists did not decrease. The enforcement of prophylactic care of the eyes of newborn babies, however, decreased the number of blind babies. Then came the great war where the youth of our so-called civilization pitted themselves one against the other in the field of battle. Some say that man in his in-

genuity could have prevented that catastrophe. However, we shall not discuss the point. Others may take up their cudgels in protecting man from his own folly in war; we as physicians will deal with his follies of health.

This week we are presenting the paper of a most earnest physician, Dr. Thomas E. Satterthwaite, who has seen many of the venereal problems that were brought to a focus during the war. While we do not agree with all he has to say, there is so much truth in what he says, that we feel it should be published, even though we do not believe in the efficacy of the tactics by which he thinks the venereal problem can be solved. He takes issue with Miss Rout, of New Zealand, Riddell, of Toronto, and a host of others on the question of the advisability of the use of prophylaxis. His two objections are: It will increase illicit intercourse, and the prophylaxis is not effective in every case. In regard to the first point, it is difficult to conceive how this would be possible on the face of things. Civilization plunging along at a mad pace, with its countless sexual stimulants, the press, the theatre, the cinema, clothes designed to lure and captivate, and the monetary incentive to prostitutes and their accessories, all these tend to sexual excitation. The gonadal powers of youth are awakened prematurely. It is difficult to conceive how venereal prophylaxis is going to increase venereal diseases under these conditions. It is well to consider the entire background and not focus too sharply on one particular spot. Dr. Satterthwaite carefully quotes only part of Miss Rout's paper, which appeared in the *NEW YORK MEDICAL JOURNAL*, October 9, 1920; he does not go into the statistics of her experience with the soldiers on leave in Paris. We all know that prostitution flourished there, especially during the war. It would be interesting to go into the economic reason for this; much food for thought would come out of this study. However, she proved that venereal infection was decreased to a minimum. She showed that continence could not be enforced. Man is a complex animal and the sexual urge is great. The intellectual level is not equal and it is not possible to prevent illicit intercourse.

How are prophylactic measures going to increase the number of illicit relationships? The feeble answer is that it will make intercourse safe. On the other hand, with the prophylactic measures a certain amount of education is necessary and is sure to follow. The prophylaxis calls to mind not the safety of the sex relationship but the danger. With the reminder and the realization that follows men

and women will seek early treatment when infected. The entire question will come to light and not be suppressed. We shall be able to discuss the subject without the age long inhibitions that have surrounded us. We shall be able to fight the foe where it can be seen. The method of suppression urged by Satterthwaite has never proved successful in any field of human affairs; we have nothing to show that it will be more effective for the venereal problem. We cannot, by force or any other means, push the problem into the dark where it will fester and break out anew. We need more light, more light.

ELECTROTHERAPEUTICS IN THE TREATMENT OF PARALYSIS.

Electrotherapy has not been accorded the position which is its due in the treatment of certain conditions. Perhaps, by some its therapeutic efficacy has been exaggerated, but in certain forms of muscular paralysis electricity plays a rôle of no mean importance. Mr. H. S. Souttar, F. R. C. S., assistant surgeon and director of surgical unit, London Hospital, in a paper read before the British Medical Association, laid emphasis on the fact that in the care of a limb in which a nerve has been severed there were many considerations other than those that appear on the surface. The inevitable paralysis of a certain group of muscles carries with it a whole train of consequences, many of which are by no means inevitable. Leaving on one side the muscles directly affected, the loss of the normal range of movement will lead to the formation of adhesions between other muscles, around tendons, and within joints. The limb may readily fall into positions of deformity which give rise to the stretching of muscles and ligaments, the skin itself will suffer from disuse, and the limb will suffer from its corresponding loss of excretory power. It is therefore evident that in estimating the value of any one method of treatment the limb as a whole must be considered and the vision must not be bounded by the narrower field of the small group of muscles which may be paralyzed.

In the application of electricity the primary object is to evoke contractions in the paralyzed muscle. By doing so it is compelled to fulfill its normal functions, in however diminished a degree, and the universal experience is that this is essential for the prevention of atrophy in any tissue. The tissues require for their nutrition something more than the supply of food, even something more than perfect innervation. They must work, and according to Souttar electrical stimulation can do for the muscle something quite out of the reach of any other method. Indeed, the *prima facie* evidence of the

value of contractions of paralyzed muscle is so overwhelming, that it would require the strongest practical evidence of their uselessness to justify their being ignored. Yet, if electrical treatment is to be really effective one condition must not be overlooked: if the muscle as a whole is to receive the same benefit as the fibres which contract, it must be made to contract as a whole, and this result is often exceedingly difficult to obtain. As Souttar pointed out, the ideal means of stimulation would be the passage through the whole limb of a current which would stimulate the paralyzed muscles, leaving the intact muscles undisturbed. This is not as yet solved, although the researches of Lapique and of Turrell have brought this ideal within measurable distance. For the contraction of paralyzed muscle special forms of current should be developed. The discovery of some simple means by which the contraction of every fibre of a paralyzed muscle could with certainty be obtained would give a powerful impetus to treatment.

Souttar holds the view that there is little fear of overfatiguing paralyzed muscles by continued stimulation. Major Cooper has put the matter to a direct test and has found that after six hundred contractions in fifteen minutes a paralyzed muscle showed no evidence of fatigue. Consequently, it seems to be indicated that each muscle might be exercised for a longer period than is usual with great advantage. As for the faradic current which does not produce contractions Souttar is of the opinion that apart from its indirect action through the muscles, it is probable that a faradic current has a direct stimulating action upon the circulation, either upon the vessels themselves or through the sympathetic system, and in this way it may have a direct action upon the vitality of the limb as a whole.

But further it has recently occurred to him that a faradic current stimulating the muscles antagonistic to those which are paralyzed, might probably have a good effect. While no evidence exists to show that the mere passage of a current through a limb has any effect on the growth of a divided nerve, there is every reason to suppose that the growth of a divided nerve is influenced by the activity of the cell from which it arises, and Souttar asks what better means could be found of stimulating the anterior horn cell than the production of the physiological reflex arising from the contraction of the antagonistic muscle group?

There is little doubt that there is a great future for the electrical treatment of paralysis caused by nerve injury. It also appears certain that the modes of applying such treatment are developing in a satisfactory manner. However, those who apply the

treatment should be experts and thoroughly understand the end they have in view. Much has been learned in this direction during the war, and it is to be hoped that this knowledge will be developed so successfully that it will be put to the best use in industrial medical practice. There is a wide scope for electrotherapeutics in this field.

PHYSICIAN-AUTHORS: DR. WILLIAM
HENRY DRUMMOND.

There are two predominating groups of people in the eastern provinces of Canada, the English and the French, and there are remote historical reasons, taking us back to the days of New France, why these two groups have not been wholly in political and social harmony, despite the fact that for so many decades they have been fellow countrymen sharing the advantages and the burdens of a great and growing dominion. Today, however, these two great groups are more nearly in sympathetic touch with one another than ever before. A number of contributing factors have brought about this spirit of concord, and Canadians of both groups agree that not the least of these factors was a big, warm hearted, whole souled Irish physician who, in odd moments of leisure when his practice was not too pressing, found time and inspiration to wield his pen for the entertainment of his family and friends. This man was Dr. William Henry Drummond, of Toronto, Ontario.

Poetry was Dr. Drummond's medium, and by means of it he interpreted with a kindly sympathy, a tender pathos and an inimitable humor the simple life and characteristics of the *habitants* of Ontario and Quebec. It was the first time the French-Canadian farmer had been utilized as a literary figure, except when some ribald scribbler poked fun at him and his patois. French-Canadians were inclined to resent Drummond's poetical effusions at first. They glanced at them without reading and assumed that they were merely another attempt to make a laughing stock of the simple minded *habitant*. But after they had been induced to read them, and realized that here was a sincere attempt to present the *habitant* in a clean and pleasing way, their praise knew no bounds, and today there are no greater admirers of Dr. Drummond's poetry than the French-Canadian element.

In the preface to his first volume, *The Habitant*, he says: "Having lived practically all my life side by side with the French-Canadian people, I have grown to love and admire them, and I have felt that while many of the English speaking people know, perhaps as well as myself, the French-Can-

adians of the cities, yet they have had little opportunity to become acquainted with the *habitant*, therefore I have endeavored to paint a few types, and in doing this it has seemed to me that I could best attain the object in view by having my friends tell their own tales in their own way, as they would relate them to English speaking auditors not conversant with the French tongue." This was the spirit, then, which served to bring the two racial divisions of *The Lady of the Snows* a step or two nearer a friendly fellow feeling. The good spirit and tempered delicacy Dr. Drummond displayed in the treatment of the *habitants* created an equally pleasing impression in the English speaking world. *The Habitant* was followed by three other volumes of French-Canadian poems—*The Voyageur*, *Johnny Courteau* and *The Great Fight*. These four volumes had a vogue in their day that was almost unparalleled in the history of modern verse, not only in Canada but in England and the United States as well. They still have a steady sale in Canada.

If Canadian literature were of maturer development perhaps Drummond's poetry would in time pass into oblivion, for it is not great poetry. But Canadian literature is still in its infancy and this man's work seems assured of perpetuity because, as Dr. Louis Frechette, the Poet Laureate of Canada, has said, "he was a new pathfinder in the land of song."

Dr. Drummond was born on April 13, 1854, in County Leitrim, Ireland, and passed his boyhood in the village of Tawley, near the Bay of Donegal. When he was ten years old the family removed to Canada, and shortly thereafter the father died. Being the eldest son, young Drummond had to set about finding ways to help his widowed mother, and so he learned telegraphy. He became a full fledged telegrapher in the lumber camp village of Bord-a-Plouffe, on the River des Prairies, and there came into contact with those *voyageurs* and *habitants* whom he later wove into his poems. The songs they sang gave to his style its mould and spirit. His poems are, for the most part, merely metrical renditions of their quaint tales of backwood life. After a few years of work he was able to attend McGill University, and later Bishop's Medical College, where he got his medical degree in 1884. His first medical work was as house surgeon at the Western Hospital in Montreal, and subsequently he took up the practice of medicine in the little village of Stornoway, near Lake Megantic. After two years there and two more at the village of Knowlton he returned to Montreal, where he practised until his death on April 6, 1907, in the Cobalt mining district, where he had gone to fight an epidemic of smallpox.

In Stornoway and Knowlton he gathered impressions and material for his pictures of *The Canadian Country Doctor* and *Ole Doctor Fiset*. In Montreal Dr. Drummond lived in an old house on Mountain Street which had been the home of Jefferson Davis, the exiled President of the Confederacy, and it was there he wrote practically all of his poems. In addition to his practice he for several years occupied the chair of medical jurisprudence in his alma mater. In recognition of his literary achievements the University of Toronto in 1902 conferred upon him the degree of LL. D. and subsequently he was elected a fellow of the Royal Society of Literature in England and of the Royal Society of Canada. These, with the degree of D. C. L. from Bishop's College, made up the sum of his literary honors.

A HUGE JOKE

To ordain by legislative enactment that alcoholic liquors shall be medicine and then watch and spy upon, haul into court and fine any doctor who oversteps the bounds set by a license commission, is one of the greatest jokes ever perpetrated on a community. This is what the Ontario Temperance Law does for the physicians of that province. The farce goes further. Seven dispensaries are distributed throughout the land, two being located in Toronto where there is only one fifth of the population. No wonder there is a lot of so-called sickness in Toronto, markedly intensified every weekend. Nearly all the illustrious legislators, many of them great legal luminaries, who were instrumental in framing and passing this wonderful piece of legislation, have by the will of the people been left to the comfort of their own firesides, and cellars, but new ones are in the saddle riding the governmental steed. They ride, but so far as controlling the beast, they lack control, for have they not a special commission inquiring into the administration of the Ontario Temperance Act which, from one end of the province to the other and from Lake Ontario and Lake Erie to the confines of Hudson Bay is of questionable repute. When the inquiry is completed the medical profession may have some measure of relief. At all events that is their prayer.

Few express any desire for a return to the open bar. Some may wish to get their so-called medicine now and again without recourse to the doctor and the added cost. The act is iniquitous in that it discriminates in the rich man's favor. To the profession it is burdensome in that they have to carry the stigma of harboring in their ranks three or four hundred unscrupulous physicians who fatten their averages by the medicinal prescription.

OCULISTS AND PEOPLES.

The beauty of a pretty workgirl is not enhanced by huge goggles, nor is a young man made more prepossessing by their use, yet, in the long processions lunchwards, homewards, which trips and stumbles and strides through our streets, there are hundreds wearing glasses. If asked by the oculist as to the lighting of store or factory or office the ready answer will be that there is "plenty of electric light; quite a glare of it." But the oculists on the Board of the Industrial Accident Commission define light as "that quantity and quality which enables normal eyes to work without discomfort," and they are trying to make employers see the economic advantages of supplying this. When the light is insufficient the eye keeps changing its focus in a vain effort to detect details. This constant drawing up and releasing action of the fine muscular construction results in strain and definite fatigue. Also, a bright light suspended in the line of vision, or a sharp contrast and flickering on the eye gives the extra work of constant adjustment. This is not only a serious strain, but introduces a neutral stage of the pupil action by the lagging of tired muscles, which results in a momentary, partial blindness, making it almost impossible for a worker to observe the graduations of a precision instrument or lay out fine work in detail.

THE NERVOUS COW.

It is little realized by the laity how much the health of animals affects our own, nor how much is being done in the veterinary world on this account. There is the question of abortion in cows and its relation to human mothers, of tuberculosis as affecting everyone, and, greatest of all, the distribution of pasteurized milk unfreed by protection against subsequent contamination. There is even published a large veterinary dentistry, but it is not difficult to imagine that a bull or a horse would require some patient handling when toothache set in. One veterinary has had a cow suffering from nervous shock. She could not bear anyone near her, and walked with a stiff, irregular gait, making the motions of stepping over an obstacle before she came to it. Sodium cacodylate and restful solitude in a darkened stall led to a complete cure. It is rather difficult to believe, but pigs also are delicate, nervous animals, and require more care than cows.

PREMATURE BURIAL.

Every year gloomy little articles are issued concerning the burying of the living and advising the dead to have their veins opened and various other devices are suggested to ascertain their real condition. Out in Akron, Ohio, one William Wirt found himself on a memorial tablet erected to those who had died in France. He says there are nearly two thousand so commemorated in different States who have since been traced as living. He suggests starting a Club of Dead Men. Perhaps he means a hermitage where they could forget the world and be forgotten by it. These soldiers have been officially declared dead. How does the law stand?

News Items.

A Vaccination Campaign in New York.—During the month of September 25,453 vaccinations were performed in Greater New York by medical inspectors of the health department, compared with 12,029 during August.

Tuberculosis Clinics in Ontario County.—Under the joint auspices of the Ontario County Tuberculosis Committee and the Geneva Health Bureau a monthly tuberculosis clinic has been established in Geneva. Up to the middle of August a total of 117 patients had been examined.

Hospital at St. Mihiel to Be War Memorial.—Cooperating with the French Government, the junior section of the American Red Cross Society will finance the erection and operation of a hospital for children at St. Mihiel, France, in memory of the first great American battle effort of the war.

The Length of Human Life.—The average duration of life in India is less than 25 years. In Sweden it is over 50 years; in Massachusetts, 45 years; in Denmark it is 51.17; in France, 47.4; in England and Wales, 45.9; in Italy, 42.9, and in Prussia, 42.8. In Geneva, where records are available for the past three centuries, the sixteenth century showed a life span of 21.2 years, the seventeenth century showed 25.7 years, the eighteenth, 33.6 years, and the nineteenth, 39.7 years.

New Quarters for Health Department Venereal Disease Clinic.—The Department of Health of the City of New York announces the removal of its Manhattan Venereal Disease Clinic to the department headquarters at 505 Pearl street. This clinic was established in compliance with the State venereal disease law and is intended for those who cannot afford to pay the charges made by dispensaries. The medical profession is invited to refer to this clinic such patients as are believed to be suitable for free treatment.

Civil Service Examination for Anatomist.—The United States Civil Service Commission announces an examination for the position of anatomist in the office of the Surgeon General, Army Medical Museum, Washington, D. C., at \$1,600 a year, plus increase granted by Congress of \$20 a month. The duties of the appointee will consist of the preparation of gross and histological material, their reproduction in drawings, photographs, or paintings for illustrative purposes. Those interested should apply for Form 1312. No applications will be received after December 7th.

New York Neurological Society.—A joint meeting of the New York Neurological Society and the Section in Neurology of the New York Academy of Medicine will be held on Tuesday evening, November 9th. Dr. Hyman Climenko will present a case of Nanism and Dr. A. L. Soresi a case of Psychosis following Surgical Operation. Dr. Joseph Byrne will read a paper on Pupil Dilatation and the Sensory Pathways, illustrated with lantern slides. Dr. Samuel Brock will present a study in motor aphasia of the Cortical or Mixed Type, with report of a case, and Dr. Karl Winfield Ney will describe the operation and findings in the case.

Improvements at Glen Ridge Sanatorium.—The Board of Supervisors of Schenectady, N. Y., has voted \$50,000 for repairs and improvements to be made at Glen Ridge Tuberculosis Sanatorium. In addition to extensive repairs, a new pavilion is to be created, a cooling system installed, and the present administration building enlarged.

Christmas Seal Campaign.—Active preparations are being made for this season's Christmas seal campaign to raise funds for antituberculosis work, which will open on December 1st. New York State's quota this year will be \$582,000. Last year a total of \$375,000 was raised in New York State, outside of New York city, for the work of national, State and local tuberculosis organizations.

Wisconsin Cancer Committee.—The State Medical Society of Wisconsin recently appointed a committee for the study of cancer, with the following membership: Dr. J. P. McMahan, of Milwaukee, chairman; Dr. Edward Evans, of La Crosse; Dr. W. A. Ground, of Superior; Dr. C. H. Bunting, of Madison, and Dr. W. K. Grey, of Milwaukee.

Menorah Hospital.—Nearly \$25,000 was contributed at a dinner held at the Hotel Bossert on October 17 to the building fund of the new Menorah Hospital at Coney Island. The new institution will be nonsectarian, and will receive both acute and chronic cases. For the purchase and equipment of the hospital \$400,000 is required.

Sanitary Survey of Interstate Park.—At the request of the Public Health Council a sanitary survey is being made of the Palisades Interstate Park. This park consists of about 36,000 acres and is situated between the palisades along the Hudson River and the Ramapo Mountains, partly in New Jersey and partly in New York. About sixty camps are maintained throughout the park and this survey includes detailed studies and inspections of the water supply and sewage disposal.

American Academy of Ophthalmology and Otolaryngology.—At the twenty-fifth annual meeting of this organization, held in Kansas City, Mo., on October 15th, the following officers were elected: President, Dr. Emil Mayer, of New York; first vice-president, Dr. John R. Newcomb, of Indianapolis; second vice-president, Dr. Robert Ridpath, of Philadelphia; third vice-president, Dr. W. C. Finnoff, of Denver; treasurer, Dr. Secord H. Lodge, of Cleveland; secretary, Dr. Luther C. Peter, of Philadelphia; editor of *Transactions*, Dr. Clarence Loeb, of Chicago. Next year's meeting will be held in Philadelphia.

Philadelphia Medical Club Nominations.—At a recent meeting of the Medical Club of Philadelphia the following officers were nominated for the coming year: President, Dr. Barton Cooke Hirst; first vice-president, Dr. Hobart A. Hare; second vice-president, Dr. Alexander MacAlister; secretary, Dr. William S. Wray; treasurer, Dr. George A. Knowles and Dr. Lewis H. Adler, Jr.; governor, Dr. G. Orm Ring and Dr. Walter L. Pyle; additional directors, Dr. John A. Sherger, Dr. B. Frank Wentz, Dr. Wilmer Krusen, Dr. Howard A. Sutton, Dr. S. MacCuen Smith, Dr. Thomas R. Neilson.

Dentists Cooperate in Campaign Against Venereal Diseases.—Of the forty thousand licensed and registered dentists in the United States, 15,252 have signified their intention of cooperating fully with the United States Public Health Service in its national campaign for venereal disease control, agreeing to report all venereal disease cases which come under their observation in their practice in accordance with the laws and board of health regulations, and to advise treatment in all such venereal disease cases which come under their observation, referring them to a clinic or to a physician known to be competent in the treatment of such cases.

The Alvarenga Prize.—The College of Physicians of Philadelphia announces that the next award of the Alvarenga Prize, amounting to about \$250, will be made on July 14, 1921, provided that an essay deemed by the Committee of Award to be worthy of the prize shall have been offered. Essays intended for competition may be upon any subject in medicine, but cannot have been published. They must be typewritten, and if written in a language other than English should be accompanied by an English translation, and must be received by the secretary of the college, Dr. John H. Girven, 19 South Twenty-Second Street, Philadelphia, on or before May 1, 1921. No prize was awarded for 1920.

Meetings of Local Medical Societies.—The following medical societies will meet in New York during the coming week:

MONDAY, *November 1st.*—Medical Society of the New York Polyclinic Medical School and Hospital.

TUESDAY, *November 2d.*—New York Academy of Medicine (Section in Dermatology and Syphilis); Medical Society of Harlem Hospital; New York Neurological Society; Society of Alumni of Lebanon Hospital.

WEDNESDAY, *November 3d.*—New York Academy of Medicine (Section in Historical Medicine); Bronx Medical Association; Harlem Medical Association; Psychiatric Society of New York; Society of Alumni of Bellevue Hospital; Brooklyn Society for Neurology.

THURSDAY, *November 4th.*—New York Academy of Medicine (stated meeting); Brooklyn Surgical Society.

FRIDAY, *November 5th.*—New York Academy of Medicine (Section in Surgery); New York Microscopical Society; Practitioners' Society of New York; Alumni Association of Roosevelt Hospital; Gynecological Society of Brooklyn (annual).

SATURDAY, *November 6th.*—Benjamin Rush Medical Society.

Gifts to Columbia University.—Among the twenty-one gifts aggregating \$27,902.80, in addition to a valuable collection of books forming the nucleus of a memorial library, announced by Columbia University, are the following:

From the Borden Company, of New York, \$10,000 to be added to their previous gift for research in food chemistry and nutrition, carried on under the direction of Professor Henry C. Sherman.

From William S. Grosvenor, of Providence, R. I., \$2,500 to establish the Grosvenor Memorial Fund in memory of Robert Grosvenor, a former member of the 1918 class in medicine. The income of the fund is to be used to purchase books for the library of the medical school.

From Mrs. Elizabeth S. Coolidge \$2,400 for the maintenance of the Coolidge Research Fellowships in Medicine.

From the classmates of the late Alexander Weinstein, a member of the class of 1920, \$800 to establish the Alexander Weinstein Memorial Fund, the interest of which is to be used for the purchase of books for the library of the medical school.

From an anonymous donor \$237.80 to be applied toward the completion of the equipment of the surgical laboratory.

War Department Sells Hospital Supplies.—The Surplus Property Branch of the Office of the Quartermaster General of the Army has sold to the Thomas & Kelly Co., of Boston, the remaining surplus of bandages and absorbent cotton, purchased for the use of the Army during the war, the sale netting the Government more than \$1,000,000. The bandages alone represent a quantity sufficient to supply the hospitals and surgeons of the United States with all their needs for at least eighteen months. Included in the sale were a million dozen roller and between two and two and one half million compressed bandages, and approximately two and one quarter million one ounce packages of absorbent cotton.

Psychiatric Institute to Be Expanded Into a Psychopathic Hospital.—A bill has been signed by Governor Smith which provides for the transfer of the Psychiatric Institute from Ward's Island to a site to be obtained in New York, where it will be expanded into a psychopathic hospital and outpatient department for the reception, study and treatment of patients. The bill authorized the appropriation of \$700,000 toward the construction of such an institution when a site was available. A hospital of this kind, by preventing and curing cases of mental disease in incipient and early stages, would save the State the expense of the continuous care of chronic cases for long terms of years in the State hospitals.

Died.

BULLOCK.—In Upland, Pa., on Monday, October 18th, Dr. Edwin G. Bullock, aged thirty-seven years.

CRONEMILLER.—In Los Angeles, Cal., on Monday, October 11th, Dr. Mary M. Cronemiller, of Sacramento, aged fifty-nine years.

EALER.—In Philadelphia, Pa., on Sunday, October 17th, Dr. Percy H. Ealer, aged sixty-two years.

EBERSOLE.—In Cleveland, Ohio, on Tuesday, October 5th, Dr. W. G. Ebersole, aged fifty-six years.

FLEISCHMER.—In Manila, Philippine Islands, on Monday, September 20th, Dr. H. J. Fleischmer, of Chicago, aged fifty-five years.

IVES.—In Pecatonica, Ill., on Sunday, October 10th, Dr. Charles G. Ives.

LYONS.—In New Rochelle, N. Y., on Tuesday, October 12th, Dr. George A. Lyons.

MACDOUGALL.—In Haverhill, Mass., on Saturday, October 16th, Dr. Duncan MacDougall, aged fifty-four years.

MACKENZIE.—In Trenton, N. J., on Tuesday, October 19th, Dr. Thomas H. MacKenzie, aged seventy-three years.

MOODY.—In Sunbury, Pa., on Saturday, October 16th, Dr. William M. Moody, aged eighty-six years.

O'REILLY.—In Middletown, N. Y., on Wednesday, October 13th, Dr. James A. O'Reilly, of Brooklyn, aged thirty-three years.

SEARS.—In Beverly, Mass., on Wednesday, October 20th, Dr. Harry E. Sears, aged fifty years.

SIMPSON.—In Banning, Cal., on Wednesday, October 13th, Dr. Jessie Harriet Simpson, of Patton, Cal., aged forty-seven years.

SPAULDING.—In Clifton Springs, N. Y., on Thursday, October 14th, Dr. Francis Wood Spaulding, aged seventy-six years.

SULLIVAN.—At Providence, R. I., on Friday, October 8th, Dr. James E. Sullivan.

Book Reviews

PLASTIC SURGERY

Plastic Surgery of the Face. Based on Selected Cases of War Injuries of the Face Including Burns. With Original Illustrations. By H. D. GILLIES, C. B. E., F. R. C. S., Major R. A. M. C., Surgical Specialist to the Queen's Hospital, Sidcup Surgeon in Charge of the Department for Plastic Surgery, and Late Surgeon in Charge of the Ear, Nose and Throat Department, Prince of Wales Hospital, Tottenham, etc. With a Chapter on the Prosthetic Problems of Plastic Surgery, by Captain W. KELSEY FRY, M. C., R. A. M. C., Senior Dental Surgeon, Queen's Hospital, etc. Remarks on Anesthesia, by Captain R. WADE, R. A. M. C., Late Senior Anesthetist, Queen's Hospital, etc. London: Henry Frowde (Oxford University Press), Hodder & Stoughton, 1920. Pp. xiii-408.

Much credit is due Gillies for the splendid work he has done in plastic surgery. His are the greatest of all contributions to the advance of this interesting reparative work which, we are told, dates back to antiquity. In America his work was first made known to the medical profession through the columns of the *NEW YORK MEDICAL JOURNAL*. Since that time many surgeons recognizing the superiority of this master workman have profited by his methods and given them wide application with excellent results. Now we have his work presented in an admirable form in his new book. Arbuthnot Lane, of intestinal stasis fame, calls our attention to the many fields of usefulness to which Gillies's technic may be applied. He lists ugly scars from burns and accidents, deformities of the nose and lips, harelip and cleft palate, abnormal protrusion or ill development of the mandible, moles, port wine stains. Surgeons know how the lives of many useful people are made ugly by the differences they present on account of various deformities and abnormalities; how they come with their appeals, vainly striving for some help to eradicate the blight which has caused them endless suffering and unhappiness.

Again, burns and accidents require surgical intervention of a plastic nature in order to allow for proper functioning. Cases have been recorded where patients have been fed for years through a tube because of inability to move their jaws. This immobility was caused by adhesions from old scars due to burns or other accidents. Frequently, too, we are called upon to repair a deficiency due to the removal of malignant growths. But why enumerate the many fields of usefulness of this method? They are well known to most of us. Many methods have been tried, but it may safely be said that none compare with the tubed pedicle method of Gillies. The reviewer recalls the crude attempts at facial repair which were attempted in the French army hospitals in the early months of the war. The best of these were poor, very poor, compared with the results obtained by Gillies. Parts of the face were used to repair the face and the process was frequently repeated over the same area in order to secure a satisfactory result. At times the results were fairly good, but the procedure was painfully slow and at best far short of what might be called good. The method of Gillies is so simple and so satisfactory by comparison that it seems strange that it was not thought of earlier.

An interesting historical outline is offered in which we are told of the very early operations in India for the repair of the punitive mutilation of the nose. The forehead flap is the operation which has survived until the present day. Cheek flaps were also used and these survived until fairly recently, but they were finally relegated to limbo. Keegan is praised for his realization of the necessity of a lining membrane for the repair of mucous lined cavities. The method of Tagliacozzi of the two stage operation from the patient's arm to nose goes back to 1415. But the tubed pedicle, the best method known to surgery, was devised by Gillies and he should be given due credit for this excellent idea.

He tells us of the preparatory steps in the conservation of the remaining tissue and various useful little hints for the hastening of recovery; warnings of what should not be done and the harm that may result from the neglect of his injunctions; of the dangers of secondary hemorrhage and how it can be avoided.

The dentist is called in to attend to the toilet of the buccal cavity and to rearrange the bony fragments. Suspensory wiring of fragments is disapproved of on account of having a foreign body in contact with inflammatory bone lesions. Bone grafting, which has been perfected by our own Dr. Albee, is highly recommended. Then come the late repair, the careful planning of the operation; the consideration of the many difficulties which experience has shown we may encounter. A careful selection of the lining membrane is a most important part of the procedure. A modification of the American Esser epithelial inlay, as revised by Waldron, of Canada, and Pickerill, of New Zealand, was used with great success. Then we are shown how every stage of the operation is important, the anesthesia, the prevention of edema, the preservation of the viability of the flaps, the cartilage that must be replaced, and the care of the bone grafts. Every detail is cared for and in every instance simplicity and common sense prevail. The various regions are taken up, every conceivable form of repair being discussed, and every problem that may be encountered is carefully considered. In order to remove the work from the abstract and bring it into the realm of complete reality, many actual cases are given. The photographs and diagrams are all that can be wished for. Finally several civil cases are shown in order that the usefulness of the work may be appreciated in this field. Lane did not mention in his list, the prenatal diseases where the technic could be applied. These include, ectopia vesicæ, hypospadias, meningocele, imperforate anus, and also the various fistulæ so commonly encountered.

Many surgeons the world over will appreciate this monumental work, but the greatest praise will come from those unhappy creatures who, as a result of this new procedure, can again take their place among the unmarked. These unfortunate beings will forever be grateful to their benefactor, H. D. Gillies of London.

MIND ENERGY.

Mind Energy. Lectures and Essays. By HENRI BERGSON, Member of the French Academy, Professor in the College de France. Translated by H. WILDON CARR, Hon. D. Litt., Professor in the University of London. New York: Henry Holt & Co., 1920. Pp. x-262.

"I have sometimes asked myself what would have happened if modern science . . . instead of bringing all its forces to converge on the study of matter, had begun by the consideration of mind—if Kepler, Galileo and Newton, for example, had been psychologists. . . . The most general laws of mental activity once discovered . . . science would have passed from pure mind to life." Bergson confesses to losing himself occasionally for a moment in such a dream to return nevertheless to the practical admission that it could not be otherwise than it is. Even if as much talent and genius had been expended upon mental phenomena as have been "consecrated to sciences of matter." Yet some things would have been found wanting. These are the very intellectual qualities which have been developed through occupation with physical matters and which are quite indispensable as methods of investigation in the mental realm. Bergson is too clear a thinker to proceed, even where the force of his genius directs him, without the precision, exactness, certitude, to adopt his words, which have become the habit of material science. Bergson is a guide whose vision may seem to alight upon mountain peaks which appear unsubstantially above the clouds, but the confidence of the most cautious is assured by his truly scientific attitude. Stimulated by his daring penetration into certain discoverable facts of mind, we can with him "adventure without fear into the scarcely explored domain of psychical realities."

His book *Mind Energy* is a series of lectures and articles given to the world from time to time. They represent the exercise of his thought upon certain often discussed questions regarding the mind, with that deeper entering into such questions which makes Bergson a stimulating leader in the science of mind study. He considers first the definition, rather the nature of mind in its distinguishing manifestation, consciousness. This word does not mean here the mere point of ordinarily recognized awareness. It stands for the entire effort of the mind toward the future through the present, with the entire storing of the past in memory. He describes it as thus conserving all necessary material, and moving on creatively to the new in its relation to life and as opposed to matter. With the latter, however, it has its reaction. The discussion of Soul and Body, in another chapter, that of Brain and Thought, are extensions of such consideration. The study of the experiencing of phantasms and the relation of such a phenomenon to psychic matter yet unestablished naturally follows the line of thought which the first essay introduces. So also does the examination of the phenomenon of false recognition as contrasted with the ordinary process of memory, the sense of having certainly before experienced the matter in question. The discussion of the phenomenon of memory brings forward those illuminating views upon memory and its service in the mental life in which Bergson has already

shown himself an authoritative leader. His carefully expressed reasoning gives therefore peculiar interest to the chapter on Intellectual Effort, where he gives a detailed exposition of the thought process and the sense of effort accompanying it. For in this he shows the method by which thought proceeds not only by darting forward under the inspiration of memory images, but also by working backward among these images for substantiation and adjustment in the mental life already there.

The chapter on Dreams is not a recent enough one to add much that is new. It represents an entrance into the conception of dreams which is growing in acceptance, and forms part of the framework on which Freud's theory rests. A reference to dreams in the chapter on False Recognition reveals even better than the special chapter Bergson's vital appreciation of dream phenomenon.

Bergson is a writer of rare power. His forcefulness is expressed in pregnant words which answer to his intuitive grasp of facts. At the same time he submits these visions of his to careful logical as well as observational testing. There is therefore no page of this small book that is not stimulating to thought. One need not follow him implicitly, not even to await the verification of some things which he claims as "probabilities," but one cannot fail to be roused at least to active questioning and quickened toward the mental processes of life.

HIGH SCHOOL BIOLOGY.

Biology for High Schools. By W. M. SMALLWOOD, IDA L. REVELEY, and GUY A. BAILEY. Illustrated. New York: Allyn & Bacon, 1920. Pp. xxi-590.

Men under thirty can hardly realize how dull and dusty were the scientific paths made in the last century. True, it was a century of magnificent works, high priced, finely illustrated, but the average student could not get these, and the writings were above the comprehension of beginners. There were a few dull volumes in schools sparsely illustrated, but none on biology, so it can be imagined that the book before us would have been eagerly welcomed not only by teachers but by pupils. One great merit is that nothing is left unexplained on the assumption that everyone knows it, and there are excellent references for those who care to know more, as well as Practical Applications, Laboratory Work, Summaries, Questions and Home Work. The first and second sections are on animal and plant biology, followed by one on human biology and a summary and review of general biology. Four hundred and thirty-nine illustrations enliven the way and the derivation of names makes the pupil feel more at home when using long words he comprehends. Nine portraits of men who have helped to smooth the biological path and coax the world to consider its marvels are inserted. It will make youth more just, in judgment, for many insects, animals and plants hitherto deemed evil are shown to be useful and harmless. Naughty Jane, who used to kill flies in our reading primers, is no longer called cruel; the fear of every snake is proved to be senseless. The chapter on forestry and preservation of woods is specially useful today. Community life as seen in nature and among

men, environment, heredity, and variation are also considered and put into simple language. It is only a guess, but the author may be imagined to have wanted to know things in his boyhood and to have had no answers from his elders; hence his anxious effort to make all things clear, in which he certainly has succeeded.

AN ASSORTMENT OF HEALTH.

Health and Social Progress. By RUDOLPH M. BINDER, Ph. D., Professor of Sociology, New York University. New York: Prentice-Hall, Inc., 1920. Pp. i-295.

Take the obverse of the title, Ill Health as an Obstacle to Social Progress, and you would come nearer the correct one for Doctor Binder's book. It is easy to imagine that in his researches the question of disease was a more fertile field than that of health. But the author is an optimist. He will drench you with horrible statistics, then cheer you up with Pasteur and Lister, Reed and Gorgas. His health researches leave no corner of the earth untouched, no peoples, ancient or modern, uncriticized. Ill Health and the Classical World; Health and the Tropics; Health and World Progress, these chapters give some idea of the ground he has trodden. His book has a wonderful amount of information, the result, evidently, of much study, yet it is suggestive of a big exhibition, not quite ready. There is an accumulation of interesting facts which leisure, or lack of power, has failed to arrange in comprehensive order, and the author resembles an eager host, newly returned from a voyage, who urges fresh treasures upon his guest before he has given due attention to those he is admiring. The portion on health and other conditions in cities merits great consideration, and he winds up optimistically with reference to the splendid work done by bureaus of research, amalgamation, of effort, and private benevolence to prepare a fit highway for the goddess of health.

AN UNACADEMIC CRITIC.

Reputations. Essays in Criticism. By DOUGLAS GOLDRING. New York: Thomas Seltzer, 1920. Pp. vii-232.

Reputations are more easily made than demolished—unfortunately. The aroma of success lingers; "lost leaders" are not really lost as soon as they should be. For this reason Douglas Goldring's book should be welcomed by those who wish to do away with false gods. Mr. Goldring has set his face against all forms of tawdriness in art—not only commercialism but the more insidious sins of respectability and middleagedness. H. G. Wells suffers as well as Compton Mackenzie. It is a glorious slaughter—and there is not an epigram in it!

Reputations opens in a noncommittal vein with an appreciation of James Elroy Flecker. Then the author proceeds to evaluate three Georgian novelists—Compton Mackenzie, Hugh Walpole, and Gilbert Cannan, and to appraise Gilbert Cannan as a writer who has not yet found himself but whose work shows the most promise of the three. He praises D. H. Lawrence, though admitting that "frequently his poems are battlefields on which he has been defeated." Arnold Bennet he terms "the Gordon Selfridge of English letters" and "one of the most

brilliant second rate minds which England has produced in the present century." Wells is in danger of becoming a "lost leader"; Wyndham Lewis is irrelevant.

But Mr. Goldring does much more than attack reputations in these papers. He voices the ideals of that keen, ruthless youth which came out of the war determined that the agencies which had wreaked such tragic waste should not have power to do the same thing again. He is for courage and a clean sweep of that which should be swept away. He is quiet about it, but firm. And yet this book is in no sense propaganda. It is the work of a man who does not strive to be literary, who is close to life as well as to books, an unacademic critic. His philosophy can perhaps best be summed up in the goal he sets up for the new criticism—and which he himself so nearly approaches:

"And if we are to have a renaissance of poetry in England we must have a new criticism to meet it—a savage, rasping criticism, speaking with the bitter notes of an idealism which longs passionately for the best, and will no longer tolerate shams. Criticism must once again become the task of those who have an uncompromising standard of values, of those whose love for what is real and sincere will not permit them to deal gently with what is false, pretentious, empty and ephemeral."

New Publications Received.

[We publish full lists of books received, but we acknowledge no obligation to review them all. Nevertheless, so far as space permits, we review those in which we think our readers are likely to be interested.]

MAC OF PLACID. By T. MORRIS LONGSTRETH. New York: The Century Company, 1920. Pp. xi-339.

DIE IMPOTENZ DES MANNES. Von Dr. WILHELM STEKEL. Berlin-Wien: Urban & Schwarzenberg, 1920.

DITTE: GIRL ALIVE. By MARTIN ANDERSON NEXÖ. Translated from the Danish. New York: Henry Holt & Co., 1920. Pp. iii-333.

A BIOGRAPHY OF GEORGE MILLER STERNBERG. By His Wife, MARTHA L. STERNBERG. Illustrated. Chicago: American Medical Association, 1920. Pp. ix-331.

THIRTY-FIRST ANNUAL REPORT OF THE STATE HOSPITAL COMMISSION, STATE OF NEW YORK. By Commissioners CHARLES W. PELRGIM, M. D., ANDREW D. MORGAN, and FREDERICK A. HIGGINS. Albany, 1920. Pp. vi-442.

LIFE. A Study of the Means of Restoring Vital Energy and Prolonging Life. By Dr. SERGE VORONOFF, Director of Experimental Surgery at the Laboratory of Physiology of the Collège de France. Translated by EVELYN BOSTWICK VORONOFF. New York: E. P. Dutton & Co., 1920. Pp. xx-160.

TEXTBOOK ON INDIGESTION. By Dr. G. HERSCHELL. Revised and Rewritten by Adolphe Abrahams, O. B. E., M. D. (Camb.), M. R. C. P. (Lond.), Assistant Physician to Westminster Hospital, to the Hampstead and North-Western General Hospital, etc. New York: Longmans, Green & Co.; London: Edward Arnold, 1920. Pp. 228.

HANDBOOK OF PULMONARY TUBERCULOSIS, ITS DIAGNOSIS, PROGNOSIS, PREVENTION, AND TREATMENT. By JEFFERSON DEMETRIUS GIBSON, M. D., Denver, Col., Member of Denver City and County Medical Society; Denver State Medical Association; American Medical Association, etc., etc. Denver: The Denver Scientific Publishing Company, 1920. Pp. 130.

Practical Therapeutics and Preventive Medicine

A Compendium of Treatment and Prophylaxis, Original and Adapted

Intravenous Injection of Iodine in Oil.—Rathery (*Presse médicale*, June 19, 1920); after experiments in animals, administered intravenous injections of iodine in oil in human subjects. The amount of oil thus given was one half to two mils. No discomfort or untoward result was experienced by the patients. After such treatment iodine was still found in the veins twenty-one days after the injection. The resulting prolongation of the therapeutic action accounted for the clinical effects obtained, which were superior to those secured upon administering potassium iodide by the mouth.

Treatment of Syphilis of the Stomach.—G. Leven (*Presse médicale*, June 19, 1920) lays stress on the frequency of incidence of gastric syphilis, having encountered many cases in which an apparently justifiable diagnosis of cancer of the stomach proved erroneous upon antisyphilitic treatment. X ray examination confirmed the cure from specific treatment in these cases. In syphilis of the stomach mercury should be given not only in injections, but also in suppositories and by inunction. Combined administration of iodides or other iodine compounds is likewise indispensable.

Treatment of Disorders of the Spinal System by the Intraspinal Method.—F. J. Farnell (*Journal of Nervous and Mental Disease*, May, 1920) says that the extradural space containing great amount of areolar tissue, which is well vascularized and contains many lymphatics, was utilized for treatment of disorders of the spinal system according to this method. This was in order to avoid the two usual obstacles in the way of those seeking treatment for spinal disease, i. e., puncture headache and loss of time from work by keeping to one's bed. Salvarvanized serum was injected into the extradural space, and removal of spinal fluid thus avoided. Excellent results were obtained, both by avoidance of untoward afterresults and for the improvement of the condition for which the patient sought treatment.

Therapeutic Pneumoconiosis in Pulmonary Tuberculosis.—E. A. Sevilla (*Plus-Ultra*, Madrid, April-May, 1920) states that a careful investigation of the action of artificial pneumoconiosis in the prevention and treatment of pulmonary tuberculosis justifies the following conclusions: 1. The inhalation of insoluble powders tends to promote healing of tuberculous lesions in the lung. 2. This absorption is brought about by an increase in the defensive cells. 3. These powders when combined with an antiseptic constitute a measure of applying antiseptics to the lung tissues. 4. There results a sclerosis of varying degree in the lung, which acts as a protective barrier. 5. Insoluble powders are convenient vehicles for the application to the lung lesions of antibacillary products of varying origin and nature, such as tuberculins, antiseptic substances, and desiccated sera. 6. This measure of therapy is capable of exerting a topical action in diverse localized pulmonary affections, such as gangrene and actinomycosis.

Opium in Acute Dilatation of the Heart.—Diego. T. R. Davison (*Semana Medica*, June 3, 1920), in reporting a case in a girl of twenty, draws attention to the fact that opium has no depressant action on the heart and that it acts beneficially in these cases of acute dilatation by quieting the accelerator nerves which by their overaction are weakening the myocardium. Rest in bed is essential, of course, for the return of the heart cavities to normal. Digitalis has been found to be of no avail in these cases either during the acute stage or later during the period of recuperation. He prefers to build up the heart muscle indirectly with arsenic and the hypophosphites.

Treatment of Rheumatism and Gout by Hypodermic Injections of Salicylic Acid.—M. J. Sejournet (*Semana Medica*, June 3, 1920) states that for the past twelve years he has treated articular rheumatism and gout by the subcutaneous injection of a three per cent. solution of salicylate of sodium. However, he found that this procedure was quite painful and he turned to the solution of salicylic acid in a strength of one in one thousand, which he injected under the skin in the neighborhood of the affected joints. Even here he found it necessary in some cases to precede the treatment with a local anesthetic. His results were so uniformly good that this has become the method of choice with him.

Effect upon Blood Pressure of Adrenalin Injections in Dementia Præcox.—Lawson G. Lowrey (*Boston Medical and Surgical Journal*, August 12, 1920) says that an analysis of the blood pressure reactions to the injection of adrenalin in seventy-eight psychopathic patients makes it clear that such an injection does not have the value in differential diagnosis which has been claimed for it, at least in early cases, since some cases of præcox show a rise and others show a fall. In fifty-four out of sixty cases of dementia præcox there was an increase in blood pressure, forty of these showing a rise of more than five mm. Hg. In eighteen cases of other types taken for comparison there was a depressor reaction in four.

Convulsive Disturbances Cured by Surgical Operations.—P. Bazy (*Bulletin de l'Académie de médecine*, June 1, 1920) reports a case in which convulsive seizures simulating epilepsy disappeared after an operation for appendicitis in a young man eighteen years of age. The manner in which the convulsions were relieved is believed to have been similar to that in which convulsive seizures in another young man who had been taking a too exclusive meat diet disappeared when a more vegetarian diet was prescribed. Two cases of convulsions accompanying undescended testicle are also reported, in which relief occurred after operation for the testicular malposition. Such convulsions are not, of course, to be held as manifestations of actual epilepsy, even if preceded by an aura. In one of the cases of testicular ectopy referred to, pain at the site of the misplaced organ was a distinct feature.

Action of Gum Acacia on the Circulation.—W. M. Bayliss (*Journal of Pharmacology and Experimental Therapeutics*, March, 1920) found, in extensive experimental work, that a solution of gum acacia of six to seven per cent. in 0.9 per cent. sodium chloride solution is capable of effectively replacing blood lost, unless the loss exceeds seventy-five per cent. of the blood volume. Hence its use in hemorrhage due to various causes. Its effect is due to the fact that the blood vessels are impermeable to colloids, so that their osmotic pressure is effective in retaining within the circulation the solution injected. It has no chemical or drug like action and can be used in large quantities. It can also be used with benefit when the blood volume is reduced owing to removal of a part of the blood from effective circulation by stagnation in the capillaries, as in wound shock and traumatic toxemia. In such cases, its primary object is to maintain a normal circulation until the toxic products are eliminated from the blood, while the blood out of circulation is restored to use. When fluid has escaped from the blood owing to the capillaries becoming permeable to colloids, as in the action of tissue toxins, gum saline restores the normal state provided the morbid condition has not lasted too long; if it has, even blood transfusion is of no avail. When the blood has become concentrated by loss of fluid from the body, gum saline is more effective than saline solution alone, even if hypertonic, since it is not so rapidly lost from the circulation. Gum saline has also proved of value in toxic anemia, e. g., in blackwater fever. Neither gum nor blood transfusion has any permanent effect when the blood vessels are deprived of control by the vasomotor centres. Gum acacia does not produce anaphylaxis nor hemolysis. It does not agglutinate the blood corpuscles in man.

The Phenolsulphonephthalein Test and the Nonprotein Nitrogen of the Blood in Chronic Nephritis.—Reginald Fitz (*Boston Medical and Surgical Journal*, August 26, 1920) presents the following conclusions: The phenolsulphonephthalein test and the nonprotein nitrogen concentration of the blood are two tests for kidney function which are being generally used for the diagnosis, prognosis, and treatment of chronic nephritis. These tests are not of obvious value in the diagnosis of chronic nephritis, as they do not point out the presence of any specific pathological type of lesion in the kidney and do not demonstrate the presence of kidney disease in the absence of common physical signs. From a pathological point of view there are two common types of chronic nephritis. The essential lesions of chronic glomerulonephritis are found in the glomeruli and of arteriosclerotic nephritis in the smaller renal vessels. Clinically both types of chronic nephritis are usually associated with cardiac hypertrophy, increased blood pressure and eye ground changes, and with a urine which contains albumin, blood, casts, or leucocytes. Both types of disease are chronic and slowly progressive. Chronic glomerulonephritis is a disease of young people. Arteriosclerotic nephritis may appear in young people, but is more often found in older people. The clinical differentiation of these types

does not depend upon studies in renal function, but upon careful history taking and routine physical examination. As the lesions of chronic nephritis advance, the phenolsulphonephthalein excretion diminishes and the nonprotein nitrogen concentration of the blood increases. At present, however, a single observation with these tests gives less prognostic information than does careful clinical examination. The present treatment of chronic nephritis is largely empirical. The phenolsulphonephthalein test and the nonprotein nitrogen concentration of the blood offer means by which physiological methods may be applied to the clinical study of individual cases. Unless the technic of these tests is properly controlled, the interpretation of their results is of little value. When these tests are properly performed, they can be used to assemble facts from an individual case which measure the progress of the disease in more or less quantitative fashion, and which make possible the establishment of a logical and systematic form of treatment.

Treatment of Human Anthrax by Normal Bovine Serum.—J. Penna, J. B. Cuenca, and R. Kraus (*Monografias del Instituto Bacteriologico del Dept. Nacional de Higiene*, Buenos Aires, January, 1920) report three hundred and eighty cases of anthrax treated with normal bovine serum with a mortality of six and two tenths per cent. They found that the normal serum was quite as efficient as the serum of animals immunized against anthrax by inoculation; furthermore they verified their former findings that serum sickness does not result from the use of bovine serum heated twice to 56° C. They also proved that the mixture of bovine serum with horse serum prevented the serum sickness which so often occurs when the latter is used alone. They used in severe cases intravenous injections of from thirty to fifty c.c. of the normal bovine serum every twenty four to thirty six hours up to a maximum of two hundred and fifty c.c. In mild or benign cases intramuscular or subcutaneous injection sufficed.

Autohemotherapy in Protracted Infections.—G. Mouriquand (*Lyon médical*, June 10, 1920) notes that some acute infections, having passed into the subfebrile stage, persist for weeks or months, as though vaccination of the patient's system could not be brought to a conclusion. Such dragging infections seem in some respects comparable to cases of pleurisy with delayed absorption, in which Gilbert has recommended autohemotherapy to initiate absorption of the fluid. A case of peliosis rheumatica is reported in which this procedure was applied, apparently with complete success. The patient was a wet nurse aged thirty years, who had been suffering for six weeks from joint involvement and erythema multiforme, which resisted salicylates and aspirin, and recurred every two or three days. The temperature had hovered about 38° C. throughout the six weeks. Four mls of the patient's own blood, collected in citrate solution, was then injected into the subcutaneous cellular tissues. On the next day the temperature descended to normal and joint and skin manifestations completely disappeared. Three weeks later they had not yet returned.

General Anesthesia.—Alberto R. Egana (*Se-mana Medica*, April 29, 1920) in an extensive consideration of the subject arrives at the following conclusions: 1. Minor surgical operations or those on the extremities are best done under nitrous oxide oxygen. 2. For all operations requiring complete muscular relaxation, especially in abdominal surgery, the nitrous oxide ether sequence is the method of choice. 3. Chloroform is too dangerous for general use, but it may more safely be mixed with ether. 4. The open method of giving ether is always to be preferred. 5. Intratracheal insufflation is of value for thoracic operations. 6. Rectal anesthesia with ether in five per cent. oily solution is suited to operations on the head and neck combined with local anesthesia. 7. Morphine and atropine injections are to be used systematically.

Local Anesthetic Action of Saligenin.—A. D. Hirshfelder, A. Lundholm and H. Norrgard (*Journal of Pharmacology and Experimental Therapeutics*, June, 1920) report experimental and clinical studies on saligenin—salicyl alcohol—and other phenyl carbinols as local anesthetics. Saligenin proved the best of the entire series of phenolic alcohols investigated. It has the lowest toxicity, the least tendency to form wheals or edema, and the highest selective action in blocking the sensory nerves. The anesthesia was found to last longer than with procaine or benzyl alcohol. In tonsillectomy anesthesia with two per cent. saligenin solution uniformly proved as satisfactory as that with 0.2 per cent. procaine. Two sebaceous cysts were removed by Stratte under two per cent. saligenin, ingrowing toenail operations performed under it by Stratte and Robitshek, an inguinal hernia dealt with satisfactorily by Tinker under one per cent. saligenin, sensory block of the mandibular nerve for over fifteen minutes obtained in two cases by Schien with a four per cent. solution, and a like solution used with success for cystoscopy by Wynne.

Herpes Iris.—A. J. Chalmers and Norman Macdonald (*Journal of Tropical Medicine and Hygiene*, June 15, 1920) note that the present tendency is to look upon all forms of erythema multiforme, including herpes iris, as being due to anaphylaxis caused by the absorption of some chemical product from the intestine or other passages, or from a diseased organ. The success of treatment by intestinal antiseptic therapy in certain cases offers some support to this theory. The essential features of herpes iris are the central vesicle or bulla, the surrounding ring of vesicles, the affection of the lips and mouth, the formation of several rings of vesicles outside the first; the slight constitutional disturbance, and the tendencies to recur if not properly treated. It is differentiated from its nearest ally, erythema iris, by the fact that in the former there is a vesicle surrounded by an erythematous blush. The first aim in the treatment should be to find the site from which some form of chemical absorption is taking place. In one of the author's cases the intestinal tract appeared to be the only possible source of trouble; the patient was placed in bed on restricted diet and given purgatives and salicin, with immediate and excellent results.

New Method of Preventing Anaphylactic Manifestations.—Kopaczewski (*Presse médicale*, June 16, 1920) has shown experimentally that anaphylactic manifestations can be obviated in animals by injecting chloroform or ether in amounts insufficient to produce anesthesia. The widely accepted theory of the important rôle played by the nervous system in anaphylactic shock is thought to be weakened by these observations. Since general and local anesthetics possess to a marked degree the property of reducing the surface tension of the blood, and since this property is also known to be the powerful factor preventing precipitation of colloids—and therefore precipitation of the blood—the author is led to consider anaphylaxis simply as a precipitation of the colloids of the blood. The precipitate formed blocks the capillaries and thus causes sudden and grave asphyxia. Widal's labors have shown that many disorders are associated with anaphylactic manifestations, e. g., asthma, hemoglobinuria, urticaria, the diathetic and dyscrasic affections, eclampsia, and serum disease.

Diagnosis and Treatment of the Hemorrhagic Diseases.—Ralph C. Larrabee (*Boston Medical and Surgical Journal*, August 5, 1920) says, concerning the treatment of these diseases, that local applications are not satisfactory. The older astringents and styptics, such as ferric chloride and alum, do little but make a nasty mess. Epinephrine solutions will often control slight bleeding from the mucous membranes, but their action is quite fleeting. Cephaline, coagulen, coagulose and other tissue extracts are of somewhat greater value locally, both in platelet cases and in hemophilia, but appear to be ineffectual when used intramuscularly or intravenously, while the possibility of producing emboli would seem to make the intravenous use inadvisable. Calcium salts are of value only where the hemorrhagic tendency is the result of calcium deficiency. In such cases, when an operation is contemplated, calcium lactate should be given in large doses by mouth for several days, and operation should be deferred until coagulation time is normal. Fresh animal serum contains prothrombin, which is absent in hemophilia and hemorrhagic disease of the newborn, but this disappears in a few hours and old serum is worse than useless. Fresh serum does not contain platelets, so can be of no value in hemorrhagic purpura and other diseases where the bleeding is due to platelet deficiency. The value of diphtheria antitoxin rests wholly on empirical grounds. Theoretically and experimentally serum is of little value. The intravenous administration of whole blood comes nearer to being a universal panacea in this group of diseases than any other procedure. It is the method of preference except in chronic obstructive jaundice, where calcium is better. Either the citrate or the parafined tube method may be used. He prefers the latter because the citrate method causes more reaction and introduces fewer platelets. When facilities for intravenous transfusion are lacking, rapid intramuscular injection of small amounts of human blood may be used, preferably in tissues near the bleeding area; especially good results have been reported in purpura hemorrhagica.

Proceedings of National and Local Societies

MEDICAL SOCIETY OF THE STATE OF NEW YORK

*One Hundred and Fourteenth Annual Meeting,
Held in New York, March 23 to 25, 1920*

The President, Dr. CLAUDE C. LYTLE, of Geneva, in the
Chair.

(Continued from page 652)

The Rôle of the Colon Bacillus in Infections of the Kidney.—Dr. EDWIN BEER, of New York, in a further discussion of the subject, asked whether Dr. Cabot was of the opinion that preliminary vaccination prevented complications with the colon bacillus following prostatectomy and requested him to discuss the question of ureteral catheter lavage of the pelvis of the kidney. Personally he had seen absolutely no results from this procedure. In cases of acute pyelitis naturally one did not care to irrigate the pelvis of the kidney, but there might be some benefit from washing out the ureter and thus cleaning out mucus plugs that were causing some interference with the outflow of urine. The reason they did not get results by this procedure was that they did not know what they were treating. The only diagnosis made was made after pus had put in its appearance. The diagnosis of kidney involvement was not made until after the fifth day. He did not believe lavage was effective. With the patient in the Trendelenburg position the silver nitrate might go to the pelvis of the kidney, but he doubted if it reached the foci of infection in the parenchyma.

Dr. Cabot said the question he had wanted to hear discussed was the possibility of the sensitization of the kidney with foreign protein. Dr. Keyes had asked a question which he could not answer. It was, however, beyond doubt that occasionally there was a case in which the use of the ureteral catheter with or without lavage of the kidney had produced spectacular results. He could not subscribe to the theory of stricture of the ureter. These cases did not occur in his experience. He had been asked whether he had retreated from his position in regard to certain anatomical relations which might account for the frequency of pyelitis in little girls. The difficulty here was that there had not been produced a sufficient amount of good work to settle the question one way or the other. Dr. Grimes and he had studied the length and position of the large intestine in females as compared with males; it was possible that there was a definite anatomical difference but it had not been shown thus far. As to the relation of the intestines to the kidney, he did not agree with Dr. Brasch. The relation between the intestine and the kidney was clear. He had a series of twenty-five men between the ages of twenty-five and thirty-five years whose urinary tracts were sound, men in good circumstances and living out of town, who had had acute illness characterized by fever and diarrhea and evidence of acute colitis, and it was observed in a few days that colon bacilli were passed in the urine. In many cases the colon bacilli disappeared from the urine, but later the patients would have another

acute attack, with symptoms of kidney infection, fever and bacilluria. The relation between pyelitis and ulcerative colitis was often striking. Dr. Brasch had laid a good deal of stress on the importance of the removal of focal infections elsewhere in the body. Such infections were occasionally due to the colon bacilli but they were oftener due to the streptococcus group; the condition he was talking about had nothing to do with that, for he did not believe that the streptococcus produced pyelitis. He believed in a search for focal infection, but he doubted that there was a connection between colon bacillus infection of the kidney and infections of the mouth and teeth. Silver nitrate might affect the organisms in the superficial epithelium and even release organisms deeper down, but he doubted whether silver nitrate did more than ameliorate symptoms. Unless the colon bacilli were permanently eliminated the patient did not stay cured. In the group of little girls he should hesitate to use the cystoscope or to catheterize the kidney; he did not believe local treatment would be of much help in this group. He was inclined to believe their hope lay in vaccines, but here the difficulty was that there was no measure of immunity and we did not know whether immunity was produced by vaccines. There were many strains of colon bacilli and it was not known whether vaccination against the strains that were producing the pyelitis could produce an immunity against those organisms.

SYMPOSIUM ON ENDOCRINE DISEASES.

Disturbance of Internal Secretions of Sex Glands.—Dr. WILLIAM C. QUINBY, of Boston, discussed the clinical and experimental evidence of function of the gonads, that is, the sex glands, and showed instances of disturbed function. The spermatozoa and ova might be considered analogous to external secretion of other glands of the endocrine system. The testicles and ovaries had a definite internal secretory function the products of which so far had not been isolated as definite chemical products. A hypothetical substance called spermin had been isolated but that was entirely impure and had no value. In the male the endocrine portion of the testis was situated in the interstitial tissue or the cells of Leidig. These cells lay between the tubules and showed different degrees of development. In the female the endocrine function was subserved also by interstitial cells and probably further by corpora lutea, but certainly before menstruation occurred the action of corpora lutea was not present. The evidence showed definitely that the internal secretion of the gonads caused the appearance of the secondary sexual characteristics. The term originated with John Hunter. Those secondary changes were the changes occurring at puberty. Certain experiments, especially those of Steinach, showed the great importance of the internal secretion of the testicles and ovaries. Steinach laid so much importance on this interstitial tissue that he named it the puberty gland, indicating that puberty depended entirely upon its action. By experiments on animals he showed that these secondary sexual characteristics could be produced. Thus male rats

which had been castrated before puberty and in whom an ovary had been transplanted took on secondary female characteristics; the same was true of rats of the opposite sex. We did not know the stimulus that called into activity this property of the gonads. It might depend on the interactivity of other endocrine glands—for instance, the hypophysis. Gonadal stimulating properties might exist in all endocrine glands. We should find clinical cases in man showing the results of hyperfunction or hypofunction of these organs; that is, we should find cases of precocious or delayed puberty in both sexes. We could also study the effects of double ovariectomy.

Mild Types of Thyroid Toxic Adenomata.—Dr. MALCOLM S. WOODBURY, of Clifton Springs, said there were two varieties of goitre which might be toxic—the exophthalmic type and toxic adenomata. The opinion was that adenomata were embryological in origin, derived from fetal rests. Work was being done on this and would be published soon. For the clinician it was important to recognize that adenomata might appear as distinct nodules or there might be a diffuse process, as shown by the microscope; the absence of nodules did not rule out this condition. The recognition of thyroid adenomata as an entity marked an advance. They might attain a large size, but usually not without toxicity. The mild ones might produce only pressure symptoms. Small adenomata might be toxic just as small exophthalmic goitres might. Plummer stated that thirty-three per cent. of all hyperfunctioning thyroids were adenomata. It was obviously of the greatest importance to differentiate toxic states associated with goitre from psychoses. The term thyrotoxicosis was better than the term hyperthyroidism when applied to adenomata. In our recent short series there was a family history in eighty per cent. of the cases and infections of the tonsils or teeth in ninety per cent.; all the patients came from districts in which goitre was rather common. Probably the etiology was somewhat as follows: It appeared that fetal rests might be transmitted more commonly in certain families; be due to the water content in localities requiring an overactivity of the thyroid in metabolism adjustment, to disturbance of the sympathetic nervous system, or to pregnancy. The cells proliferated and took on the form of adenomata. Whether the activity was due to cells in the adenoma *per se* or the surrounding cells was not yet established. Nervous symptoms in the cases of adenomata were no different from those in the exophthalmic cases. In adenomata fifty per cent. of the patients complained of depression which was different from the depression of psychoses in the absence of selfaccusatory delusions. Definite nodules could be felt in half the cases, although palpation must be done carefully to detect them. Dr. Woodbury described his method of palpating the thyroid to detect adenomata. With the patient sitting with the head on a head rest turned toward the side on which the examiner stood, the landmark to palpate was the oblique ridge on the alæ of the thyroid cartilage when the patient swallowed.

The metabolism rate had received a great deal of attention since the portable apparatus of Benedict had come into use, but too much reliance must not be placed on it and it was necessary to allow for differences in weight, age and sex. An increase of not more than fifteen per cent. was to be considered normal. Adenomatous cases might show only a slight increase in basal metabolism or no increase at all, and the question arose whether these were cases in which a toxic element was playing a part. Dr. Woodbury thought they were. The Goetsch test was positive. The patients were operated on by Dr. C. W. Webb, with good results where the gland was available for operation. The Goetsch test had distinct value in the diagnosis. One point to be emphasized was that solutions of adrenalin chloride varied a great deal according to the age of the solution. This ought to be taken into consideration. Folin had described a test for determining the purity of adrenalin. Dr. Woodbury did not regard the Goetsch test as positive unless there was a rise of over ten points in blood pressure together with subjective symptoms, including tremor. One is hardly justified in ruling out all thought of a thyrotoxic state because the basal metabolism according to our present methods ran within normal limits. It seemed that cases occurred in which there was no definite rise. The Goetsch test was not an absolutely reliable criterion. Certainly for the diagnosis of mildly toxic cases of adenomata study of the individual patient must be made and all available points of diagnosis utilized.

SYMPOSIUM ON GASTROINTESTINAL DISEASES

Practical Clinical Laboratory Diagnosis in Gastrointestinal Disease.—Dr. HOWARD F. SHATTUCK and Dr. JOHN KILLIAN, of New York, prepared this paper, which was read by Dr. Killian. They stated that some of the new methods of examination, particularly the x ray, had lessened the use of chemical examinations or rendered the consideration of them less important, yet they often yielded findings in clinical problems where every bit of evidence was needed. In a series of examinations made at the Postgraduate Hospital the authors were impressed by the great amount of free hydrochloric acid in cases of gastric ulcer as compared with duodenal ulcer. The average per cent. of free hydrochloric acid was under 0.50 in cases of duodenal ulcer, while it ranged from 0.53 to 0.80 per cent. in cases of gastric ulcer. In carcinoma of the stomach the average percentage of the free hydrochloric acid was very much under 0.50, reaching that figure in only one instance. A large group of miscellaneous conditions yielded results in which the total percentage of free hydrochloric acid was under 0.50. A second interesting point was the association of hydrochloric acid and lactic acid in cases without retention. It was common to find lactic acid in the gastric contents with retention, and rarely was lactic acid present without retention.

In regard to the value of the Wolff-Junghans test: Smithies reported that next to the Boas-Oppler bacillus a positive Wolff test was the most frequent finding in gastric cancer. This test was positive in eighty per cent. of the cases; lactic acid

was present in seventy-five per cent.; the Boas-Oppler bacillus was present in ninety per cent. In the authors' group of cancer cases eighty per cent. gave a positive or suspicious Wolff test. The test had been of value in distinguishing the malignant from the benign achylas. The records of gastric cases had brought out the great value of gastric analysis in the differentiation of true achylas from psychic achylas. In none of the cases of true achylia gastrica or pernicious anemia were they able to demonstrate the presence of free hydrochloric acid at any time in the digestive cycle. There were cases simulating true cases which proved on examination to be spurious or psychic achylas. In these cases improvement was obtained by the use of hydrochloric acid.

As regards enzyme activity of the duodenal contents, Einhorn had shown the value of this procedure in pancreatitis. It gave qualitative rather than quantitative results. The duodenal contents were obtained by any of the duodenal tubes after test meals and removed at intervals. In thirty-one cases, the pancreatic enzymes were present except in the cases of pancreatitis, in which the protease was absent and the lipase present in small amount.

What the authors wished to emphasize from the data obtained was the proportion of the total acidity in the form of free hydrochloric acid. In a series of normal cases they found that the free hydrochloric acid formed about forty per cent. of the total acid in the Ewald meal and about thirty per cent. in the retention meal. It was always less than fifty per cent. In a series of cases of gastric ulcer they were impressed with the fact that the total acidity was never very high. In only two cases was there marked hyperacidity. The constant feature of these gastric ulcers was that the proportion of the free acid to the total was always greater than fifty per cent. and in most cases it approached seventy-five per cents. That was true of the Ewald meal. In the retention meal the percentage of free hydrochloric was even greater. The secretion of hydrochloric acid seemed to be free from the stimulus of food. In a series of duodenal ulcers divided into two groups, postpyloric and other types, in the postpyloric the total acidity and the free acid were relatively high, and the percentage of free acid was greater than fifty per cent.; it was similar to the condition in gastric ulcer, but in the retention meal the percentage was less than in the Ewald meal. In none of these cases of postpyloric ulcer were there evidences of retention and in none was lactic acid found. In the other type of duodenal ulcer the percentage of free acid did not exceed fifty per cent. and in the retention meal it ranged from zero up to thirty-two per cent. In gastric carcinoma the free hydrochloric acid ranged from zero up to forty, and in the retention meal it ranged from zero up to twenty. In these cases there was free hydrochloric acid.

In normal cases the average percentage of free to total acid was forty following the Ewald test meal. In gastric ulcer the proportion of free to total was greater in the retention meal than in the Ewald meal. In postpyloric ulcers the percentage of free hydrochloric acid was not as high as in gastric ulcers after the retention meal.

So far as examination of the feces was concerned, there were two factors; one was the diastase activity of the stool and the other was the presence of occult blood. In the diastase the normal activity of the stool varied from twenty-five to thirty per cent. When stools were incubated with starch thirty per cent. of the starch was converted into sugar. In diseases of the pancreas the diastase activity of the blood was increased, whereas the diastase activity of the stool was either absent or greatly decreased.

Practical Clinical Examination of Upper Gastrointestinal Tract.—Dr. ALLEN A. JONES, of Buffalo, presented a tabulation of diseases most commonly encountered. In gastric and duodenal ulcer, pain was one of the most important manifestations. Many times in young women the first symptom was hematemesis. He had noticed pain to be more frequent in men than in women. Pain was relieved by digestion, and it supervened sooner after eating in gastric than in duodenal ulcer. If the ulcer was located far back postprandial pains occurred; the pain was intermittent in cases with peristalsis. Typical hunger pain usually felt as a gnawing, was strongly indicative of duodenal ulcer. The pain of gastric and duodenal ulcers was temporarily relieved by alkalis. Pain simulating hunger pain might arise from extragastric conditions. Vomiting or lavage relieved the pain of ulcer but not the pain from extragastric conditions. In perforation the pain was excruciating and prostrating and was accompanied by increased frequency of the pulse and muscular rigidity; a leucocytosis was found soon after perforation occurred. Pain in the back at or near the tenth dorsal vertebra was an important symptom, as it indicated ulcer on the posterior wall of the stomach. Tenderness due to ulcer was usually present in some part of the epigastric region. A full stomach gave rise to tenderness. Vomiting was not common in ulcer unless stenosis existed. Hematemesis was one of the classical symptoms of ulcer. In some cases of ulcer with hyperesthesia vomiting was present. Fever might be present if there was suppurative peritonitis. Anemia was common in gastric ulcer.

The most important symptoms of cholecystitis and cholelithiasis were the irregular temperature, pain, and tenderness in the region of the gallbladder. Suppurative cholecystitis might be suspected if there was a decided leucocytosis. If cholangitis accompanied cholecystitis there was evidence of some degree of jaundice. In rupture there were tenderness over the liver, rising pulse, and shock. The symptoms of cholelithiasis often occasioned confusion. This affection was often painless and the symptoms might be gastric. Some sensory gastric disturbances might be present. Tenderness over the liver was a varying factor, which might be elicited only on pressure or by Murphy's hammer stroke over the liver. Pyloric spasm, turbid bile withdrawn through Einhorn's tube, and traces of bile in the urine were not infrequently found in gallbladder disease.

Acute gastritis with its distress after eating should be remembered as a cause of sudden pain in the upper abdomen.

THE ENDOCRINES IN GYNECOLOGY.

BY WILLIAM P. GRAVES, M. D.,

Boston,

Professor of Gynecology, Harvard University.

In writing a paper on the endocrines in gynecology I am confronted with two alternatives, one of which is to prepare a general review of the subject; the other is to confine myself to those phases of it to which my personal interest and work have been especially directed. A comprehensive presentation of the entire subject in a brief review is a difficult task, and one which has been so notably well performed in a recent article by Dr. Bandler, that I feel that any attempt at repetition on my part would be of little value. I shall, therefore, restrict myself to a discussion in some detail of two topics which have seemed to me to be of especial importance in gynecological endocrinology. They are, first, the relationship of the endocrines to the specific neuroses of patients suffering from pelvic disease; and, secondly, the histogenesis and function of the internal secreting cells of the ovary.

THE NEUROSES.

No one can practise the science of gynecology long without becoming impressed with the extreme importance of the nervous element in the symptomatology of his patients. In order to give some definite figures to illustrate this point I have reviewed the consecutive histories of one thousand private patients and find that in 837 or 84 per cent. nervousness is a more or less serious part of their complaints. In a considerable number of cases it appears as the most prominent symptom, for which the patient seeks relief.

Although in employing the term nervousness one is dealing with a very loose expression, nevertheless popular usage, both among the laity and the profession, has confined its meaning to rather definite limits. Thus a patient who states that she is extremely nervous is describing a symptom that to her is entirely specific, and one which to the physician is perfectly intelligible. To the term nervousness, however, it is almost impossible to give a strict definition on account of its well nigh limitless manifestations. We are, in the present discussion, not so much concerned with the various phases of nervousness as with the underlying conditions that cause it. We shall use the expression in its popular sense and direct our attention only to those cases in which the symptom nervous-

ness may be regarded as a functional disturbance. We shall leave out of the discussion altogether those cases in which the nervous symptoms indicate some essential mental deviation.

Functional nervousness may be constitutional or acquired. By constitutional we mean a neurotic habit which is either the result of an unstable nervous inheritance, or one which has been fixed during childhood, or one in which both factors have played a part. By an acquired neurosis we mean one which, appearing after the complete formation of character, may be referred to some intercurrent physical disability, such, for example, as a pelvic lesion.

The excellent work of the psychoanalysts has taught us much concerning the constitutional neuroses. From Freud we have become acquainted with the great field of unconscious thought, and learned the influence of childhood fixations on future character. Sidis, though not a psychoanalyst, has demonstrated the importance of fear in the production of neuroses. Adler has traced the neurotic constitution to the sense of inferiority induced by congenitally deficient organs. The psychoanalysts, however, have paid little attention to the specifically acquired neuroses that are of especial interest to the gynecologist, nor have they given due consideration to the important rôle played by the internal secretions in all emotional and affective states. The gynecologist is therefore thrown to some extent on his own resources in estimating the cause, character and therapeutics of those neurotic conditions which he as a specialist is called upon to treat.

You will doubtless agree that the condition popularly called nervousness is, irrespective of its cause, an emotional state, and that this emotional state is always associated with certain physiological body changes whether the inciting cause of the emotion be some acute mental excitement or a chronic physical disability, or a subconscious mental repression. In order to understand this statement fully it is necessary to have in mind a clear conception of the term emotion.

Emotions were formerly regarded as purely mental states which gave rise to specific bodily expressions, as for example, anger, fear, joy, and many others. It was common to regard them as definite psychic attributes, component parts, as it were, of our mental equipment, just as our organs of sense or limbs are parts of our physical ap-

paratus. William James was perhaps the first to emphasize the idea that emotions are not themselves psychic states but are physical sensations resulting from actual bodily changes. Thus he says that "our feeling of the bodily changes that ensue after the perception of an exciting fact is the emotion" and invites us to imagine ourselves as being angry, for example, from a purely intellectual viewpoint, eliminating entirely our bodily sensations. James, unfortunately, knew little of the glands of internal secretion, and therefore was unable to describe completely the physiology of those bodily changes to which he referred in his description of the emotions. His theory of the emotions, however, has received remarkable confirmation from the researches of scientific physiology. Animal experimentation has shown that during emotional excitement such as that induced by fear, anger, pain and hunger, there is a markedly increased production and absorption in the blood of adrenalin. Cannon has demonstrated the reciprocating action between adrenalin and the sympathetic nervous system, by which certain bodily changes such as an increase of respiration and pulse beat, inhibition of the digestive secretions and an increase in the production of adrenalin are maintained during emotional states. He has proved that the action of adrenalin on the general organism when artificially introduced into the circulation is precisely that of the sympathetic nerves. In other words, the sympathetic system provides the organism with a material which by its presence in the blood automatically prolongs the effects which the stimulated nerves initiated.

This reciprocating mechanism, as Cannon states, is undoubtedly a provision of nature to stimulate the organism to a higher degree of motor activity for combat and defense. It may readily be imagined, however, that these bodily changes which are of immense benefit to the individual in a temporary crisis, may under the influence of constant stimulation become a serious detriment to health. And this is precisely what happens in the case of the neurotic in whom some unremitting physical or mental irritation maintains a state of continuous emotional excitement.

The scientific discoveries of the physiologists introduces into psychology a new factor of great interest since they prove beyond dispute the influence on the organism during emotion, not only of the sympathetic system of nerves, but also of the glands of internal secretion. Accurate experimentation has been carried out along these lines chiefly with the secretion of the adrenal gland. Nevertheless from our knowledge of the intimate interrelationship that exists between all the endocrines it is entirely probable that the adrenal gland is not the only one that takes part in producing the sensations of the emotional states. In fact this is sufficiently evident from the observation of patients who suffer from diseases of the internal secretory glands, examples of which are the emotional excitability of persons with organic hyperthyroidism, and the mental dulness of those affected by the opposite condition, the exaltation of the bodily and mental functions seen in those with early pituitary

disease, and the premature decay of the same functions as the disease progresses, and finally the marked dispositional changes in those who have undergone early castration.

Just what part the individual glands take in the emotions must at present remain a matter of speculation. Next to the adrenals, one would expect the thyroid to be the most important. The nervous manifestations of pathological hyperthyroidism are so well defined that not infrequently in the reactions of functionally nervous patients one recognizes symptoms of an unmistakably hyperthyroidal character. Furthermore we know that the adrenals and thyroid are rather closely and harmoniously related in their physiological properties. During sexual emotion it seems evident that all the glands of internal secretion become active. Of these it is probable that the adrenals, thyroid and pituitary play the most important rôle, the ovaries apparently being of minor significance.

With this brief survey of the subject we are justified in describing functional nervousness as a continuous state of emotional excitement, sensory in character, and induced by the reciprocal action, under stimulation, of the autonomic nervous system and certain glands of internal secretion. This definition is incomplete in that it leaves out of account the element of causation, and to this we must now direct our attention.

We have already referred to the lessons that we have learned from the psychoanalysts. To Freud is due the lasting credit of proving the enormous influence on character and behavior of unconscious repressions. In attempting, however, to apply his libidinal theory of causation to the specific gynecological neuroses we at once meet with serious obstacles. It is indeed true that the gynecologist encounters numerous sexual neurotics who are suffering from pelvic disease and in some cases the pelvic lesion bears some causal relationship to the neurosis, but to attribute all female nervousness to sexual repression is an absurd fiction, requiring as it does an acceptance of the untenable doctrine of the extreme Freudians, that the libido in its literal sense is the basis of all human motivation. I have in other articles called the attention of gynecologists to the theories of Alfred Adler and shown how they may be applied to the subject in hand. Adler in brief explains the neurotic constitution on the ground of a sense of inferiority resulting from organ deficiency. He ably and convincingly deals with the confirmed neurotic whose constitutional habit has been established at an early age. The sense of inferiority continues as an unconscious repression in the Freudian sense and may or may not be of a sexual nature. In an unpublished monograph, in which an attempt is made to apply Adler's theory to motivation in general, I have endeavored to show that the perception of inferiority is the basic cause of all disquieting emotions such as anger, fear, pain, and other emotions. It is the exciting force that sets in action the reciprocal mechanism of the autonomic nervous system and the glands of internal secretion. This theory lends itself admirably to the explanation of the acquired gynecological neuroses. A pelvic

lesion, such for example as one due to the injuries of childbirth, constitutes a definite organ inferiority, and may in a short time produce in the most normal individual all the symptoms exhibited by the so-called constitutional neurotic.

It is of the utmost importance that the gynecologist be able to classify his nervous patients with reference to causation for only in this way can he avoid making mistakes in treatment especially in cases that involve the question of a surgical operation. One must distinguish the neuroses that have definitely been acquired as a result of pelvic changes from the constitutional fixations of childhood, or from those of a purely psychic character. One must recognize those cases in which there is a superactivity of the glands in contradistinction to those in which there is a glandular deficiency. And above all it is necessary to detect the cases wherein the nervous manifestations are due to the circulation of abnormal secretions like that in hyperthyroidism. The differential therapy to be employed in these various types of cases is of extreme importance, but does not come within the scope of this paper. The wise gynecologist will constantly seek the aid of the neurologist and medical internist, and in making the critical decisions as to treatment will require all his resources of education, in which psychology and philosophy are assets of unequivocal value.

In concluding this part of the paper it may be remarked that the more one studies the so-called nervousness of women, the more one is impressed with the possibility that the purely nervous mechanism of the body is of secondary importance. It is quite credible that the nerves are only the keys or instruments which are played upon by more dominant agents in the form of the endocrine glands. In comparison with men, women are said to be peculiarly nervous. Would it not be more accurate to say that on account of the undoubted instability of their internal glandular equipment women are peculiarly endocrinous? Whether this theory be true or not there is no doubt whatever that the gynecologist accomplishes more accurate results if he estimates his nervous patients from an endocrinological rather than from a purely neurological viewpoint.

THE OVARIES.

The second part of this paper deals primarily with the histogenesis of the secreting cells of the ovary and is presented with the hope of pointing out some practical lessons that may be gained thereby. It has been asserted and is more or less generally believed that the ovary is a compound secreting gland with at least two systems of secreting cells, analogous in that respect to the hypophysis and adrenals. Thus the hypophysis as a whole is composed of two very distinct parts which differ in their histogenesis, their effects on the body under the influence of disease and in the specific action of their respective internal secretions. The posterior lobe is nervous, or ectodermic in origin. Early disease of the lobe produces a dwarfish individual. Extract of the lobe, commonly called pituitrin, exerts an influence on the autonomic nervous system and is efficacious in the treatment

of atonic conditions of the smooth muscles of the bladder, intestines, and uterus. The anterior lobe on the other hand, is glandular, hence mesodermal in origin. Early disease produces gigantism, while extracts of the lobe affect chiefly the sexual system.

In like manner the adrenals are made up of two separate tissue structures, which are so distinct in their anatomical and physiological characteristics that they may properly be regarded as different organs, that happen to have developed in juxtaposition. The medulla has a common ectodermal origin with the sympathetic nervous system, from which it becomes separated during the process of embryonic evolution. The medullary cells are not only contained within the cortex of the adrenal body but are scattered along the sympathetic nerves or ganglia in isolated bodies. The intimate reciprocal association of the sympathetic and medullary systems we have already mentioned in our discussion of the influence on the emotions of adrenalin, the specific secretion of the medullary cells.

The cortical cells of the adrenals, on the other hand, are mesodermal in origin and are intimately related to the cells that compose the ovary. They spring from the same peritoneal layer from which the ovaries take their origin. The cortical cells resemble the cells of the corpus luteum so closely that attempts have been made to establish some sort of identity between them. As in the case with the adrenal medulla, the cortical cells are not confined to the adrenal body, but are found scattered along the track traveled by the ovary in its descent into the pelvis. Physiologically the internal secretory function is sexual, though comparatively little is known of its action.

Reasoning by analogy to the hypophysis and adrenals some have made the claim that the ovary is also a double functioning organ, the two sources of secretion being ascribed to the corpus luteum or follicle apparatus on the one hand and the ovarian stroma on the other. A study of the histogenesis and development of the cells that compose the ovarian tissue dispels the notion of a close analogy between the ovary and the other two glands mentioned, for it can be shown from an embryological viewpoint that the ovary is a single homogeneous organ and that the differences that exist between the various cell elements are due to a process of differentiation during the development of cells that have a common origin. A detailed description of the histological development of the ovary can only be referred to in briefest outline.

The ovaries are developed in the peritoneum and from the peritoneum. Their primary growth is characterized by a thickening in the peritoneal membrane due to a localized multiplication and change in form of the peritoneal cells. These cells constitute what is known as the germinal epithelium. The ovaries, at first simple thickened ridges in the peritoneum, attain their fusiform contour by a downgrowth of the germinal epithelium, into the subperitoneal connective tissue.

The germinal epithelium possesses a wonderful power of differentiation and growth. Owing to the researches of Allen, MacIlroy, Goodall, and others it is now known that all the inherent cell

structures of the ovaries with the exception of the connective tissue supporting framework are derived from the germinal epithelium. This includes the embryonic reté ovarii, and cords of Pflüger, the interstitial cells that crowd the stroma and surround the follicles, the granulosa cells that line the follicles, and finally the very ova themselves. The early investigators of the ovary as a gland of internal secretion believed that the source of the secretion resided solely in the corpus luteal cells, which in turn were thought to be exclusively modified granulosa cells. Further studies revealed that before the age of puberty the internal secretory function is performed by the interstitial cells, the existence of which had long been known. This idea then became prevalent that there are two secretions; one produced by the interstitial cells and one by the corpus luteum, and that these two secretions possess selective functional powers.

However, it has been shown that the main part of the corpus luteum cells, the theca lutein cells of follicle atresia and the cells of the interstitial gland found in animals, are all activating interstitial cells. Until comparatively recently it was generally supposed, as stated by Tandler and Gross, that the interstitial cells are derived from the connective tissue of the ovarian stroma, but this mystery has been solved by observations that the stroma of the ovary is actually composed chiefly of interstitial cells originally derived from the germinal epithelium and supported by a connective tissue which acts only as a supporting frame work. We must conclude, therefore, that all the cellular elements to which the source of an internal secretion may be ascribed are interstitial in character and origin.

This conclusion disposes of the theory that there exist in the ovary two separate and independently functioning endocrine organs. As a practical proof of the truth of these observations one would expect to find little or no qualitative difference in the clinical results from the administration of such extracts as those respectively from the corpus luteum, the whole ovary and from the stroma. And such in fact is the case. Early in our experience we gave up corpus luteum preparations in favor of those compounded from the whole ovary, not because there was any inherent qualitative difference in their action, but because we found that for the various gynecological purposes to which we applied them the products of the whole ovary were more reliable and more intensive than those from the corpus luteum alone. In order to test the actual value of the corpus luteum we excluded it altogether and treated a large number of patients with preparations from the rest of the ovary. It was not difficult to obtain the material, for up to this time it had been discarded, so far as medicinal purposes were concerned, during the manufacture of corpus luteum preparations, hence the name ovarian residue. It was no surprise to discover that the residue compared favorably with the whole ovary products, and that in some respects it appeared to be superior.

Though our observations and deductions lead us to deny the existence of two independent secretory organs in the ovary, we must admit the possibility

of a minor selective action on the part of different portions of the ovarian secreting substance but even here the variation is probably a quantitative one. Thus in our cases we have found the whole extract and the residue more efficacious than the corpus luteum in treating hot flushes, but the superiority is one of degree rather than one of kind. Other observers have found corpus luteum preparations of especial value in the nausea and vomiting of pregnancy. The finer distinctions drawn by some in the treatment of certain menstrual irregularities do not seem to us to have been unequivocally proved.

In the light of theoretical, experimental, and anatomical knowledge combined with long continued observations, our general estimate of the ovary as a gland of internal secretion may be briefly summarized as follows.

1. For complete somatic growth and sexual development the normal secretion of the ovary is essential. To what extent the action of the secretion is direct, and how far it serves as a balance to other more powerful secretory influences is a matter of speculation.

2. During menstrual life and especially during the years of adolescence, the proper functioning of the ovaries has a very important bearing on the physical and mental character of the individual.

3. Dysfunctions of the ovaries are usually attended with various neuroses. Some of these may be due to the direct disharmonious action of other endocrines, especially those that have an affinity for the autonomic nervous system. In evaluating these neuroses one must also take into account those neurotic habits which we have mentioned in the first part of this paper, as being the result of a sense of physical inferiority, and characterized as a continued endocrinous emotional state.

4. In the adult the ovarian secretion plays a somewhat minor rôle in the human economy, as is indicated by the comparatively slight physical changes that take place after ablation or the natural menopause. This has an important bearing on the question of removing the ovaries during hysterectomy.

5. During adult life the most definite evidence of the existence of a true internal secretion from the ovaries is the occurrence of hot flushes and genital atrophy after ablation. These symptoms point to a balancing rather than a direct action of the ovarian secretion.

6. From an organotherapeutic viewpoint, the ovary must be regarded as primarily a homogeneous gland, the essential secreting structure being the interstitial cells. Variations in secretions of different parts of the gland are probably differences of degree rather than of kind. A selective action of the secretion from different parts of the gland is not yet proved and if it exists is probably quantitative.

7. The therapeutic value of ovarian preparations in our experience, may be stated somewhat as follows: All the ovarian preparations exert a specific influence on hot flushes. In this respect the residue is the most intensive, but the difference in efficacy of the various preparations depends to some extent on the idiosyncrasy of the patient.

In the treatment of menstrual irregularities ovarian extracts exhibit an undoubted specific action but this action is inconstant. In temporary functional amenorrhea, delayed menses, dribbling before and after catamenia, and small clotting, ovarian therapy is fairly reliable, and is at least the best asset that the gynecologist at present possesses for these symptoms. Theoretically for these affections the ovarian action may be enhanced by the addition of thyroid and pituitary extracts, but of this our personal clinical experience has not been entirely convincing.

For the permanent amenorrheas, especially those associated with pluriglandular disturbances, ovarian therapy has little or no effect on restoring the menstrual function, but is of undoubted value in improving the patient's general health. It is best in these cases to administer the ovarian treatment in considerable doses, separately from the other gland extracts.

In certain types of dysmenorrhea ovarian feeding is efficacious, occasionally brilliantly so, but it is unreliable and often disappointing after giving early promise. In the severe types of dysmenorrhea it is of comparatively little help. For menorrhagia and metrorrhagia ovarian therapy is not indicated.

THE OBSTETRICAL DEPARTMENT OF A MODERN MEDICAL SCHOOL.*

The Equipment, Organization, and Scope of Teaching.

BY BARTON COOKE HIRST, M. D.,
Philadelphia.

It is a noteworthy fact that the revolutionary changes in the teaching and practice of obstetrics in the United States during the past twenty years has received little attention. In the forty-four volumes of the transactions of the American Gynecological Society, among the many papers presented at the annual meetings I remember but one that dealt with the improved training of young physicians who will be our successors. Has not the American Gynecological Society thus lost an opportunity for leadership which would have added to its prestige and influence? The trustees of medical schools, advisory committees, state legislatures and boards, naturally turning to the leading national society for advice and information, must have been astounded at its aridity in this field. My endeavor in this communication is to make a tardy amend for the neglect of a question which, it would seem, might have excited interest and received careful consideration long ago.

There are medical schools still undergoing reorganization under private control. Legislatures must give this matter thought in organizing the increasing number of schools supported by the State, the expense of technical education often making private management impracticable.

It is in the hope of furnishing information for the governing bodies of such institutions, and to give aid and support to the teachers who are ambitious

to have their departments as nearly as possible on an ideal basis, that the following propositions are advanced. In a medical school designed for about four hundred students in a four years' course, the equipment of an obstetrical department which entitles it to a respectable position must consist of:

1. A hospital of at least one hundred beds, with a clinical amphitheatre; a separate operating room for septic patients and an isolated space for infected women. The apportionment of beds should exceed that for surgery or medicine, for the average instructive capacity of each case in obstetrics is limited in the majority of instances to one or two students.

2. An ambulatory dispensary for the preliminary study of patients and for the followup observation and treatment of all patients after discharge from the hospital. Such a dispensary accumulates in time a large service illustrating all the pathological sequellæ of parturition, including practically all the diseases of women. It should be equipped with every appliance, including electrical, for treating women, and should have a social service department attached to it.

3. An outpatient department, with the necessary personnel of nurses, physicians and social service workers. This department should have a separate ambulatory dispensary. On a basis of about two thousand women cared for in their homes annually an enormous dispensary attendance can be secured of women awaiting delivery and, by a followup system, of women suffering from any of the complications or sequellæ of the process of generation at any stage. This service is a valuable feeder to the central hospital, to which all patients requiring operative or other hospital treatment are referred.

It is evident that such an organization gives the obstetrical department an amount of clinical material in all the conditions peculiar to women that no other department can rival or even approach. What is more important, every therapeutic measure required by women can be shown to the student; the preventive treatment of gynecological affections by the proper management of labor; the relationship of diseases of the pelvic organs to the reproductive function; the effect of operative measures on subsequent childbearing and vice versa. In short, to any intelligent student the necessity is made obvious, of a closely correlated study of all the pathological and physiological phenomena of the female generative organs; the effect of the former on fecundity and reproduction, and the causative relationship of parturition to the vast majority of women's diseases.

Such is the broad view of modern education, contrasting strikingly with the provincial American practice of the past; an obstetrical department concerned only with the delivery of women without regard to their future and a misnamed gynecological department dealing only with a moiety of the subject; busily engaged for the most part in patching up the results of other physicians' bad obstetrics. Such an arrangement was evidently doomed to extinction by modern progress and could no more be revived than we could recall to life the elder Mr. Weller.

The medical pedagogues of America must agree

*Read before the American Gynecological Society.

with their confrères in the rest of the world that the scope of obstetrical teaching embraces not only the physiology and pathology of reproduction but necessarily all the diseases of women. The chief of an obstetrical department must be a thoroughly trained abdominal and pelvic surgeon maintaining proficiency in his art by constant practice. Otherwise he is not fit for his position and would be incompetent to deal with the cases that may be admitted to his clinic at any moment; ruptured uterus with injury of intestines, requiring resection; diaphragmatic hernia in pregnancy; discovery of disease of the gallbladder in the course of an abdominal operation, and so on through a long list. In brief he must be prepared to deal surgically or otherwise with all the ills of women whether complicating pregnancy, labor and the puerperium or often their indirect consequence.

We have in the University of Pennsylvania a voluntary and a compulsory student's internship in the maternity hospital; the amount of material he sees, the notes he takes, and his conduct on the service are collated to establish his rating in the final examination. I find this record of a student's clinical opportunities during a voluntary internship of two weeks: Seven normal deliveries, an extraperitoneal Cæsarean section, transverse presentation with version, Cæsarean section for placenta prævia, compound presentation with two feet, hand, occiput and prolapsed cord, a Cæsarean section for a monster, dicephalus tetrabrachius, ten plastic operations, two ovarian cysts, a hydrosalpinx, a salpingitis, an exploratory laparotomy, a supravaginal hysterectomy, a large ovarian cyst, a cancer of the sigmoid: resection, six dilatations and curettage, three appendectomies, a gas anesthesia, a radium application, two intravenous injections of salt solution, a blood transfusion, two inevitable abortions, a uterine irrigation, and a ruptured ectopic gestation.

This same intern had another compulsory week's internship in the hospital; a two weeks' voluntary service in the outpatient department and another compulsory ten day period; a year of theoretical lectures; another year of clinics, conferences, section work and ward classes in which he saw, heard described, and personally assisted in the treatment of a large additional number of cases, such as have just been detailed. The following question naturally suggests itself: If the chief of an obstetrical department must be an accomplished pelvic and abdominal surgeon; if his department, properly organized and conducted, controls an amount of clinical material that no other can rival; if he alone in the medical faculty can teach all the conditions which the physician must treat in women, is it pedagogically or economically justifiable to maintain in a medical school a so-called gynecological department, which can only duplicate the teaching of the surgical and obstetrical departments and in a manner necessarily inferior to both? This question has already been answered in the only way it could be answered by the majority of our best medical schools; it is being answered as opportunity occurs by vacancies in existing chairs, and it will presently be answered conclusively and finally.

As an interested observer, an occasional participant in the transactions and an old member of the American Gynecological Society, it appears to me impolitic to allow a movement which vitally concerns us all to gain irresistible headway and to reach its ultimate goal, apparently ignored by the very organization that should have fostered and directed it.

The reason for our attitude is obvious: some of the members might fear an interference with their vested interests. Others, disinterested, might, in the spirit of a *laudator temporis acti*, be honestly convinced that the old order should not be disturbed. But the issue is too important to be influenced by selfinterest or unprogressive minds. This is the only country in the world now rich enough to adequately equip its medical schools; consequently the hegemony of the medical education of the world lies within our grasp if, having the money, we have the wit to seize it.

Apparently the world's centre of wealth, power and civilization, shifting with the ages from Mesopotamia, Egypt, Greece, Rome, and Northern Europe, is moving to this continent. It is an inspiring thought that each one of us puny mortals in his tiny sphere may play a part in such a stupendous cosmic drama. Let us teachers of one of the most important medical branches put our house in order, that we may merit a place among those who assist and do not hinder the passage to America of the world's leadership in medical education.

TREATMENT OF DISPLACEMENT OF THE UTERUS.

By P. BROOKE BLAND, M. D., F. A. C. S.,
Philadelphia,

Gynecologist to St. Joseph's Hospital, Assistant Gynecologist to
Jefferson Hospital, Assistant Professor of Gynecology, Jefferson
Medical College.

PROGRESS IN GYNECOLOGY.

No division of medical science has made more rational and definite progress than that of gynecology. Nearly all the lesions affecting the pelvic organs of women have become so definitely classified that there is practically universal unanimity as to the methods to be instituted in treatment. Today indiscriminate sacrifice of reproductive structures has given place to judicious conservatism. Acute pelvic infection is no longer considered or treated as a surgical emergency with the accompanying high degree of mortality, morbidity and the useless sacrifice of the most vital organs of a woman's body. Postabortive and postpuerperal infections are now largely regarded as medical and not surgical conditions and, therefore, are treated along conservative medical lines. Premalignant conditions of the cervix are recognized and their serious significance is becoming more and more appreciated. These lesions, fortunately, are being treated less and less by expectant medical measures and prophylactic surgical procedures are being promptly applied. There is no longer discussion as to the proper course in ruptured extrauterine pregnancy, a topic that prominently held the stage until a few years ago. The introduction of radium,

however, has somewhat upset the established views concerning the treatment of uterine fibroids and carcinoma, but the majority of investigators are unanimous in believing that early surgical intervention is still the method of choice. This is as it should be, because no human mind can fully comprehend the true cellular nature of a neoplasm involving the organs concealed within the pelvic cavity.

GENERAL CONSIDERATION OF MALPOSITION.

However, in the treatment of malpositions of the uterus, there is still a divergence of opinion, but the majority of authors are advocating and employing surgical methods. This is due to the fact that no attempt has been made to draw a sharp dividing line between what constitutes on the one hand a medical, and on the other a true surgical displacement. Hence many men apply operative measures indiscriminately to all. Before instituting any plan, the indications for treatment should be most thoroughly considered and surgical methods only should be utilized in those cases associated with distinct concrete surgical complications, such as lesions involving the vaginal walls, the cervix, the uterine body or the structures in intimate pelvic relation with this organ. Medical and mechanical means are definitely indicated in the simple, uncomplicated malpositions. These methods should be utilized especially in virgin women, in young married women, in freely movable uteri and also in the prolapsus of elderly women of poor surgical resistance. Indeed, no simple, uncomplicated malposition of the uterus should be regarded as a surgical lesion and, therefore, displacements of this nature should not be corrected by surgical methods. A simple displacement is defined as one not associated with pathological change in the organ itself or in the surrounding structures. This definition seems entirely superfluous, but yet, as previously remarked, the distinction between this form and the so-called pathological type is not sharply drawn and surgical measures are applied to all.

Unquestionably, today, the uterus in simple malposition is more sinned against than sinning. This is especially true in this country, and have we not swung the surgical pendulum a little too far? Are not too many patients being operated upon? Are we not building up a major surgical condition from a minor, medical lesion? Certainly we have been more assiduously attentive in a surgical way to this condition than our confrères in Europe. Too frequently, indeed, we utilize surgical intervention without paying due regard to the causative factors, and I am persuaded that before deciding on any method we should weigh more carefully, investigate more thoroughly, not only the pelvic, but the systemic condition of our patients as well. Surely one cannot hope to afford relief by operating upon patients who are nervously and muscularly wracked. It is needless to state that a stem pessary cannot possibly accomplish good for a patient with a congenitally antiflexed, ill developed uterus, yet this so-called simple, but really dangerous and at times harmful, procedure is employed all too commonly. A uterus of this type is not the disease, but only a local pelvic manifestation of systemic trouble. A

rudimentary organ of this character usually occurs in large, obese women. This feature tells the tale of ductless glands or endocrine dysfunction and should be ample warning to any observer as to the futility of operation, such as curettage, the use of the metranoikter, stem pessary, or any of the other operative procedures commonly in vogue today. It is inconceivable that the Dudley or Pozzi operations should ever be performed for the condition described above and that these means should afford relief is likewise beyond comprehension. In these patients a general survey of the body should be a signal sufficient to tell us to leave the uterus alone. The multiplicity of surgical agencies recommended and employed in acute anteflexion should also be sufficient evidence to show that we are still distant from an infallible remedy and, moreover, that surgical treatment has failed to afford the results desired. Will any operation prove beneficent to poor nervously and muscularly incompetent women with the intraabdominal structures in a state of general dependency or ptosis? In these cases, should not the malposed uterus be regarded as a concomitant of the condition and not as a separate entity? The urologist and general surgeon have recognized the true status of the so-called floating kidney and the voluminous reports of operation for this condition which formerly appeared in our literature have practically disappeared. Will we, as gynecologists, study the physiognomy of the malposed uterus with the same degree of interest and intelligent interpretation?

LAW OF MALPOSITION.

It is absolutely incumbent upon the profession to keep in mind that no set rule applies to all cases. Every displacement is a distinct law unto itself, and will require, therefore, specific methods of treatment. Undoubtedly many patients will never get well unless operated upon, but it is not the function of this paper to discuss displacements of a surgical nature. It is my purpose to limit the consideration of the subject to medical and mechanical treatment and I shall consider the various malpositions separately. One of the most annoying, discouraging and distressing types of malposition is so-called acute anteflexion.

ACUTE ANTEFLEXION.

The condition described under this term rarely, if ever, occurs as a distinct concrete pathological lesion. Indeed, as a separate entity it is of doubtful existence. In the light of our present knowledge concerning the endocrine system, should it not be regarded as a physical phenomenon or sign of ductless gland disturbance and not a pathological condition of the uterus? Certainly the very unhappy and discouraging results obtained by local surgical treatment should be sufficient to force us to place acute anteflexion in the category of disease in which it rightfully belongs. While associated with local symptoms, such as scanty or absent menstrual flow, dysmenorrhea and sterility, these symptoms are seldom overcome by the local surgical agencies in common employment today. Rarely are these patients permanently benefited by curettage, the use of the metranoikter, the stem pessary, Dudley or

Pozzi operation, or any other surgical measure used at the present time. I have never seen the stem drain or pessary overcome sterility nor relieve dysmenorrhea for more than a period of three or four months, and most assuredly these implements cannot possibly have any influence in establishing a normal menstrual flow. I have personally seen serious damage result from the use of these instruments and the untold harm that results from their general employment is incalculable. Infection and permanent functional damage frequently result from the use of the curette. This is likewise true of the stem drain and the latter instrument cannot, indeed, be used without danger.

We have at the present time under our care two young women suffering from extensive pelvic peritonitis resulting from the use of the latter implement. Recently we operated upon a girl nineteen years of age for a vesicovaginal fistula. The opening in the bladder wall was three eighths of an inch in diameter and resulted from the bar or the arm of the pessary rubbing and perforating the bladder cavity. Therefore, should not the unhappy results obtained by the surgical methods as practised today be sufficient grounds to bar their continuance or at least modify their use? For some years I have entirely abandoned the use of curettage and the stem pessary in the treatment of acute ante flexion and I most emphatically disapprove of their use for this condition. A uterus in the majority of cases in acute ante flexion should be looked upon as a local evidence of systemic disease and any effort at treatment, therefore, must be directed along systemic medical lines. One should keep in mind that a certain proportion of these patients will not be benefited at all by any measure and in so far as the local uterine condition is concerned, it should be placed in the category of incurables. No known medical or operative agency will cause a uterus to grow. An infantile uterus in an adult woman will remain infantile forever, regardless of any plan of treatment, and the sterility associated with the condition will likewise persist indefinitely. The obesity, amenorrhea and dysmenorrhea, so frequently an accompaniment of the trouble, may be (to a certain degree) modified, but not cured. In a moderate degree of infantilism, however, function in a small proportion of cases occasionally is restored, but in pronounced cases never. Should we not, therefore, cease chasing the will o' the wisp and not only face the truth, but tell the truth as well? Too frequently these patients are persuaded to believe their symptoms will be overcome by surgery and all too soon is their dream of promised happiness shattered.

TREATMENT OF ACUTE ANTEFLEXION.

In the condition under discussion, four conditions are confronted, each demanding specific consideration and attention. First, obesity; second, sterility; third, partial or complete amenorrhea, and fourth, painful menstruation or dysmenorrhea. Perhaps the condition can well be described by outlining a typical case.

CASE.—At the present time, I have under my care a single woman, twenty-six years of age. She is five feet two inches in height, and weighs 236

pounds. Her menstruation was established at four-teen and always has been more or less irregular.

At present it recurs every three or four months and is manifested not by a flow, but simple spotting. The duration is less than a day and the discharge is accompanied by violent pelvic pain. Her uterus is typical of the infantile type. The cervix is long and its diameter does not exceed the tip of my little finger. The dimensions of the uterine body are all contracted and the organ is half the size of the normal virgin structure. Systemically she presents the train of nervous phenomena associated with endocrine dysfunction and rarely, as personally expressed, "do I enjoy a well day." This patient is responding well to treatment. During the first four weeks she lost twenty-six pounds in weight. Her nervous state is much improved. Her menstruation recurs regularly. The flow is moderate in amount, the duration is from two to three days, and the pain has been decidedly relieved. There is no palpable change in the uterine cervix or body, but the general improvement and the restoration of ovarian function have been remarkable indeed.

The marked obesity observed in these patients must be overcome by a strict dietary régime. It should be the custom to strike and strike hard at this phase of the trouble and endeavor to reduce the patient twenty or twenty-five pounds during the first four weeks of treatment. This can be readily accomplished by feeding the patient proteid broths, green vegetables, raw fruit and fruit juices. We generally instruct the patient to begin feeding at seven or eight a. m. and eat regularly every three hours for twelve hours or from seven or eight a. m. to seven or eight p. m., taking a cup of hot broth with a vegetable, a raw fruit or fruit juice. Tea or coffee without sugar or cream may also be taken. This régime is rarely a hardship and we have never experienced any difficulty in having the plan carried out. After the initial rapid loss, the diet is still restricted so that a progressive loss of from five to ten pounds a month is maintained until the patient returns to a relatively normal weight. We have succeeded by this plan in subtracting from fifty pounds, in mild cases, to seventy-five pounds or more in marked cases. In addition to a strict dietary régime, scrupulous attention should be given to the bowels. Two evacuations daily should be insisted upon and these should be accomplished, if necessary, by the use of a saline purge. The skin should be kept active by systematic exercise, obtained either in employment or by walking and also by a hot tub bath on retiring.

The obesity and other systemic phenomena are also favorably influenced by the administration of the organic extracts and furthermore these substances, in many instances, exert a happy effect on the menstrual disturbance. Frequently, these agents will increase, prolong, regulate, and occasionally reestablish the flow. Occasionally, also, the dysmenorrhea is relieved. While not wishing to go on record as asserting that these agents will cure sterility, yet I have seen apparently hopeless cases of the condition overcome and patients conceive. Even so I still ask myself: "Was the result

a coincidence or due to the drugs?" For several years we have used singly and in combination all of the organic preparations, but for the past three years we have settled down to a combination of three: Thyroid extract, pituitary extract, and ovarian extract. We begin with a small dose, starting with one grain of each in capsule three times daily and continue for three weeks. We then stop for a period of one week, at the end of which time we begin with two grains in capsule three times daily for three weeks, again discontinuing the preparation for a week. We then give three grains of each drug in a capsule three times daily for another three weeks, stopping a week and then continuing with the figure three, three grains, three capsules, three times daily, three weeks, for a period of six months or a year. By thus increasing the materials gradually and with a rest period no cumulative action, toxic or untoward effects have occurred. Despite the plan herewith outlined, dysmenorrhea frequently persists and we are not familiar with any agent that will afford complete or permanent relief. Benzyl benzoate, a substance on which we all based so much confidence and hope, has been generally disappointing. The coal tar preparations are not satisfying and opium or any of its derivatives we never recommend or use. Therapeutically, dysmenorrhea has no specific and is one condition, to use a homely yet descriptive phrase, in which we are truly "up against it."

UTEROVAGINAL PROLAPSE.

This, excepting inversion, is the most infrequent type of malposition and is more of an obstetrical than a gynecological problem. It constitutes about five per cent. of all displacements and usually follows a recent labor. The term is descriptive and implies that the displacement involves primarily the uterine body. It usually follows a long, hard, tedious labor in a patient unable to obtain the requisite rest of a normal lying-in period. It is seen in women who are unable or unwilling to take advantage of necessary care after labor. Therefore, the trouble can largely be prevented by proper prophylactic measures. Indeed, if all labor cases could be cared for properly, uterovaginal prolapse would exist only in name. On the part of the obstetrician, three conditions may be mentioned as causative factors: hastily forced delivery, neglect in failing to carry out primary repair of all lacerations, and failure to insist on requisite rest after delivery; on the part of the patient, too early resumption of the care of the baby and household duties, habitual overdistention of bladder, and violent straining in endeavoring to evacuate the bowels. The treatment then is summed up largely in the word prophylactic, on the part of both doctor and patient. If, however, one is confronted with an actual condition, the patient should be forced to secure absolute rest. The care of the baby so far as possible should be placed in hands other than those of the mother. The knee chest position should be assumed for fifteen minutes morning and evening, the bladder should be emptied every three or four hours and the bowels should be evacuated daily without straining, assisted, if necessary, with one of the heavy mineral oils or a low cleansing enema. If

the uterus is enlarged, subinvolved and heavy, depletion and reduction should be accomplished by glycerinized tampons and copious hot vaginal douches. The uterus should also be maintained in position by the introduction of a properly fitting pessary, preferably of the Thomas-Munde type. Finally the *sine qua non* is rest, and no treatment will avail unless this is placed first in importance.

VAGINOUTERINE PROLAPSE.

This is the most common type of surgical displacement and an advanced degree of this condition cannot possibly be corrected permanently and completely without surgical treatment. No medical or mechanical measure can overcome the second or third degree of the lesion, but the majority of cases of the first stage, as expressed in the term retroversion or retroflexion, if uncomplicated, can be treated successfully by medical and mechanical means. Included then under this heading are mild uncomplicated cases of prolapsus, retroversion and retroflexion. Before considering specifically the treatment of these conditions, I should like to refer to their symptomatology. Undoubtedly the accusations charged against these lesions have no foundation in fact. It is, indeed, questionable whether uncomplicated retrodisplacements ever cause any symptoms, although all varieties of disturbances are attributed to them. All forms of autonomic nerve phenomena are frequently assumed to originate in displacements of this character. Locally, backache, pelvic discomfort or pain, bladder irritation, rectal irritability and gastrointestinal disorders are described as symptoms resulting from malpositions of this nature. This description of the symptomatology is far from the truth, as abundantly proved by the small percentage of symptomatic recoveries occurring in patients operated upon. Rarely, indeed, does surgical procedure relieve either the local or general disturbance and the symptoms persist despite operative correction. Therefore, to attribute such a vast symptomatology to this condition is fallacious. Rather should the uterine condition be regarded as a result, not a cause of the autonomic relaxation. No normal movable appendage ever creaks or breaks the back of the parent tree and the same may be said of the uterus. It cannot possibly cause backache, nervous phenomena or any other of the great train of symptoms of which it is accused, regardless of position, so long as the organ remains natural in size and normal in mobility. Too many so-called backaches are attributed to the "uterus pressing against the spine," and the sooner we sever ourselves from this hereditary belief the sooner will we care for our patients more intelligently, the sooner escape the deserved opprobrium in failing to give our patients relief.

The first consideration in treatment of uncomplicated retrodisplacements should be directed along systemic lines. Every possible effort should be exerted to restore the patient to a normal physical and psychological status. The importance of muscular rehabilitation must also be kept constantly in mind. Nerve and muscle reconstruction are accomplished by freeing the patient from all nervous worry and fatigue, by obtaining for her an abundance of

physical and mental rest, by systematic forced feeding and by graduated exercise in wholesome fresh air. Proper and well fitting clothing should be worn. Overdistention of the bladder should be prohibited and a daily easy evacuation of the bowels should be insisted upon, for no other factors are so active in causation as these. Constipation must be absolutely overcome, for recovery cannot possibly occur with the patient violently increasing the intraabdominal pressure with every attempt at fecal evacuation. For this purpose drugs should not be employed, unless absolutely necessary. Mineral oil may be utilized, but a laxative diet with massage and exercise of the abdominal muscles are more desirable and more lastingly efficient. Locally, a copious hot vaginal douche of one or two gallons of plain hot water should be taken morning and evening. If the uterus is large and heavy, glycerinized tampons should be introduced twice weekly. The knee chest posture should be assumed for a period of fifteen minutes, morning and evening. Manual reposition of the uterine body should be performed and its position maintained by the introduction of a properly fitting hard rubber pessary.

PROLAPSUS IN ELDERLY WOMEN.

In marked prolapsus of elderly women of low surgical resistance, even in complete prolapsus, medical and mechanical methods, while not curative, will afford the patients untold relief. Again the importance of regular bladder and bowel action cannot be overemphasized. Overcome constipation and uterine displacements, a fertile field for the gynecologist, would largely disappear. Accomplish reduction or replacement manually and follow this by the introduction of a Menge pessary. The patient should be instructed to keep the parts scrupulously clean by using a plain hot water douche morning and evening. At the end of six or eight weeks the pessary should be removed, cleansed and reintroduced. If the parts have undergone involution or contraction, as frequently occurs, a smaller sized instrument should be used. If the pessary is worn for a considerable period of time involution of the vaginal walls always takes place and progressive reduction in the size of the implement, therefore, becomes absolutely imperative. After wearing the instrument for six months or a year, the patient may be allowed to discard it for a period of two or three months at a time; indeed, in some instances recovery is so marked that one could almost term it complete.

SUMMARY.

1. Therapeutically there is a distinct need for a specific line of division between medical and surgical malpositions.
2. The symptomatology of uterine displacements, in general, as taught today is erroneous. This is confirmed by the small percentage of so-called cures following operation.
3. Uncomplicated malpositions should be treated by medical and mechanical means. Operative measures should be applied to those associated with distinct surgical complications.
4. Operative intervention should not be utilized in the simple malpositions of virgins or young married women.

5. The infantile uterus never requires, nor is the condition benefited by surgery. Endocrine dysfunction as an etiological factor should be remembered. This condition should be treated and not the uterus.

6. Nerve and muscle relaxation (backache) should be regarded as a causative factor and not the result of uterine malposition.

7. Restoration of nerve and muscle power should be restored in all cases and is best accomplished by rest and generous feeding.

8. In no case of retroflexion or retroversion will the patient recover in the presence of obstinate constipation or bladder overdistention. Overcome constipation and malpositions will largely disappear.

9. The prolapsus of old women with low surgical resistance is best treated mechanically by the Menge pessary.

1621 SPRUCE STREET.

DISEASES OF THE CERVIX UTERI.*

By ALFRED HEINEBERG, P. D., M. D.,
Philadelphia,

Associate in Gynecology, Jefferson Medical College; Obstetrician to the Jewish Maternity; Assistant Gynecologist, St. Agnes Hospital.

The ease with which the cervix may be amputated has, I am convinced, frequently led to its removal without due consideration of other possible means of restoring it to a healthy condition. A careful study of the aftereffects of amputation of the cervix, as ordinarily performed, must reveal that frequently the immediate result and at times the influence upon subsequent pregnancy leave much to be desired. In most instances the amputation is done to remove a cervix which has undergone hypertrophy and erosion. Such conditions result from laceration and eversion with exposure of the mucous lining of the cervical canal to infection, trauma and irritation of the acid vaginal secretion. To insure complete removal of the diseased cervical mucosa and eroded area, the internal incision in the formation of the flaps must be made so high across the mucous membrane of the cervical canal in most cases that the canal or internal os may be impaired. The latter may be left in a state of wide dilatation; the former may be tightly constricted by a ring of cicatrix perpendicular to the long axis of the cervix formed at the edges of the apposed flaps. A permanently dilated internal os favors infection of the uterine cavity, with the production of a leucorrhoeal discharge which is much more difficult to cure than that which resulted from the preexisting cervical disease. More important than the annoyance of the discharge is the influence of the infected uterine mucosa and widely patulous os upon subsequent pregnancy. Both produce unfavorable conditions for the retention of the impregnated ovum in the uterine cavity. Several cases of inevitable abortion have come under my observation in women who, before amputation of the cervix, had had no difficulty whatsoever in carrying a fetus to full term.

I recall especially one patient from whom I had to remove retained products of conception as a

*Read before the Northern Medical Association of Philadelphia, May 14, 1920.

result of spontaneous abortion in the twelfth week of gestation, two years after a high cervical amputation. She had undergone three normal pregnancies prior to the operation. About a year following the abortion I was asked to see her again

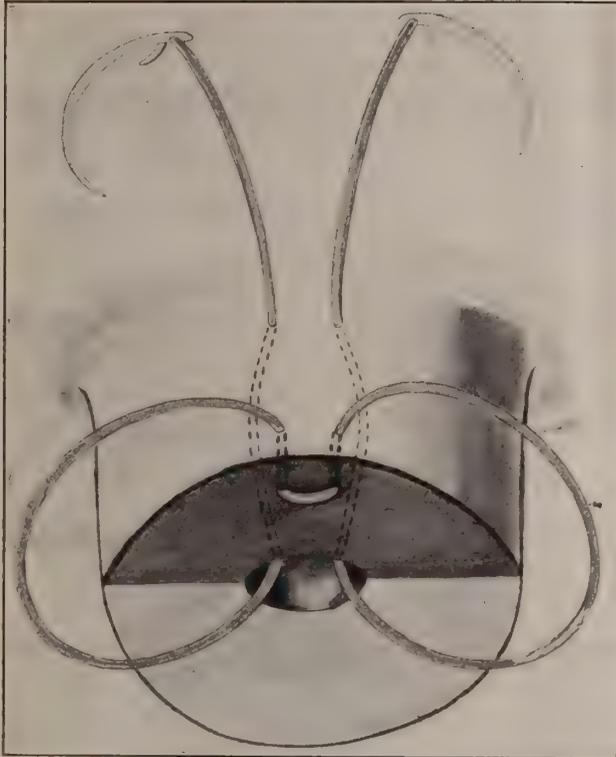

FIG. 1.—Introduction of sutures in the modified Bonney suture.

by her physician, and found her in the tenth week of gestation with evidences of another threatened abortion, and it was only by enforced rest in bed for a number of weeks that we were able to insure the continuation of the pregnancy.

Leonard (1) has reported abortion or premature labor in fifty-five per cent. of the pregnancies occurring in women whose records could be traced after amputation of the cervix in Johns Hopkins Hospital.

Stenosis of the cervical canal produced by a dense ring of scar tissue formed along the edges of the flaps may obstruct the flow of menstrual discharge and be the cause of dysmenorrhea. Such a cicatricial ring may produce a prolonged and exhausting labor and uterine dystocia because of the inability of the cervix to dilate properly. Indeed in some instances the cicatrix may refuse to dilate sufficiently to permit the passage of the fetus. Leonard found that in nearly seventy per cent. of the cases of amputation of the cervix the patients subsequently had difficult labor. In two patients I was forced to make bilateral incisions in such a cicatrix to insure complete dilatation of the cervix and permit the progress of the fetus through the birth canal. In addition to the unsatisfactory results thus far considered, failure to produce pleasing cosmetic effects by the usual method of suturing the flaps in the high Schroeder amputation of the cervix has induced me to seek and finally adopt measures which

have served to overcome the objectionable features of the older operations. These I shall describe later on.

No method of operation, however, will diminish the necessity for high amputation of the cervix in cases of extensive hypertrophy and erosion, because an operation which does not remove all of the pathological tissue, especially the eroded surface, is only partially successful. Any part of the erosion which is allowed to remain will continue to discharge and in time spread over the adjacent surface of the repaired cervix and thus lessen the benefit which the operation should have afforded. In so far then as amputation of the cervix is concerned, the following possibilities always may confront us: a, stenosis of the canal; b, permanent dilatation of the internal os, and, c, failure resulting from insufficient removal of diseased tissue.

Since the amount of cervical tissue to be removed must be controlled by the extent of the erosion, endocervicitis and hypertrophy, it would seem advisable to reduce these pathological changes, if possible, by other methods of treatment in order to limit the extent of the amputation or to abolish the necessity for its performance. Emmet and others of the older operators recognized the advisability of such procedure, but its practice has been neglected in recent years, much to the detriment of the patient. It has been my practice in the last three years to subject all patients suffering from a combination of erosion, endocervicitis, laceration and hypertrophy of the cervix to a method of treatment found to be uniformly successful in restoring the cervix to a healthy state before operation. In many instances operations have been avoided on cervixes which would formerly have been subjected to high amputation. It is the method employed in producing these results that I want particularly to describe.

The secret of success lies in the preparation of

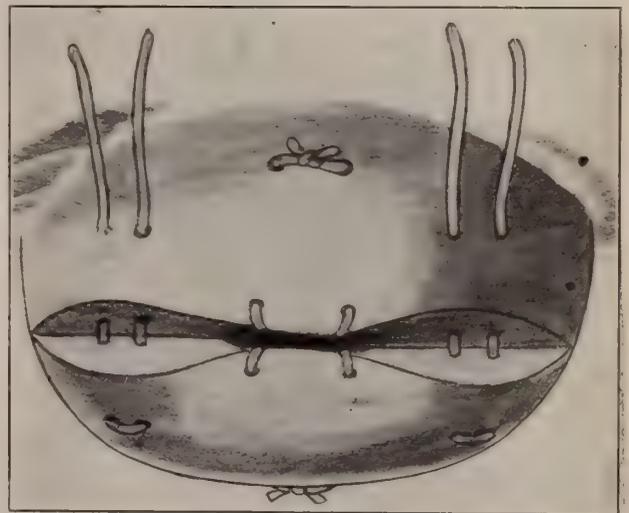

FIG. 2.—Sutures in the cervical wall at the edge of the internal flap.

the cervical mucous membrane for the reception of the active medicating agent. We know that the cervical canal in health contains a plug of clear, tenacious mucus. In pathological conditions the cervical secretion is increased in quantity and be-

comes thick, cloudy, mucopurulent, and still more tenacious. Most of the medicinal agents, such as silver nitrate, phenol, formalin or the organic silver compounds, which are useful in the treatment of diseased mucous membrane, coagulate mucus as soon as they come in contact with it. The resulting dense

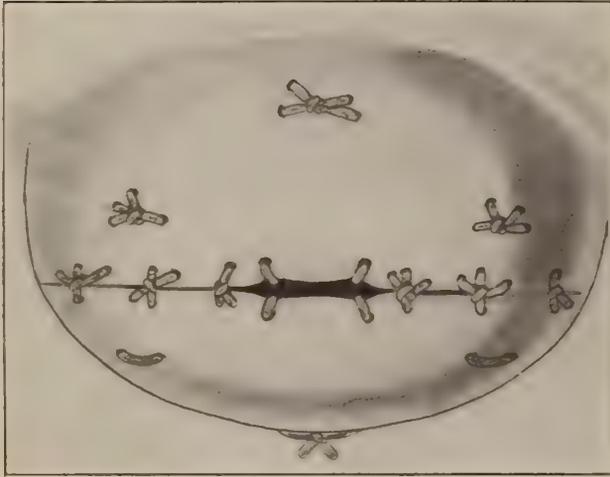

FIG. 3.—Sutures completed showing the tension distributed.

wall of coagulum acts as a barrier to the access of the medicinal agent to the mucous membrane and diminishes whatever effect it might have. Complete removal of the secretion cannot be effected by swabbing with gauze or cotton, or by the use of a suction apparatus, and these methods when persisted in frequently cause bleeding, which still further counteracts the action of the medicament.

After experimenting with different methods, I have found that the cervical discharge can be easily and thoroughly dissolved or dislodged by irrigation of the cervical canal with a weak alkaline solution of the following formula:

Sodii bicarb.,	} āā.....	gr. xl
Sodii chlorid,		
Sodii borat,		
Aqua, q. s.....		.01

I use for the purpose a large syringe, the tip of which is introduced well into the cervical canal and the fluid expelled under sufficient pressure to dislodge the mucus. Several injections may be necessary. There is not much likelihood of forcing the

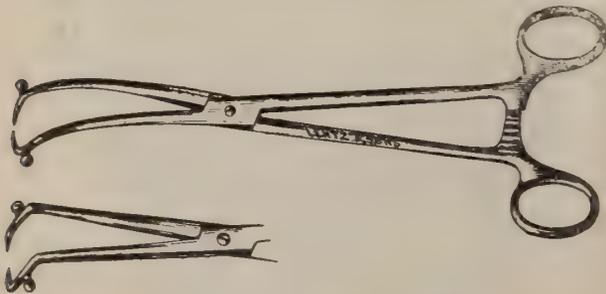

FIG. 4.—Angulated tenacula for hemostasis.

solution into the uterine cavity, unless the internal os is dilated or too much force is employed. Before beginning the treatment, the condition of the internal os should be determined with a thin sterile probe. If it is found too much dilated, as it rarely

is, the alkaline solution should be applied on cotton wrapped applicators instead of by irrigation. After the cervical mucous membrane is entirely clean it should be thoroughly dried with absorbent cotton, when it is ready for the application of the medicating agent. I find no drug so good as silver nitrate for the purpose of curing erosion and endocervicitis. In the aggravated cases of long standing, in which the mucosa is greatly thickened and the erosion extensive, I begin the treatment with a fifty per cent. solution, applied every three or four days. The first few applications are likely to cause bleeding from the eroded surface. As the discharge lessens in amount and becomes thinner and less purulent, the strength of the solution is gradually decreased to ten per cent.

If the cervix is large and boggy, the applications of the silver nitrate are supplemented with boroglycerin tampons until the cervix is reduced in size. The patient is given a prescription for the alkaline powder, with directions to use one tablespoonful in

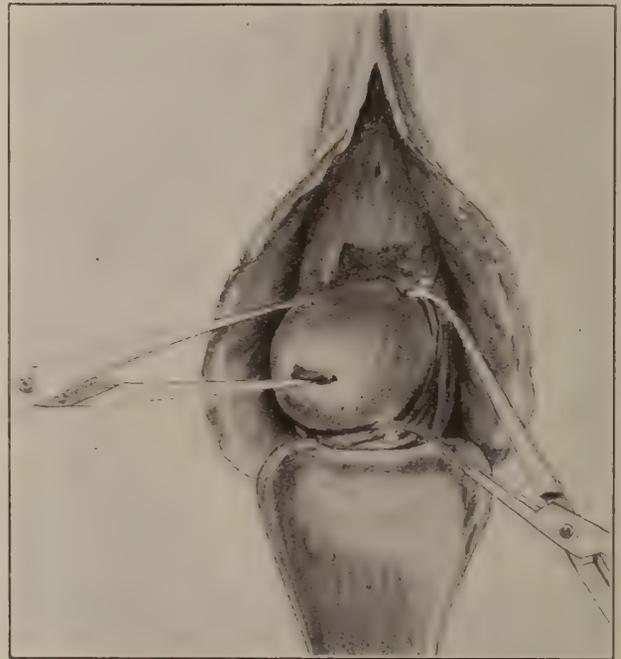

FIG. 5.—Angulated forceps applied to cervix above level of amputation.

two quarts of water as a vaginal douche once or twice a day, depending upon the amount of discharge. It is most gratifying to observe the changes which take place in the cervix under this treatment. The erosion gradually decreases in area through substitution of stratified squamous for the thin columnar epithelium. The change can be well seen at the edges where the ingrowth of squamous epithelium radiates toward the internal os. In addition, islands of squamous epithelium may be frequently observed in the centre of the erosion, looking very much like small skin grafts on a granulating surface.

By the time the erosion has disappeared, the cervical mucosa has returned to its normal state, the discharge has decreased in amount, and resumed its clear, mucoid character. Furthermore, the size of the cervix will have perceptibly diminished through the removal of the underlying cause of the

hypertrophy, except in those cases of a very tough, fibrous cervix. In many cases I have observed a shrinkage of fifty per cent. in the size of the cervix. The time required to produce the desired results by this treatment varies between three and six months. Its distinct advantage is that it lessens the

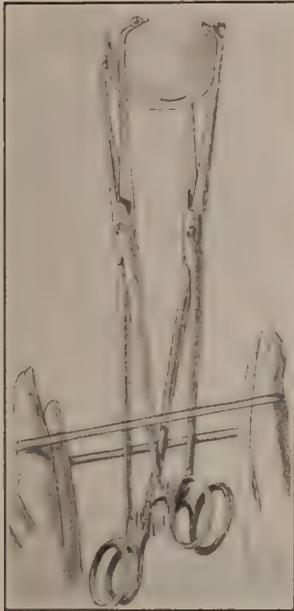

FIG. 6.—Seventh stage in technic of bloodless repair.

necessity for extensive amputation. The cases of bad erosion and ectropion which were formerly subjected to high amputation in order to get rid of the diseased tissue require after the treatment only trachelorrhaphy or a moderate amputation, if any at all.

In Leonard's most instructive and important essay, to which reference has been made, he has brought out the advantages of trachelorrhaphy over amputation. He showed that after trachelorrhaphy, as compared with amputation, there was an increase in fertility, a decrease in the frequency of

abortion and premature labor, and a more favorable influence upon the character of the first labor after the operation. He reports fertility in thirty-eight per cent. of the cases after trachelorrhaphy as against nineteen and four tenths per cent. after the amputation. Abortion and premature delivery occurred in twenty-eight per cent. of the trachelorrhaphy cases and in fifty-five per cent. of the amputation cases. The character of the first labor after each operation is interesting. "Following amputation of the cervix, the first labor was difficult in seven of the eleven cases. In striking contrast to this result is the fact that in eight of the ten cases of full term pregnancy following trachelorrhaphy labor had been easy." In addition to these figures of Leonard, other authors have shown that dystocia after amputation of the cervix (due to cicatricial stenosis) is not only of frequent occurrence but it may reach any extreme, even causing rupture of the uterus. "After trachelorrhaphy, dystocia has evidently seldom been met with, for references to its occurrence are very scarce."

If after the treatment of the cervix described herein an amputation of moderate extent is still required to reduce the hypertrophy and relieve the ectropion, it should be undertaken. In order to reduce the stenosis following the amputation and to eliminate the uneven surface produced by the older plan of tying the sutures over the edges of the flaps, I resorted to the Bonney suture to invert the long, external flap of the amputated cervix. Unfortunately, the traction of the suture not infrequently caused sloughing of the central area of the inverted flap, and left an ulceration which occasionally per-

sisted for a long time and in cicatrization caused a depression resembling a laceration, which detracted from an otherwise satisfactory result. This defect of the Bonney suture has been overcome in my later cases by introducing both ends of the suture about one quarter of an inch back of the edge of the external flap and then carrying them through the cervical wall at the edge of the internal flap before they are tied to each other. (Figs. 1, 2 and 3.) This modified method eliminates the pressure caused by tying the suture over the edge of the flap, distributes the tension over a wider area, prevents sloughing, and gives a better cosmetic result.

During the last two years I have further improved the cosmetic effect of amputation by exercising greater precision in fashioning the flaps and more exact coaptation of their edges. These results have been rendered easier by securing a bloodless field of operation.

The technic of bloodless repair which I have elsewhere described combines simplicity, ease of application, and efficiency. Hemostasis is secured through the use of two angulated tenaculum forceps (Fig. 4) and a rubber band about one quarter inch wide. The chief feature of the forceps, in addition to the angulation, is a pedunculated ball which is attached to the outer aspect of each blade

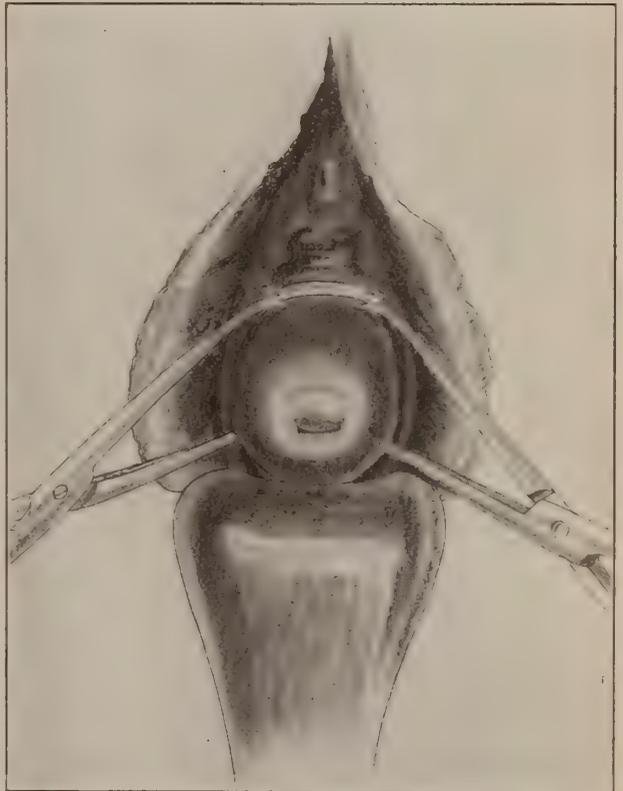

FIG. 7.—Handles of forceps separated to be held by the assistant.

above the angle. The balls serve the purpose of retaining the rubber band in a position to compress the cervix above the grasp of the forceps. The technic is as follows:

1. Introduce a selfretaining speculum into the vagina.

2. Grasp the anterior lip of the cervix in the median line with an ordinary double tenaculum.

3. Dilate the cervix moderately, chiefly to determine the precise location and direction of the canal.

4. Draw the cervix toward one side and apply the angulated forceps to the cervix, well above the level of the proposed amputation or denudation. (Fig. 5.)

5. Draw the cervix to the other side and apply the second angulated forceps opposite the first one.

6. Remove the ordinary tenaculum.

7. Place the handles of the forceps together, stretch the rubber ring over them and push the ring up on the cervix to a point above the retaining balls. (Fig. 6.)

8. Separate the handles of the forceps and hand them to an assistant. (Fig. 7.)

It will be observed that the forceps thus held act also as lateral retractors of the vagina. During the progress of the operation, the assistant should avoid undue tension on the forceps or unnecessary separation of the handles, in order to prevent making a ragged tear in the cervix with the points of the forceps. After the repair has been completed, cut the rubber ring and remove the forceps. The forceps and ring may be removed before the sutures are tied.

The application of these methods in over one hundred cases personally treated has shown that in more than half of them medical treatment alone was sufficient to cure the existing cervical disease. In most of the others, either trachelorrhaphy or moderate amputation restored the cervix to a practically normal state.

SIXTEENTH AND SPRUCE STREETS.

AMPUTATION OF THE CERVIX UTERI.

BY JAMES N. WEST, M. D.,
New York.

Professor of Diseases of Women, Post-Graduate Medical
School and Hospital.

This operation I believe to be one of the most important that the surgeon is called upon to perform, on account of the frequency with which the necessity for it arises, and its effectiveness in accomplishing the objects desired. The fact that its performance is usually required upon women in the most active and responsible period of their lives, where the necessity for health and freedom from symptoms accompanying laceration of the cervix is most important to their well being and efficiency must also be considered. Perhaps its greatest and most important use is in prevention of cancer. The writer believes that he has demonstrated with many others, that the incidence of cancer of the lacerated cervix is about six times as frequent as in the unlacerated (1 to 9). If this is true, the surgeon has no better field of endeavor in cancer prevention than here, where, by restoring the cervix to a healthy condition, he could prevent five out of six

cases of cancer of this part of the body. For cancer of the cervix occurs about six times as frequently in lacerated cervixes as it does in the unlacerated. The writer does not believe in doing everything possible to increase the human population of the world, for he believes that many evils and infinite distress come from over population, but when a being has once arrived in the world, that he should be condemned to a death of a lingering, loathsome, painful character is one of the most distressing thoughts.

It seems that cancer is on the increase among civilized peoples, and its prevention by any possible means therefore assumes proportionately greater importance. In the writer's experience the most frequent indications for amputation of the cervix occur in the following order:

1. For extensive laceration and disease of the cervix due to childbirth.

2. Elongation and hypertrophied cervix occurring in prolapse of the uterus.

3. Dysmenorrhea and sterility due to acute ante-flexion of the uterus.

4. Removal of the cervix for chronic gonorrheal endocervicitis where the tubes have already been removed.

Amputation of the cervix for malignant disease is not included here because today if we find malignant disease of the cervix we do much more extensive operations, although two decades ago the operation done with a cautery was advocated by Byrnes of Brooklyn and had a considerable vogue for a time. But since this time the clinic of Wertheim in operative cases of cancer has centered the attention of the profession upon the most radical procedures.

The technic of the operation is practically the same in each of these conditions except the second where it is varied to meet other operative procedures which are resorted to for the cure of procidentia. The importance of a careful technic here cannot be exaggerated, as the chief use of amputation of the cervix is in relief of chronic irritation and the restoration of the vaginal vault to a healthy state. If the operation is done hurriedly and carelessly, leaving little points of tissue to granulate and areas to cicatrize, the object for which it is performed will not be accomplished. It must be borne in mind that it is a small organ, not much larger than the eye, and that therefore proper instruments, proper suture material, and a careful technic should be used.

As a preliminary step, there should be a gentle but careful curettage of the uterus, for in nearly all cases of laceration of the cervix there is endometrium hypertrophy as a result of the laceration. Following the curettage it is wise to make an application to the endometrium of equal parts of carbolic acid and iodine, wiping away the excess from the vaginal part of the cervix, but not from the body of the uterus. I advise the use of ten day chromicized catgut sutures as they have given satisfactory results. If plain catgut is used it is absorbed too soon and gaping of the wound may result. For some reason wounds of the cervix do not heal as quickly as those of other tissues of

the body. The suture material used should last at least ten days.

OPERATION.

A point is selected upon the left side of the cervix above the diseased part of the mucous membrane and the mucous membrane is cut through to the solid tissue of the cervix. The scissors are pushed along beneath the mucous membrane care-

fibres in the cervix which keep it closed having been cut away. As soon as its tissues become softened as a result of pregnancy and the fetus begins to attain weight, it sags down into the lower segment which starts dilatation with the invariable result of being expelled.

If the amputation is made to extend to a point within one third of an inch of the internal os, it will easily accomplish the purpose attempted and at the same time preserve for the patient the ability to carry a fetus to term.

A modification of this operation which has a distinct field of usefulness constitutes a combination amputation trachelorrhaphy. This is suitable for cases in which the laceration has extended to or almost to the internal os. The amputation if carried beyond the point of the laceration would remove so much of the cervix that childbearing would not be possible. By amputation of the anterior and posterior lips, and then by cutting out a wedge shaped piece from the site of the laceration on the sides, the operation may be completed, yet leaving a sufficient amount of the cervix to make childbearing possible. In labors following amputation of the cervix, it is not especially prone to tearing, but if this should occur it should be repaired again.

Since amputation of the cervix is frequently one of several operations done at the same time, the postoperative care is embraced in that which is observed for the sum total of the operations done. But where it is the primary and chief operation,

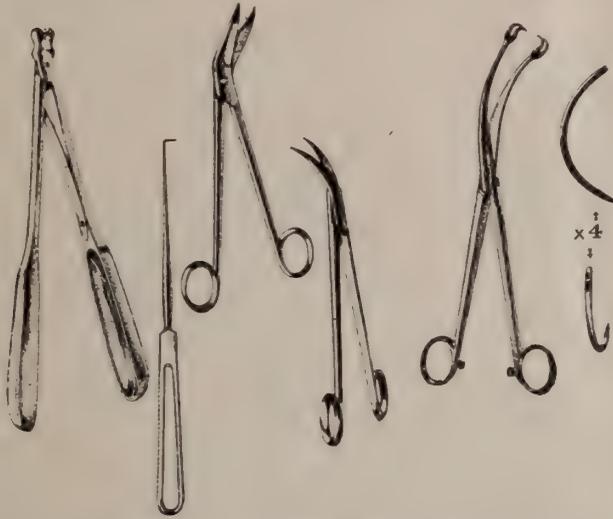

FIG. 1.—Cleveland's needle holder; Emmet's tenaculum; Tuttle's cervix scissors (right and left); double volsella forceps; Dudley's cervix needle.

fully preserving the proper distance from the os and surrounding the cervix with a circular incision, which usually corresponds to the line surrounding the cervix at its greatest periphery. The mucous membrane of the vagina is then wiped back with gauze to the desired height, that is, to a point above the diseased tissue. The cervix is then amputated with scissors by clean cuts at right angles to the long axis of the uterus. Two sutures are placed in the centre, in front, and two behind to bind the mucous membrane of the vagina to that of the cervix to insure a new canal which will not contract. These are passed first, then the sutures passing from before backward, picking up the mucous membrane of the vagina, then entering the solid tissue of the cervix beside the canal, emerging and picking up the vaginal mucous membrane of the posterior wall. From three to five sutures are used on either side at intervals of about one quarter of an inch, picking up the solid tissue of the cervix as well as the mucous membrane in front and behind. After all sutures have been passed, they are tied, beginning with the central ones, which pass into the cervical canal, then tying those on the side. For better understanding of the technic, see Figs. 1 and 2. The instruments used are also shown in Fig. 1.

HEIGHT OF AMPUTATION.

In cases of severe dysmenorrhea accompanying anteversion and where sterility also exists, care must be used not to amputate the cervix too high. If the amputation extends as far as the internal os, the patient will be unable to carry a fetus to term and abortion will occur almost invariably between the third and fourth month, the circular

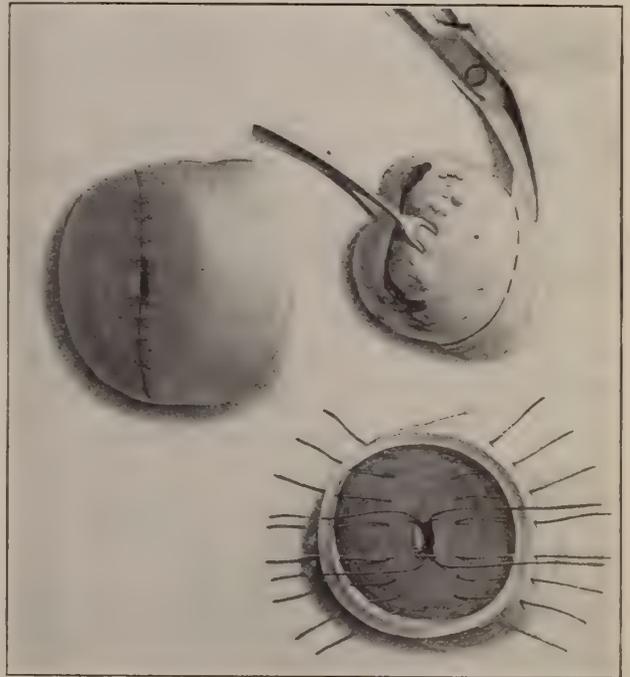

FIG. 2.—Amputation of the cervix (Emmet's method).

the care resolves itself to that of amputation of the cervix alone. A patient should remain in bed for at least ten days. Douches are unnecessary, except at about the tenth day, when a bichloride douche of one to six thousand may be given and repeated every other day for eight days. Other

aftertreatment consists in the usual attention to the bowels, the diet and the general comfort of the patient. It is unnecessary and bad technic to place gauze in or against the cervix after operation.

CERVICAL LACERATION, CYSTOCELE, PROLAPSUS UTERI, AND MULTIPLE FIBROMATA.

BY W. FRANK FOWLER, M. D.,
Rochester, N. Y.

Justification for making this report rests upon several remarkable features of the case under discussion and the information to be gained by a consideration of the various etiological, pathological, diagnostic and surgical problems incident to it.

CASE.—Mrs. S., a rather obese woman, aged forty-one, had always menstruated regularly every twenty-one days except during pregnancies. Her first pregnancy occurred in 1901 when a long and painful labor was terminated by instrumental delivery at her home in the city. Immediate repair of an extensive perineal laceration was made. On the day following delivery packing was inserted and left *in situ* for several days with the object, she surmised, of controlling hemorrhage. She remained in bed three weeks. Her strength returned rather promptly.

In 1903 she moved to a farm where a full term pregnancy was terminated spontaneously after a fairly easy labor lasting seven hours. Six months later she was annoyed by a bearing down feeling and pain in the back and sides and she noticed something protruding from the vulva.

In 1905 her third full term pregnancy ended in spontaneous delivery after an easy labor lasting four hours. The bulging later became more noticeable and she began wearing a cup pessary. Without this support she was greatly troubled with frequent urination if she was on her feet.

In 1907 she again became pregnant. She was miserable much of the time, the protrusion from the vulva became very marked and during early pregnancy there was profuse yellow leucorrhœa which became bloody occasionally. She flowed every day during the fifth, sixth and seventh months. This pregnancy ended at the eighth month in a

spontaneous delivery after a labor lasting six hours. The child lived only two hours. Again she experienced, as after the preceding pregnancy, an increased protrusion if the pessary was not worn. The three spontaneous deliveries were endured without anesthesia. During the past ten years she had had leucorrhœa. One year ago she began to gain in weight. Recently the pessary had failed to function and disability due to the cystocele had become extreme. Otherwise she felt perfectly well.

Examination under anesthesia revealed a very large cystocele and a second degree prolapsus uteri. The cervix, apparently, was the seat of an extensive bilateral laceration of the usual type with widely separated anterior and posterior lips. Further examination, however, disclosed a slit seemingly in the posterior lip and extending clear through it. Investigation of this opening showed that it was, in reality, the lower cervical canal terminating below in the external os. The relatively small posterior lip was behind it. The condition, then, proved to be a transverse tear slightly below the cervico-vaginal junction extending entirely through the anterior lip and across the midcervical canal. The bulky portion of the anterior lip below the tear had swung down and concealed the posterior lip behind it. The walls of the tear were amply protected by epithelial covering, but the floor consisted of eroded mucosa.

Operation March 11, 1920: The Mayo procedure for the relief of cystocele and uterine prolapse was done. The ovaries and fallopian tubes were not removed. The operation was unduly prolonged, first, because the general nodular irregularity of uterine outline due to unsuspected multiple fibromata contributed to the difficulties of hysterectomy, (one tumor, in particular, the size of a walnut, bulged into the septum between the uterus and the bladder), and second, because approximation and suture of the broad ligaments behind the clamps was difficult due to tension. It was decided, on account of the time consumed, to repair the perineum ten days later. Recovery from both operations was uncomplicated. The suggestion of Frank (1) that the administration of ether causes a constant lowering of the carbon dioxide capacity of the blood plasma in direct proportion to the duration of anesthesia merits serious consideration.

Pathological report: Multiple leiomyofibromata, subperitoneal, intramural and submucous; mild cystic glandular hyperplasia of cervix with active chronic cervicitis; greatly increased vascularity of cervix with hyperkeratosis.

Mayo (2) mentions, among the indications for his operation, the usual age limits of forty-five to sixty-five years and a particular applicability to the relief of uterine prolapse of the third and fourth degree. He also reminds us that when difficulty in approximation of the broad ligaments is anticipated uterine tissue may be retained on both sides. Although my patient was only forty-one years old, the prolapsus was merely of the second degree and uterine tissue could not be utilized to bridge the gap, nevertheless, the procedure seemed well adapted to relieve the pathological entity.

The indications for cervical repair or amputation,

Goldspohn (3) observes, are to be found in the pathological induration resulting from previous infection and inflammation following laceration rather than the laceration *per se*. Goldspohn believes that the pathological condition requiring operation is so generalized in the cervical tissues that amputation of the gland bearing lower half of the cervix is the operation of choice. Sturmdorf (4) also states that the occurrence of infection rather than the mere incidence or degree of laceration determines the morbidity of a cervical lesion. Sturmdorf notes, too, that the theory of reflex neuroses from alleged "pinching of the cervical nerves by scar tissue in the angles of laceration," is almost, but not quite, obsolete.

Regarding the occurrence of carcinoma following cervical lacerations, Ewing (5) writes, "Cervical carcinoma is strongly influenced by childbirths, which average over five in such patients. While carcinoma seldom develops in scars, yet repeated cervical lacerations disturb the normal structure and functions of this tissue, interfere with its nutrition and expose its weakened structure to chronic irritation and inflammation. A chronic endocervicitis precedes cancer in a majority of cases and the routine examination of this tissue reveals abnormalities in the morphology and position of the epithelium which constitute precancerous conditions. The most prominent of these conditions is the cervical erosion, many of which show suspicious hypertrophy and heterotopia of the lining epithelium."

In view of the fact that the patient in the case under discussion had three deliveries through a shortened cervical canal, a consideration of the effect of amputation of the cervix upon future pregnancies, from the viewpoint of tissue loss, at least, would not be amiss. Leonard (6) concludes, from a careful investigation of the literature, that "a pregnancy occurring after amputation of the cervix has not more than an even chance of progressing to term."

Pavlik (7) reports a personal case with the following history:

CASE.—Mrs. S., aged twenty-five, married six years, had a difficult forceps delivery eighteen months after marriage. She had a miscarriage a year later at three months. Shortly afterward an amputation of a badly lacerated cervix was done. Since the operation she has had three miscarriages at six and a half, four and three months respectively. I saw her in the third month of her sixth pregnancy. She complained of pain and bleeding. Two days later she miscarried. At present she is again about two months pregnant."

Pavlik emphasizes the importance of determining, if possible, the rôle played by the cervix during pregnancy and labor, and states his belief that at all events "the cervix acts as does a puckering string to a bag, or as a stopper to a bottle, so far as it relates to the gestating uterus, and its removal subjects the patient to the danger of uterine evacuation at all stages of pregnancy."

Holmes (8), on the other hand, admits the possibility of premature labor following amputation of the cervix but not so early that a living child might not be delivered, because it is very near ter-

mination of labor before the internal os gives way. Holmes concludes, therefore, that the cervix plays an unimportant part in gestation. Sturmdorf concurs with a statement that pregnancy and labor are intrinsically corporeal functions. Clinically, Holmes found, merely, that after amputation of the cervix the earmarks of labor were lost and the labor was exceedingly easy and uneventful. Heaney (9) also has observed easy labors following amputation of the cervix.

The question of the advisability of conserving normal ovaries in hysterectomy invites discussion. Culbertson (10) defines the menopause as a functional derangement on the part of various glands of the endocrine system subsequent to the cessation of the ovarian secretion. During the early years following puberty, for example, before glandular harmony has become established, castration is productive of but slight disturbance. Later, with some variations, the longer the gonad has been functionally associated with the endocrine group the greater disturbance there will be when that gonad is withdrawn, and further, the syndromes following the cessation of ovarian secretion present familiar pictures of underactivity or overactivity of the various ductless glands. This glandular interrelation has been discussed, also, by Frank (11), Goetsch (12), Graves (13), Loeb (14), Marine (15), Richardson (16), Vincent (17), and others. Culbertson believes that ovarian tissue should be retained whenever surgically possible.

Graves states that during maturity until the menopause the ovary plays a subordinate but not an insignificant rôle in the endocrine group. In the reproductive system, on the other hand, it is a predominant but not independent factor, since its proper function depends upon a normal relation with the uterus and its endometrium. The breaking of this relationship and the consequent upset of the physiological balance of the endocrine group, whether by removal of the ovaries or of the uterus, is of slight difference symptomatically. Retention of the ovaries after hysterectomy or of the uterus after oophorectomy are both potentially troublesome.

The investigation of Sampson (18) into the blood supply of the ovary convinces him that the actual supply is derived from the ovarian and uterine arteries. The potential supply is found in the communications between the arteries of the tube and of the broad ligament, branches of uterine and ovarian origin. The blood supply is considerably jeopardized by salpingectomy. The surgeon should therefore cut close to the tube and avoid mass ligatures of the broad ligament. Sampson has followed, with satisfaction, the safer plan suggested by Dickinson (19) of retaining the tubes in hysterectomy when the ovaries are conserved. Dickinson, in 1912, strongly advocated retention of normal ovaries.

Polak (20) believes that preservation of the menstrual function is the important consideration. To that end, when infected tubes require removal and one or both ovaries can be conserved, he protects the ovarian blood supply by a technic similar to that suggested by Dickinson with the addition

of removal of the fundus uteri. Polak (21) states, however, that in hysterectomy, with ligation of the uterine arteries, the ovarian blood supply is seriously reduced. The ovaries, too, when hysterectomy is indicated, are frequently abnormal. The life history of the retained ovary is only about two years. Polak has reoperated upon seventy-three women for painful and cystic ovaries within five years of the primary procedure.

Vineberg (22), in 1915, had reoperated upon two patients for cystic degeneration of the ovaries following hysterectomy for fibroma. Vineberg concludes that:

1. There is still uncertainty as to which tissue in the ovary produces the internal secretion.

2. Although the follicles continue to develop in the conserved ovary after hysterectomy, it is uncertain that the function of the internal secretion continues uninfluenced by the great changes in the blood supply and by the traumatism to the pelvic sympathetic nerves incident to the operation.

3. The relative influence upon the climacteric syndrome of oophorectomy and injury to the pelvic nerves during operation is undetermined.

4. Clinically, there is slight symptomatic differ-

FIG 1.—Posterolateral view showing the relatively small posterior lip, the long glass rod protruding from the external os and above, the enormous anterior lip with an angle of the laceration.

ence between hysterectomy with and hysterectomy without oophorectomy.

5. Logically, the ovaries should be retained at all ages and not limited to those under forty-five years, as is done by most of the advocates of conservation, since it has been shown that of the women who suffered most severely from the artificial menopause twenty-three per cent. were over forty-five years of age.

6. Subsequent disease of the conserved ovary occurs in some cases.

7. The clinical advantages accruing from retaining the ovaries in hysterectomy are doubtful and the likelihood of subsequent disease and adhesions of such ovaries is great. The ovaries should not be retained in hysterectomy unless enough of the lower uterine segment with its endometrium could be left to insure menstruation.

Vineberg cites a case in which supravaginal hysterectomy had been performed elsewhere. At reoperation sixteen months later Vineberg found the ovaries to be free from adhesions. One ovary was removed and proved to be normal microscopically. Vineberg notes that conditions were favorable for conservation of the ovaries since the uterus had been about normal in size and there was no dislo-

cation of the site of the ovaries as occurs frequently with fibroid growths of the uterus.

Richardson concludes, on the other hand, that our knowledge of the complex ovarian function is incomplete; that the uterus is not essential to a continuation of ovarian function except as regards menstruation and reproduction; that the disturbances of ovarian function attributed to hysterectomy are partly those associated with normal menstruation (the clinical syndromes of menstruation and of the physiological and artificial menopause differ chiefly in degree and rate of development), and partly those arising from damage to the ovary through unnecessary operative trauma or disease; that the weight of evidence furnished by anatomical, experimental and clinical investigations is overwhelmingly in favor of retention of sound ovaries both before and after the menopause age.

In response to a questionnaire the following replies were received:

Dr. J. Wesley Bovee (23): Normal ovaries should not be removed with the uterus in women under forty years of age. Since interference with the ovarian blood supply is so great in hysterectomy by the ordinary technic that rapid atrophy of the ovaries ensues we can only expect a slower and nearer normal type of menopause from thus leaving in the ovaries.

Dr. John G. Clark (24): I have always positively taken the ground that whenever it is possible to conserve the ovaries, particularly in young women, it is the wise plan to pursue. . . . I have worked on this basis for fifteen years and personally have seen no reason to deviate from that rule.

Dr. Edward P. Davis (25): Up to the age of thirty-five the ovaries, if healthy, should remain. The tubes should be removed in hysterectomy. In older women the ovaries should be removed with the body of the uterus, since, at this time, the ovary is most prone to degenerative changes. Ovaries retained after hysterectomy probably undergo rapid atrophy. It is practically impossible to remove the body of the uterus and the fallopian tubes without so interfering with the ovarian blood supply that atrophy or degeneration soon occur. This is the only reason why most operators invariably remove ovaries in hysterectomy. I have had several cases in which hysterectomy was done and the ovaries left, in which menstruation occurred from the uterine stump for an indefinite time. There seemed to be no inconvenience and the mental effect was good as the patient thought she was having no menopause.

Dr. E. C. Dudley (26): I have not removed ovaries in hysterectomy cases. They have not, in my observation, done any harm; on the contrary, there is apparently a more normal menopause and a more normal period of senility when the ovaries are left.

Dr. George Gellhorn (27): Cystic degeneration of the retained ovaries is usual. There have been adhesions around the ovary, or where the tunica albuginea shows thickening and smoothing out of the irregular folds of the surface, the saving of the ovary is a mistake. Without the uterus even a

normal ovary soon becomes atrophic. The symptoms of artificial menopause are greatly ameliorated by the administration of ovarian substance or corpus luteum extract. A radical rather than a sentimental attitude now influences me.

Dr. B. C. Hirst (28): If the woman is ap-

FIG. 2.—Anterolateral view showing the long glass rod protruding from the external os, traversing the laceration and entering the internal os, and the tear extending through the anterior lip and across the cervical canal, with margins widely separated by the short rod. (The specimen is somewhat distorted by the fixing solution.)

proaching the menopause I remove the ovaries. If she is younger I prefer leaving them on condition that I do not remove the tubes or interfere with the circulation of the broad ligament; otherwise I would prefer removing them as cystic degeneration would probably occur.

Dr. C. Jeff Miller (29): I retain normal ovaries in hysterectomy if the patient is under forty years of age. The ovarian circulation is carefully guarded because, if the ovarian vessels are tied cystic changes so commonly occur that it is best to remove the ovary. I am unable to determine, however, that the menopausal symptoms have been greatly reduced by retention of the ovaries.

Dr. Reuben Peterson (30): "I always retain one or both normal ovaries after a hysterectomy, whether it is supravaginal or panhysterectomy. I am firmly convinced that the patients suffer less from the effects of the menopause if this practice is followed."

Dr. G. W. Roberts (31): I have been removing troublesome tubes and ovaries from patients who had had the uterus removed at previous operations for the past twenty years. If I do anything which destroys the ability of the pelvic organs of a woman to function I make a clean sweep down to the internal os uteri, unless definitely commanded by the patient not to do so.

Dr. Arnold Sturmdorf (32): I always remove ovaries and tubes when performing a hysterectomy. Some of my reasons are that the ovaries and tubes present links in the reproductive chain of organs. Removal of the uterus breaks the chain by destroying an essential link. We find the surgical climacteric as pronounced in the cases in which the ovaries are preserved. Preservation of the ovaries after hysterectomy is a delusion, inasmuch as their arterial supply is cut off more or less completely. Ovaries left behind usually undergo various forms of degeneration, some of which are productive of symptoms that demand secondary removal. All arguments in favor of preserving the ovaries are

based upon a purely theoretical idealism and sentiment.

Dr. Howard C. Taylor (33): If the ovary is not removed and the tube is normal I retain the tube also as by doing so there is less chance of interfering with the blood supply of the ovary. Beyond the age of forty-five I make little or no effort to retain the ovary. Under the age of thirty-five I make every effort to do so. Between these ages, if the patient is inclined to be fat, it is an additional reason for saving the ovaries. In general I am sure that I make less effort to retain the ovaries than many men.

A comprehensive survey of the subject of ovarian conservation is beyond the scope of this paper. However, the wide divergence of opinion elicited by the queries of Vineberg in 1915 is equally apparent in the responses to my questionnaire. Dr. John G. Clark informs me that he has recently been making a careful study of the question with the hope that definite conclusions may be reached. The personal opinion of Dr. Clark is quoted elsewhere in this paper.

SUMMARY.

The subject of this report had a forceps delivery in 1901. At intervals of two years she had three subsequent pregnancies, all of which terminated spontaneously after short labors, two at full term, the third at the eighth month. After the second delivery she noticed a protrusion from the vulva, which increased after each of two later pregnancies. In 1920 she sought surgical relief for the disability resulting from the cystocele which a pessary would no longer support.

Examination prior to operation revealed an extensive laceration through the anterior lip and across the cervical canal, due presumably to instru-

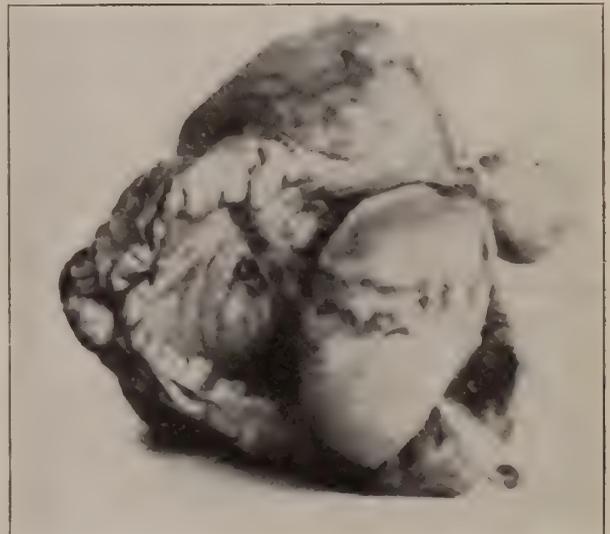

FIG. 3.—Showing, at the right, the long rod in the external os, in the centre the bulk of the anterior lip and to the left the gaping laceration and the remainder of the anterior lip. (Uterine fibromata are apparent in all three views.)

mental traumatism during the first delivery nineteen years ago. The tear had apparently remained undiagnosed, certainly untreated, during this long period. Examination of the uterus *in situ* and

after removal afforded convincing evidence that the three spontaneous deliveries had taken place through the rent in the anterior lip rather than through the external os. It is remarkable that this extensive laceration produced such a slight pathological change in the cervix; that three spontaneous deliveries occurred through it, and finally that surgical relief was sought after nineteen years solely for the disability due to the cystocele.

CONCLUSIONS.

1. A thorough gynecological examination three months after delivery should be routine practice.
2. The disability following cervical lacerations is dependent upon the degree of subsequent pathological condition rather than the tear, *per se*.
3. Premature or precipitate labors following amputations of the cervix are probably due to some other factor than the mere loss of tissue.
4. Operative morbidity and mortality will be decreased by multiple stage operations in lieu of one prolonged procedure.
5. The advisability of conserving normal ovaries in hysterectomy is still undetermined.

183 ALEXANDER STREET.

THE ROLE OF THE RECTAL EXAMINATION IN OBSTETRICS.*

BY WILLIAM E. PARKE, M. D., F. A. C. S.
Philadelphia.

When I began the practice of obstetrics I felt that it was my duty to sit at the bedside of my patient with my examining finger tugging at the perineum from time to time to dilate the soft parts and stimulate pains. The women expected it and were encouraged, by the bystanders at least, to think that the doctor was helping them. Those of you who attended the lectures of the elder Penrose will remember his inimitable monologue and demonstration on the manikin, Mrs. O'Flaherty, of the conduct of labor. He taught that it was good for the young physician to familiarize himself with the process of parturition by keeping his hand in contact with the parts. This was modestly done under cover until the presenting part was about to be born; and this I think was typical of obstetrical practice at the end of the last century. Now the fashion has changed; the pendulum has swung to the other extreme and even vaginal examinations are anathema with some physicians.

Let us consider briefly—1. What can we learn from a rectal examination? 2. What advantage do we gain by this method? and 3. Is there any objection to a vaginal examination?

Considering the last question first, it cannot be denied that in a well conducted clinic or proper environment, vaginal examinations with the gloved hand or the carefully cleansed bare hand can be practised without detriment from the examiner's hand. And every one who has attended women even in very unsanitary surroundings, without clean towels or bedding, knows that they commonly succeed in avoiding infection. This fact, however,

*Read before the Philadelphia Clinical Association, October 4, 1920.

does not warrant one in disregarding the ordinary rules of sterility. As to the patients themselves they are the hosts of a variety of organisms which increase in virulence from the cervix to the vulva. The folds about the clitoris and the glandular discharges about the posterior commissure of the vulva are especially likely to harbor infective germs. The Döderlein bacillus is credited with immunizing the upper part of the vaginal tract against infection. Now it is impossible to make a vaginal examination without carrying germs from the lower to the upper part of the vaginal canal; and if these are of a virulent type the risk to the patient is not avoided by any preparation of the doctor's hands, no matter how careful he is. Routh, of London, has shown, with respect to Cæsarean section, that where repeated vaginal examinations have been made and where attempts at forceps delivery have been undertaken the mortality following the operation was vastly greater than where the same operation was done on patients in labor with unruptured membranes and few examinations. Dr. Beck in reporting a series of Cæsarean sections done at the Long Island College Hospital observed that the morbidity following the operations was thirty per cent. in cases where vaginal examinations had been made, whereas it was only twelve per cent. in cases where no vaginal examinations had been made. DeLee (1) records the occurrence of two deaths from infection in the service of the Chicago Lying-in-Hospital due to coitus shortly before parturition. These citations—and many more could be adduced—show the harmful effect of invading the birth canal shortly before labor.

Let us consider, for example, the patient to whom we wish to give the test of labor. Such a one is a potential case for operation and examination from time to time over a period of twenty-four hours or more would be the usual practice. If in the end section is resorted to, the patient's well-being both as to morbidity and mortality will be enhanced if no vaginal examinations have been made, or what is only a little less satisfactory if only one vaginal examination is made immediately prior to delivery; for it is the repeated examinations over a long period that are most likely to give rise to infection.

In the normal course of delivery Nature provides a flushing of the birth canal when the bag of waters ruptures, when the fetal ellipse advances, and again when the afterbirth and membranes are discharged—the current being always from above downward. Such patients quite uniformly do well, if the doctor fails to arrive on time, thus emphasizing the implied suggestion not to meddle with Nature's plan by introducing something from below to the upper part of the canal.

What can we learn from a rectal examination? The tyro learns nothing, and it is difficult to convince the beginner that it is worth while to practise the method often enough to acquire confidence in his findings, for a large experience is required to learn the finer points. The reason for making any examination is, of course, to learn whether the patient is in labor; how far advanced the labor is;

and whether there is any malposition or disproportion.

It is not difficult to determine whether the head is high up or low down. Anyone can do this. If the cervix is not effaced it is readily felt through the bowel. However, if it is partially dilated and thinned out to the thickness of a knife blade it becomes a difficult matter to recognize it; but patience and perseverance even in these circumstances will often reveal the exact amount of dilatation. One first endeavors to recognize the thinnest area over the presenting part and then by gently thrusting the finger tip around in different directions one will be able to insinuate it beneath the rim of the cervix at some point in its circumference, and having done so to follow around its whole circumference. When the head is well in the pelvis it is not difficult to recognize the direction in which the sagittal suture lies. This information supplemented by the external findings, namely, the location of the small parts, the back and the fetal heart sounds will very definitely point to the position of the occiput. Thus in ninety per cent. or more of the cases one can get all the information that is needed in the conduct of a labor. By careful examination, when the head is low down, one should recognize the cranium, and in the event of another part of the fetus presenting, recognize that it is not the cranium. Thus a foot or hand is easy to recognize. It is more difficult to recognize a breech. The latter has been mistaken for a head both by vaginal and rectal examination. A face presentation by its irregularity and lack of rotundity should excite the suspicion of the examiner, so that if need be a vaginal examination can be resorted to. And in all cases, for whatever reason, when aid is to be invoked a thorough vaginal examination should be made. When the presenting part is high in the birth canal or movable above the brim, this fact is recognizable by rectal and external examination, although one would scarcely rely on such an examination for making a prognosis. When no advance is made, after a prolonged period of severe pain, sufficient to make an impress on the mother's or baby's pulse, then of course a vaginal examination would be in order before deciding on the plan of giving aid.

What advantage do we gain from this method? From the point of view of the patient, we avoid pushing any germs from the lower zone of the birth canal to the upper. An examination shortly before the completion of the second stage is less deleterious than repeated examinations over a period of twenty-four hours or more. From the doctor's viewpoint there is this to be said: There is no diversity of opinion as to the propriety of using sterile gloves, or in lieu of that, preparing the hands as if for an operation, or indeed of doing both when making vaginal examinations. This takes time and, in winter especially, is hard on the hands, and soon causes chafing or worse. Now if one adopts the rectal method of examination it is necessary only to put on a clean rubber glove—it need not be sterile—apply a lubricant and insert the finger into the rectum and thus acquire all needed information without loss of time, or skin

in scrubbing. By all needed information I mean that we learn that the labor is progressing normally or, on the other hand, that it is not progressing normally and some aid will have to be given. In the latter event, of course, we make a vaginal examination since we are going to work through the vagina.

CONCLUSIONS.

There is a distinct risk, in making vaginal examinations, of carrying up into the birth canal organisms which under favorable conditions may prove deleterious.

One can learn from a rectal examination all that is necessary to know in order properly to conduct a delivery in ninety per cent. of the cases.

From the patient's viewpoint this method does not go contrary to Nature's method of protecting the puerperal woman.

From the doctor's viewpoint it is attended with much less waste of time and trouble, and is therefore a procedure well worth the effort spent in acquiring confidence in it.

CÆSAREAN SECTION FOR ECLAMPSIA.*

By EDWIN G. LANGROCK, M. D.,
New York,

Assistant Visiting Obstetrician Harlem Hospital.

CASE.—The patient was admitted to the obstetrical service of Dr. Brodhead at the Harlem Hospital on November 23, 1919 at six p. m. Her age was twenty-one, and she was pregnant for the first time. She was in a state of coma and had had three general convulsions before admission, one convulsion while being admitted, and one twenty minutes later. From then until she was operated upon at 7:30 p. m., she had three more severe generalized convulsions, making eight in all. Her urine showed about two per cent. albumin and all varieties of casts and blood. Her blood pressure was 158 systolic. She was eight and one half months along in her first pregnancy. The baby was of moderate size and presenting with the vertex in the right occipitoanterior position. Her pelvis was ample in size. The patient was not in labor and her cervix was long, conical and closed.

Since the prognosis in eclampsia depends upon the earliest possible delivery of the baby, after the first convulsion a Cæsarean section was decided upon. At 7:30 p. m. the classical operation was performed. An incision six inches long was made in the midline one third above and two thirds below the navel. In making the incision it was noted that the abdominal wall was markedly edematous, the tissues being water logged. The remainder of the operation was easily performed and a living baby, weighing seven pounds, was extracted. In placing the sutures, twice the usual number of silk-worm gut retention stitches were taken on account of the condition of the abdominal wall.

*Case reported at a meeting of the Harlem Medical Society, February, 1920.

The patient was given the usual eclamptic treatment of hot packs, colon irrigations, etc. She had no convulsions after her operation and in forty-eight hours was conscious and rational. Her condition was excellent until the third day when examining the dressing it was found to be saturated with a brownish fluid, her temperature being normal, and pulse 106 the same as it had been since the operation.

On removing the dressing a mass of intestine was found on the abdominal wall. The patient was immediately taken to the operating room and anesthetized and the wound resutured. About two feet of small intestine had been extruded through the abdominal incision, six inches of which was adherent to adhesive plaster, with which the gauze dressing had been fastened to the abdominal wall. This was gently separated from the intestine by pouring ether over it. The intestinal mass everywhere covered by plastic exudate was replaced in the abdominal cavity and the wound resutured.

The patient left the hospital three weeks later with complete union of the abdominal wound, there having been no further difficulty except a small stitch abscess.

The patient's temperature was over 100° F. only once, and that was on the fifteenth day from some extraneous cause.

INTERESTING FEATURES OF THE CASE.

1. The treatment of the eclampsia by Cæsarean section, the patient having no convulsions after the delivery.
2. The edematous condition of the tissues in eclampsia which must be taken into consideration in placing the sutures.
3. The fortunate outcome of the case in spite of the possibility of peritonitis.

REPAIR OF INJURIES TO THE PELVIC FLOOR.

By W. CLOVIS CUMMINGS, M. D.,
Oklahoma City, Okla.,

Surgeon and Gynecologist to St. Luke's Hospital.

It is only within a comparatively recent period that the female perineum, its nature and functions, have been properly understood. In the study of human anatomy the female perineum has not received the attention that its surgical importance warrants. Most textbooks make its description secondary to that of the male perineum, emphasizing only the important structural differences. Probably this custom originated at a time when gynecology was little studied and operations were relatively much more frequently performed on the male perineum than on the female.

The pelvic floor is made up of skin, superficial and deep fasciæ, and muscles. The muscles are eight in number—two ischiocavernosi, two bulbocavernosi, two transverse perineal, the levator ani and the sphincter ani. These muscles blend with each other and form a complete muscular diaphragm, which fills the bony outlet of the pelvis. These muscles are still further strengthened by lay-

ers of strong pelvic fascia which bind them together and increase their power. The muscular elements which enter into the construction of the floor are its chief source of strength, and the levator ani is the most important of all muscles, as the support which is afforded to the pelvic viscera depends entirely upon its integrity.

If we compare the perineal region of a woman who has not borne children with that of one who has, a difference is at once noticed. A difference exists even though there has been no visible tear in the second woman or only a tear which has been treated by the usual primary operation. If the nullipara is young and a virgin it will be seen that the anus is well forward and that the perineal body is short in its ventrodorsal diameter. In a woman who has given birth to a child the anus is always displaced dorsally. If the perineal body is superficially intact the ventrodorsal diameter will be greatly lengthened; if torn, the perineal body will be shortened, the mucous membrane everted, and the vulva will gape. If torn and repaired primarily, the perineal body will be lengthened ventrodorsally and, therefore, shortened vertically. The dorsal displacement of the anus is a constant deformity. There are three types of injury of the pelvic floor: superficial median tears, median tears involving the sphincter ani, and lateral tears involving the vaginal sulci.

SUPERFICIAL MEDIAN TEARS

A superficial median tear extends in the median line from the fourchette either backward toward the anus or upward into the vagina or both. It splits the tissues between the posterior border of the vulvovaginal orifice and the anus, and occasionally extends internally an inch or more up the posterior wall of the vagina. These tears are of no practical importance as the integrity of the levator ani muscle is not damaged nor destroyed. Occasionally, however, the cicatrix which is formed may become irritable and cause local tenderness and reflex disturbances.

MEDIAN TEARS

Median tears involving the sphincter ani extend backward in the median line from the fourchette through the sphincter ani muscle, and in some cases may continue up the rectovaginal septum for a distance of an inch or more. Sometimes all the fibres of the sphincter are not completely divided and the appearance of the tear may be deceptive. These tears permanently destroy the function of the sphincter muscle. The levator ani muscle is not torn and consequently the supporting power of the pelvic floor remains unimpaired.

LATERAL TEARS

Lateral tears involving the vaginal sulci extend from the fourchette up into one or both of the vaginal sulci and are usually accompanied by a superficial median tear toward the anus. This laceration is, as a rule, bilateral, though in rare cases the injury may occur on only one side of the vagina. In this type of laceration the function of the levator ani muscle is destroyed and the pelvic organs, as well as the terminal ends of the urethra, vagina and rectum, are no longer supported or maintained by the pelvic floor. As a rule involution of the uterus and vagina

is arrested and in time the uterine ligaments as well as the pelvic connective tissue become elongated and stretched, resulting in prolapse of all the pelvic organs.

The treatment of lacerated perineum and of injuries to the pelvic floor is exclusively surgical. Unless the condition of the patient is a contraindication, immediate repair of all lacerations should be made within twenty-four hours of delivery. A physician who attends a case of labor is grossly negligent if he fails to make a careful inspection of the pelvic floor as soon after delivery of the child as is consistent with the safety of the mother.

It is with unrepaired tears of the third variety that this paper is concerned. An operation which has proved satisfactory is performed as follows:

A U or V shaped or transverse incision is made along the mucocutaneous line. The scar tissue is removed by denudation with the scissors to allow access to the deeper and more important structures. In inserting the scissors care must be exercised to keep the points pressed against the vaginal wall. By delicate manipulation with the scissors, or perhaps better with the gauze covered finger, the plane of fascia separating the vaginal and rectal walls is found and the underlying tissues are quickly rolled off the vaginal wall so as to expose the two walls. The tissues are easily and safely separated as far as desired without producing any bleeding. The flap should now be elevated and care should be used to see that the dissection extends sufficiently high on either side to expose the upper border of the levator ani muscle. The layer of veins is the guide to safety and one should keep within the line of cleavage so as to avoid injuring the rectum.

The method of introducing the sutures is no less important than that of denudation. The wound is preferably closed in two layers. The first row of sutures approximates the levator ani muscle and fascia in the median line. Each suture should include deep bites of the muscle and fascia on either side. This puts the muscle and fascia on either side on tension and brings them into view, thus giving a broad surface for approximation by figure of eight sutures. The second row of sutures unites the mucous membrane and skin down into the muscle and fascia. The wound is closed by running sutures, locked at intervals. Twenty-day chromicized catgut should be used for approximation. Where this is not available, tension sutures of silk-worm gut should be employed. Care should be taken to keep sutures and scar tissue from the immediate vicinity of the vulvovaginal glands. Otherwise a hypersensitive and troublesome scar or cyst formation may result.

235 AMERICAN NATIONAL BANK BUILDING.

Rôle of the Ovary in the Female Organism.—Alfred Labhardt (*Schweizerische medizinische Wochenschrift*, May 6, 1920) uses much space to say that the influence of the ovary on the general condition of the body is much less than that of the other endocrine glands, yet this influence is great, not only on the genital system, but also on the entire organism.

THE FEMALE PELVIC URETERS.*

BY DAVID W. TOVEY, M. D.,
New York,

Adjunct Professor of Gynecology, Polyclinic Medical School and Hospital, Gynecologist to Harlem Dispensary.

Palpation of the pelvic ureters should be a part of every vaginal examination. During examination there is nothing between the fingers and the ureter but the vaginal wall. The ureters can be felt from the bladder to the pelvic brim. At the New York Polyclinic Hospital it was easy to teach students to palpate the ureters, after they had learned their position, by inserting ureteral catheters into them.

The ureters are an inch apart in the trigone, about an inch behind the internal urethral opening, and two inches behind the external meatus. They are about two inches apart at their entrance into the bladder, where they run through the bladder wall for three quarters of an inch. These points are about half an inch in front of the cervix on the anterior vaginal wall, and about an inch from the crossing of the ureter by the uterine artery. After leaving the bladder the ureters curve over the anterior vaginal wall and lateral fornix, to a point half way between the lateral border of the cervix and the pelvic wall, where they are crossed by the uterine artery on a level with the internal os, about an inch from the lateral border of the cervix, two inches from the ureteral openings. From the point of crossing, the uterine artery accompanies the ureter for one or two inches through the base of the broad ligament, to a point on the pelvic wall just above the spine of the ischium, where they turn upward on the pelvic wall covered by peritoneum, sometimes in front and sometimes behind the internal iliac to the pelvic brim, where they leave the pelvis through the infundibular pelvic ligament behind the ovarian artery. The right ureter is more often in front of the division of the common iliac, the left one behind it. The ureters are often outlined on the anterior wall by the ureteral ridges. In 1880 Pawlick catheterized the ureters using the ridges as landmarks.

TECHNIC OF PALPATION

To palpate the ureter from the bladder to the base of the broad ligament to orient the position imagine a line from a point, about half an inch in front of the cervix, to a point half way between the lateral border of the cervix and the lateral pelvic wall. The point half an inch in front of the cervix where the ureter enters the bladder, varies with the position of the cervix. The point half way between the lateral border of the cervix and the lateral pelvic wall, is where the uterine artery crosses the cervix and is fixed.

The vaginal fingers are introduced into the anterior lateral vault of the vagina. Counterpressure is made downward through the abdominal wall. The fingers are drawn forward. As the tissues slip through the fingers, the ureter is palpated as a flattened cordlike body, smaller than a goose quill, displaced in its bed of loose cellular tissue, as it slips through the fingers. It can be rolled from side to side under the palpating fingers by moving

the fingers toward the bladder, or toward the broad ligament. The ureter is felt from the bladder to the base of the broad ligament. Posterior to the broad ligament it is felt just above the spine of the ischium, covered by the peritoneum, to the pelvic brim, by palpating it against the pelvic wall. It may run as high as an inch above the ischial spine. Judd (1) advises sweeping the fingers above its location, bending the fingers as in picking a guitar. In the latter part of pregnancy the ureters do not follow the pelvic wall to the spines of the ischium, but after accompanying the internal iliac artery they pass beneath the broad ligament just below the pelvic brim.

EXAMINATION OF THE URETER BY RECTUM

The finger is inserted to the bifurcation of the iliac artery, which is located and traced downward with the tip of the finger. The palpation is done behind, at the side, and in front of the artery. The ureter can be followed in its course until it passes under the broad ligament. The normal ureters never cause pain. If diseased, they are enlarged from the size of a goose quill to that of a lead pencil, or larger; if tender, pressure brings an intense desire to urinate. The tuberculous ureter feels like a string of beads. Calculus, pyelitis, tuberculous kidney, gonorrhoea, cervicitis, lacerations, and infections from the cervix cause urethritis, periureteritis and stricture, and because of the nerve plexus of the abdominal sympathetic, pain is diffuse and causes symptoms in adjacent abdominal viscera, bladder, uterus, ovary, appendix, stomach, gallbladder and other organs. If irritation passes over the intercostal nerves, pain in the abdominal wall results; if over the lumbar plexus, pain in the inguinal hypogastric and external genital regions; over the sacral plexus, pain in external genitals, rectum, thigh, legs; the uterine plexus where artery crosses ureter, pain in uterus; ovarian plexus to ovaries, gastric to stomach, mesentery to intestines.

Bladder symptoms following hysterectomy, in which the cystoscope shows a normal bladder, are due to ureteritis and not to cystitis. Sanger in 1886 reported cases of ureteritis treated for long periods as cystitis. Judd reported a case of early pregnancy with ureteritis and spotting, which was mistaken for ectopic pregnancy. Hunner has reported a large number of strictures of the lower ureter, which were mistaken for all sorts of abdominal conditions. The Mayos report that most of the cases of kidney and ureteral stone which they encountered have been mistaken for other abdominal conditions and the patients operated upon for disease of the stomach, gallbladder, ovary or appendix. Kelly (2) states that gonorrhoea is a common cause of ureteritis and stricture.

Chronic pyelitis and ureteritis cause stricture of the ureter followed by hydronephrosis if the condition is not treated. Ureteritis due to lacerations and infections of the cervix, if treated early, will not result in strictures. In patients treated for various abdominal disorders the condition is made clear by palpation of the pelvic ureter.

EXAMPLES OF CASES.

CASE I.—R. J., aged thirty-five. Since the birth of her child five years ago, the patient had had pain

*Read before the American Association of Obstetricians and Gynecologists, Atlantic City, N. J., September 21, 1920.

in the left side of her abdomen and back, which had been very severe at times, and had also complained of frequent urination, which was painful. She was advised to have her ovaries removed, and had been treated for constipation, cystitis, ulcer of the stomach, and various other things. The examination showed the pelvic organs to be normal, the cervix was lacerated, eroded, and infected. The left ureter was enlarged and very tender; palpation brought intense desire to urinate. The injection of collargol showed the ureter to be slightly dilated just over the bladder and the kidney pelvis slightly dilated. Pain was relieved after ureteral catheterization.

CASE II.—A. G., aged sixty years, a patient of Dr. Wells; sent to New York Polyclinic Hospital. Patient complained of acute pain in right side of abdomen over gallbladder region, which was tender and rigid over right abdomen; half a grain of morphine brought only partial relief. An examination showed that the right ureter was enlarged, tender, and very sensitive, and a small stone was felt just above the bladder. Cystoscopic examination showed the right ureteral meatus to be red and swollen, and the catheter was obstructed at two cm. above the

FIG. 1.—Sagittal section of the female pelvis, showing bimanual palpation of lower end of ureter.

bladder. An injection of collargol disclosed a small stone in the pelvic ureter with ureter dilated above it; the kidney pelvis was moderately dilated. The patient was relieved immediately after examination and four days later a gallstone the size of a shoe button was passed.

CASE III.—G., aged thirty years, single. The patient had pain in the right abdomen, suffered from indigestion, and was sent to the hospital to have the appendix removed. Examination showed the pelvic organ to be normal; the right ureter thickened and tender, and pressure brought desire to urinate. Injection of collargol showed stricture just above the bladder, dilatation of the ureter above it, and small hydronephrosis. The patient was cured by dilatation of the ureter.

CASE IV.—R. S., aged twenty-two years; married four years, has one child three years old. The patient had had three miscarriages brought on by a midwife; was operated on two years ago for gall-

stones, and again a year later for adhesions of gland, bladder. She complained of pain in the right abdomen, backache, which was worse on walking, and had frequent urination and profuse leucorrhoea. Examination showed that the right ureter was enlarged and tender and palpation brought on a desire to pass urine. The cervix was found to be eroded and infected. Collargol injection showed that the ureter was slightly dilated above the bladder. Treatment of the cervix and vault of the vagina brought relief.

CASE V.—A patient of Dr. Wells, aged thirty-two years; married, with one child five years of age. Last menses had been three months before, at which time she suffered severe pain in right ovarian region, which was accompanied by spotting. The patient was sent to the Polyclinic Hospital for operation for ectopy. Examination showed the uterus to be enlarged and that she had been pregnant for three months. The right ureter was enlarged and very tender, and pressure caused the desire to pass urine. Treatment of the vault of the vagina, urotropin, and lavage of the kidney pelvis brought relief.

CASE VI.—K., aged forty years. Patient had fever, chills, and a tumor in the right side of abdomen, diagnosed by different men as gallbladder and ovarian cyst. Frequent urination was also present, and at times there were blood clots in the urine. These were attributed by different physicians to an inflamed ureteral meatus. Examination showed that the right ureter was much enlarged and tender, and a cystoscopic examination showed that the bladder was normal and the right ureteral meatus reddened and contracted. An injection of collargol revealed a soft stone in the kidney pelvis about the size of a plum, which had not been shown by the x ray. The large pus kidney with a very soft stone was removed.

CASE VII.—I. R., aged twenty-five years; married three years. The patient complained of pain in the right side which was made worse by walking, of indigestion and of constipation. The appendix had been removed without giving relief, and the patient was told to have the ovary removed. Examination showed that the right ureter was enlarged and very tender and palpation caused an intense desire to pass urine. A small, hard mass, believed to be a stone, was felt at the entrance of the ureter into the bladder. The cystoscope revealed a small reddish brown stone sticking out of the ureteral meatus. An x ray showed that there was a stone half an inch long at the entrance to the bladder. A few days later, the x ray revealed a stone two inches higher up in the ureter. At the first examination it was impossible to dislodge this stone, but upon dilating the ureter the stone passed.

CASE VIII.—M. K., aged thirty-seven years. Another surgeon operated on the patient two years ago for tuboovarian abscess. For the past year there had been pain in the left kidney and abdomen, frequent urination—every half hour at night—and the pain had been most severe lately. Examination showed that the uterus was slightly fixed and the left ureter thickened and tender. Palpation brought on intense desire to urinate, and there was pain in the left kidney region. Cystoscopy showed that the left meatus was contracted and retracted, and the

atheter was obstructed at six cm. from the bladder. The ureteral meatus contracted, but no urine passed. An operation was performed and a small hydronephrotic kidney, lined by thickened membrane, was removed.

CASE IX.—J. M., aged thirty-five years. Since the birth of her last child, three years ago, the patient had suffered from indigestion, pain over the right kidney and right abdomen. Frequent and sometimes painful urination was present at times. She was treated for cystitis and advised to have the appendix removed. Pain in the region of the ovary was present during the menstrual period. Examination showed that the pelvis was normal, and the right ureter enlarged and tender. Palpation caused intense desire to urinate. The cervix was lacerated, eroded and infected. The cystoscope revealed a normal bladder and collargol injection showed the ureter to be dilated three inches above the bladder. Treatment was given to the cervix and vault of the vagina.

THE VALUE OF ABDOMINAL EXERCISES BEFORE AND AFTER DELIVERY.*

By H. KOSTER, M. D.,
Brooklyn, N. Y.,

Assistant Gynecologist and Obstetrician, Kings County Hospital;
Adjunct Gynecologist, Beth Moses Hospital; Associate Gynecologist and Obstetrician, Bikur Cholim Hospital.

Considering the enormous amount of attention paid to the development of prophylactic measures in gynecology and obstetrics, it is rather surprising that so little work has been done in the direction of improving the tone of the abdominal muscles; particularly so, when it is universally conceded that the element of muscular activity, as a factor in the mechanics of labor and in the maintenance of good health at all other times, it is a matter of utmost importance.

Everyone is familiar with the flabby, flaccid, pendulous abdominal wall, which cannot be counted on as an asset during parturition, and which is distinctly a liability during the nonparturient period, being a causative factor in the production of ptoses of the abdominal viscera. During labor such an abdominal wall plays a negligible part in assisting the expulsive activity of the uterus; indeed, in many instances the relaxation encountered is so great that it allows of marked deviation of the uterus from the axis of expulsion. At all other times, a wall of this character offers no support to the abdominal viscera, the continued absence of this support ultimately resulting in the acquired form of visceral ptosis.

Remembering that the abdominal walls of the type previously described belong almost always to multiparæ, and also that not all women who have born children have visceral ptoses consequent to re-

laxed abdominal walls, the quest for the causative factor narrows down to the relation of the amount of strain to the quantity and quality of muscle.

In the normal state the muscles extending from bone to bone are slightly stretched. This state of elastic tension insures a more prompt and effective contraction, as

shown experimentally by the fact that the amount of rise of a lever to which a muscle is attached, when excited by an electrical stimulus of definite strength, is greater when the muscle is placed under tension

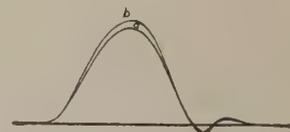

FIG. 1.—Record of contraction of frog's gastrocnemius muscle; myogram, a, muscle not weighted; myogram, b, muscle carrying a load of five grams.

by adding a slight weight, than if no weight is added (Fig. 1). Muscle is extensible and perfectly elastic within limits. The extensibility of muscle for successive equal increments of weight gradually decreases, approaching zero as a limit. Before that limit is reached, removal of the weights results in a perfect elastic recoil. If the weight is increased beyond the zero limit, which is also the elasticity limit, the amount of extension then increases with increasing increments of weight up to the rupture point, and elastic recoil from beyond the elasticity limit is not perfect (Fig. 2).

Frequently an abdomen is seen, the wall of which is under tension only while the woman is in the upright position. When she is placed in the dorsal recumbent position, the loose redundant wall spreads over the flanks and the pubes. It is evident that the tonus in these muscles is low and also that they have previously been stretched beyond their elastic recoil limit. That wall does not support the abdominal viscera, and is one of the most frequent causes of the acquired form of visceral ptosis. A saggital section of the body shows the outline of the abdominal cavity to be somewhat pearshaped with the large end uppermost. The posterior wall, consisting of the psoas muscle and a fat pad, is inclined backward from below upward at an angle of about fifty degrees, and it forms a padded shelf which helps to support the organs of the upper abdomen. Its value, however, depends upon a firm anterior abdominal wall, because the inclination is so steep that unaided by any other force than the mesenteric attachments the heavy organs would tend to slide downward. The force of the anterior abdominal wall being exerted inward

and that of the posterior wall diagonally upward, the resultant of the two forces is applied in a direction best calculated to give support (Fig. 3).

Recognition of these facts has resulted in palliative efforts through the use of various anterior rein-

forcements, pads, and bandages, with considerable success. Such relief, however, is not permanent. When the mechanical support is removed, the symptoms recur because nothing has been done to strengthen the muscles which have lost their natural elasticity after having been subjected to a period of increasingly forcible extension, exceeding the

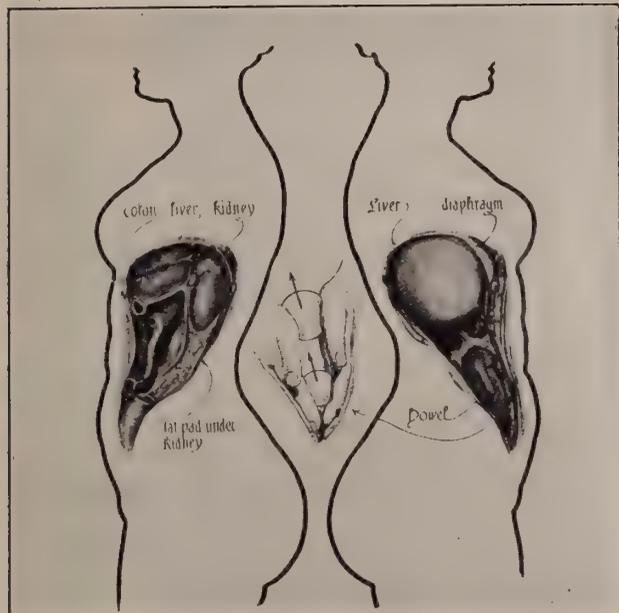

FIG. 3.—Support of the organs of the upper abdomen by the abdominal wall.

limit of physiological extensibility with perfect elastic recoil.

The careful analysis of obstetrical case records yields as one of the conclusions the belief that many forceps deliveries might have been avoided by the application of a tight abdominal binder. The proper development of the muscles of the abdominal wall before pregnancy will obviate the use of an abdominal binder. If the tone of these muscles had been raised sufficiently before pregnancy, the wall would yield less readily and less completely to the gradually increasing pressure of the enlarging uterus, and their synergistic rhythmic contractions during the uterine expulsive efforts would furnish valuable aid. A point in the improvement could also be reached which would allow a margin of extensibility beyond that encountered in the parturient period without reaching the elastic recoil limit, and thus insure perfect elastic recoil.

Progressive muscular exercise can raise the quality of muscle to a higher standard of efficiency. That the elastic tension of any muscle may be increased by exercise, has been demonstrated beyond controversy. This is well exemplified in the partial flexion during rest of the forearm of the blacksmith, and the great degree of flexion of the phalanges of the trained weight lifter or the day laborer. Before maternity, therefore, the abdominal muscles should be prepared for the expected strain by raising their power through progressive exercise, increasing the limit of extensibility with complete elastic recoil, beyond the amount of extension encountered in pregnancy. In the case of muscles already relaxed, their tone must be increased and a

corresponding diminution in muscle length obtained, to secure a wall which will offer resistance to the tendency of the viscera to prolapse, and which will also be a valuable aid in subsequent pregnancy.

An exercise is here suggested which is ideal, inasmuch as it meets with all requirements regarding results, is capable of universal application because it can be practised at home without apparatus, and presents a wide range of gradation of effort necessary for its accomplishment, thus making it applicable to individuals having different strengths of abdominal walls.

With the patient lying flat on her back, the entire lower extremities from the hips down, acting like a single lever, are flexed on the abdomen to a line perpendicular to the resting surface, and then lowered (Fig. 4). Throughout the exercise there should be no flexion at the knee joints. This movement should be repeated as many times as possible and the number noted, at each succeeding trial, strenuous effort being made to increase the number of movements. This exercise should be practised in the morning, before dressing, or at bedtime, the former, however, being preferable, as it is then not superimposed on the arduous labors of the day.

When the exercise is first attempted, the average woman will find difficulty in repeating the manœuvre twenty-five times without pause, but it is astonishing to note the rapidity of increase possible, and the concomitant improvement in muscular tone. For the flabby, muscularly unfit woman, who might not be able to perform the exercise properly even once, the simple modification of allowing slight flexion at the knee joints, brings it within the range of her possibilities, and in her case, the first aim of progression should be the development of enough power to perform the exercise without flexion. An expen-

FIG. 4.—Flexion of lower extremity on the abdomen.

diture of no more than four minutes is necessary for the performance of the movement one hundred consecutive times, which is all that is needed ultimately to develop a firm, elastic, supporting wall. There is no reason why the abdominal muscles of woman should not be at least as well developed as those of man, and the faithful performance of the movement described above, daily for the period of a year, will develop in woman an abdominal wall similar to an anatomical cut.

With renewed interest, on the part of the specialist in diseases of women, in the development of the abdominal muscles, the indication for the use of forceps, pituitrin, and the abdominal binder will arise less frequently, and one of the etiological factors in the acquired form of visceral ptosis become negligible.

PERIODIC HEADACHES OF OVARIAN ORIGIN.

BY GEORGE KNAPP ABBOTT, A. B., M. D.,
Sanatorium, Cal.

In the fall of 1916 a married woman aged thirty-eight years came to me, seeking relief from headaches. This patient was a second wife, having two children of her own. The headaches of which she complained dated back over many years, but had become very troublesome only in the last few months. They were coincident with the menses, beginning slightly before and lasting five to seven days. Sometimes a less severe headache would appear half way between her periods. The headaches were always exaggerated by social responsibilities, and by art work in which the patient engaged considerably, although these factors never provoked headaches at other times. On further questioning the fact was elicited that these headaches were entirely absent during pregnancy. Here is a patient whose headaches are definitely associated with the menstrual function, who has no headaches when that function ceases because of pregnancy and who has recurrence after its termination. Some chemical or possibly some hormonal change is obviously implicated in, and is possibly the cause of, these headaches.

What holds them in abeyance during pregnancy? Is there in this patient some endocrine deficiency periodic in recurrence, during the nonpregnant state which is fully supplied during the period of gestation? My attention was at once centered upon the production of the corpus luteum as the possible and probable explanation of this phenomenon. So definite and suggestive was the history that I immediately determined to administer dried corpora lutea. Five grains of a standard product was given in capsule form three times a day. The patient was instructed to continue this until a perceptible result was obtained and after that to reduce the dose for the next two weeks after each period, but return to the full dose twelve to fourteen days prior to the period. After three months the patient returned, reporting that the headache occurring with the first menses after beginning treatment was not so severe as usual. The second one was but slight, and there was no headache at all with the third period. The patient did not come again for five or six months. At this third visit she reported that she had stopped the medicine entirely after the third month of treatment and that she had no headaches for about three months more, when a recurrence took place and the medicine was resumed.

For a few times she took the medicine before each period and has had no headaches since the first recurrence. Over two years from the begin-

ning of treatment the patient reported that she had taken no capsules for a year and had had no menstrual headaches.

Since treating this first patient I have treated about twenty-five women with headaches of this type. The results have been highly gratifying. With the majority of patients, however, it seems to be necessary to repeat monthly a brief course of corpora lutea prior to each menstrual period. Some require larger doses than others and for a longer time before the menses. The treatment has never provoked an increased flow or any other untoward symptoms. One patient about thirty-nine years of age, who had had menstrual headaches for many years, summed up the result of three months' treatment by saying, "Life is now worth living. I wish I could have had this years ago."

A trained nurse who had three children took the corpus luteum negligently for two months and stopped it, feeling she received little benefit commensurate with the expense. Later her headaches returned with the usual severity and she resumed the medicine, obtaining by more continuous dosage full satisfactory results, although when last heard from she had to take the capsules every month.

Having spent about twelve years in institutional work, where I came in contact with many forms of chronic headache, and having seen these cases treated on the supposititious etiology of autointoxication and Haig's uric acid diathesis by most thorough and rigid dieting, eliminative hydrotherapy and everything else a sanatorium régime could bring to bear upon such cases, all with very slight or no results at all, I naturally became very sceptical of the possibility of benefit from any form of therapy. The result of corpus luteum feeding has been so uniformly satisfactory and the apparent physiological basis so definite clinically that the results seem to be well worth recording. A specialist has assured me that there is, up to this time, nothing at all recorded in the literature along this line in the treatment of periodic headaches.

In order to obtain definite results the cases must be carefully selected, discarding all that do not fall under the definite symptomatology and course outlined below. This type of headache always occurs, in the first place, with some definite time relation to the menses. It may be during the period only. It may begin a few hours or even a week before the period. In some cases it always comes after the close of the menstrual flow. However, these latter cases are less common and in my experience give somewhat less complete results. In some patients an intermenstrual headache occurs with quite definite regularity and in others it is both menstrual and intermenstrual in time.

These headaches, which for want of a better designation I have called periodic headaches of ovarian origin, never occur during pregnancy. This feature has been absolutely uniform in those women who have borne children or who have had children since the inception of this type of headache. This was especially definite in the case of one patient who had had four children and in whom the headaches were very severe and of many years' standing. During pregnancy she was free from headaches.

A third feature of these headaches is that they become worse as the patient approaches the menopause and reach their maximum with the usual height of the nervous symptoms of this period of life. Some patients are not troubled until after their thirty-fifth year. Others give a history of such menstrual headaches from puberty or within a few years thereafter. In two or three cases severe headaches antedated puberty by five years or so, and after puberty seem to become merged in the menstrual headaches and appear thereafter largely to be of this type. Such patients have headaches at other times than those which bear a definite time relation to the menses. These latter, however, are never missed.

Periodic headaches of ovarian origin cease after the full completion of the ovarian atrophy of the climacteric. The cessation of such headaches will therefore occur after the operative removal of the ovaries for any cause whatsoever and will be very materially hastened by proper dosage of x ray or radium.

When very severe, this type of headache is usually accompanied by nausea and vomiting, beginning several hours after the onset of the headache. For this reason women often speak of them as sick headaches. Care should be observed that this does not lead to confusion with other forms of headache associated with nausea or vomiting, or both.

In connection with the subject of periodic nervous disturbances of apparent ovarian origin, the history of the following case now under treatment may be instructive and possibly offer a suggestion for the endocrine therapy of other nerve disturbances associated in certain cases with the periodic function of the ovaries or uterus.

CASE.—A single woman, thirty-two years of age, with negative family history as regards nervous or mental disorders, gives the following personal history. She was well up to nineteen at which age the catamenia began. These were regular at a twenty-eight day interval and of three day type. With each period she suffered from severe headaches and pelvic pain, both of two weeks' duration, beginning one week before and lasting one week after the period. For twenty-four hours at the beginning of the menses the pelvic pain was extremely severe. There was a free interval of two weeks. This programme continued for four years, when convulsions began to occur from one to four times during the week of headaches preceding each period. The convulsions became worse during the next four years. The left ovary was found to be cystic and was removed. Its size was almost that of an orange. The patient was then twenty-seven years old. For nearly three years following this operation the patient was free from headaches and pelvic pain and had no convulsions. She then had convulsions at two different periods, after which the right ovary was removed. It was reported that this ovary was not cystic. This was in the patient's thirtieth year. She was then again free from all symptoms for two years until August, 1919, when the same symptoms—headache, pain and convulsions—reappeared, though in milder form than before. The latest symptoms have been of two weeks'

duration, periodic in recurrence, which is four weeks from the beginning of one to the beginning of the next. She has had no menses since two years ago, when her second ovary was removed. When the time came for a third attack of this series she rested in bed one week and all symptoms were absent except pain in the right side centering about McBurney's point. Her appendix was removed at the second operation, but examination shows marked tenderness in this region.

Treatment with five grains of corpus luteum three times a day was begun and the patient ordered to rest with each periodic recurrence of the former menstrual dates. August 31st, one month from the beginning of treatment, the patient reported that she passed an entire week at the usual period without symptoms. She had rested as much as possible, which, however, was not in bed nor at all complete. The side was still sore. In September, four examinations revealed tenderness slightly internal to McBurney's point and above along the approximate course of the right ureter. As the urine showed pus hexamethylenamin and monobasic sodium phosphate were prescribed.

In October the patient had a convulsive attack not observed by anyone. She has not followed the prescribed rest, but has worked fairly steadily as usual. In January, 1920, an attack occurred which lasted a few minutes only. A friend reported that the attack in May, before treatment was begun, lasted about forty minutes, i. e., that the twitching of the muscles continued during that time. The July attack, also before treatment was begun, lasted twenty minutes. In addition to having attacks of lesser severity and shorter duration, the patient reports that these last attacks, since beginning the corpus luteum, have left her feeling well and ready for work without headache, whereas prior to this the three attacks at the first of this series ended in a headache and several days of indisposition. It will also be noticed that while a monthly periodic disturbance with headache and pain still occurs, the convulsions have not occurred every month, but when they have appeared it has been bimonthly both before and since treatment was begun.

From January to October, 1920, the patient has had but one convulsion. This was a very mild one without aftereffects. It occurred at the beginning of a menstrual date which had been preceded by a two hours' session in the dentist's chair. With this exception there have been none of the usual symptoms for nine months. The patient feels better and works regularly, usually eight hours a day. She continues to use the corpus luteum three times a day.

There are several interesting questions that may be propounded regarding this particular case: 1. What structure in her body maintains her periodicity of symptoms exactly coinciding in time with her former menses? 2. To use endocrine phraseology, did she not have an ovarian struma with dysovarianism or hypoovarianism? 3. Was the epilepsy directly due to any endocrine disorder or only to excessive nerve irritation arising from severe headaches and pelvic pain? 4. Were not the headaches of the same type as those under discussion, viz., periodic of dysovarian etiology?

tation through the mail as second class matter.

NEW YORK, SATURDAY, NOVEMBER 6, 1920.

A NEW ERA IN GYNECOLOGY.

It is not so far back that the study of gynecology assumed enough importance to rank as a specialty. With the coming of each specialty some of the more farsighted were fearful that the person surrendered to the care of the specialist for diagnosis and treatment would cease to become an individual and would go through the stages of being a patient, a case, and finally go down into the records as a history number; the features of the malady which were of especial interest to the specialist would help swell the statistics and these would be added to the formidable list with which he was armed. These statistics, when brandished before the less fortunate practitioner who seldom saw more than a few of the variants of certain maladies, did much to overawe him. The specialists increased. The fields became ever more narrow and those philosophers found among medical men from time to time shook their heads dolefully as they saw this change and witnessed the passing of the individual, while the microscope was trained upon the patient. The patient was measured and weighed in the laboratory and with the focusing of the picture on a small detail the entire background of the patient's personality, makeup and environment was blurred. The operations were more and more successful, but was the patient benefited?

With the growth of the specialty of gynecology came other specialties in other fields. Psychiatry grew by leaps and bounds and established itself on a more substantial basis, with the possibility of the

exploration of the unconscious made possible by the work of Freud. Endocrinology, entrusted for a time to the laboratory, more recently has been invading the wider field of practical therapy. Once the results of its application were seen, the new science flourished like a flower allowed to see the sun, and yet these studies are practically in their embryonal form. Then Adler [*The Study of Organ Inferiority, Nervous and Mental Disease Monograph Series*] presented his most valuable hypothesis of organ inferiority and the various psychical and physical compensations which took place.

Now, the question may be asked, What has all this to do with the new era in gynecology? The answer will be found in the splendid paper by Graves in this week's issue of the NEW YORK MEDICAL JOURNAL, in another paper by Bandler which will appear in next week's issue, and in other papers by him which we have been fortunate enough to publish. Other papers which appear in these special gynecological numbers show signs of this new movement. These men have begun to realize how important it is to look upon the patient as an individual, to consider the general background and the endocrine status of the patient. They have begun to realize that many factors must be considered when an attempt is made to find the cause of a disordered cycle of menstruation. The pituitary, that tiny gland which controls the rhythmicity of bodily functions and the appreciation of rhythm, may be at fault. Psychic disorders originating in unfulfilled wishes, which seek a somatic outlet as a manifestation, may be causing havoc. Or the body may be marshalling its armies of defense against an anemia which in turn may have any one of many causative factors.

This is only given as an example. The lesson may be carried on to every branch of the complex specialty of gynecology. A few of the more progressive men have realized the importance of considering all the factors which may enter into a given case. First of all, the entire picture must be in focus, then the finer details may be explored and elaborated. If necessary a part of a patient may be sent to the laboratory as an aid in diagnosis, but the patient as an individual must always be before our eyes. For this reason the philosophers who prophesied that the specialists would find themselves in blind alleys may be reassured. The work of synthesis has begun before analysis became too minute. The architect must know the strength of each beam and girder, but he must not lose sight of the structure as a whole.

RICKETS AND THE VITAMINES.

Rickets is one of the diseases believed by many investigators to be due to a deficiency of the vitamine element. There is, however, another band of observers who believe in the prime importance of defective hygiene in its etiology and yet others who hold the theory that the condition is brought about, not only by a deficiency or lack of vitamins but by a deficiency of certain articles of diet which produces ill balanced metabolism. Hess and Unger undertook a series of clinical experiments, the results of which were published in the *Journal of the American Medical Association*, 74, 1920, which appear to show that deficiency in the fat soluble vitamine has little to do with the causation of rickets.

In a paper read before the British Medical Association recently, Dr. F. Gowland Hopkins, professor of biochemistry in the University of Cambridge, subjected these experiments to criticism. He remarked that though they were of considerable importance, they failed to set the question at rest and he was struck with the exceptional constitution of the diet upon which infants were placed when it was intended to create a vitamine deficiency. He pointed out that in respect of rickets developing in the infants when they were placed on an apparently normal fat supply, no full analysis of the cases was given. Only two cases were mentioned in detail. The most striking of these, one in which rickets developed in the child while it was on a very full supply of whole milk, showed at the same time some added abnormality because the generous milk diet, with the addition of spinach, failed to produce growth.

Hopkins thought it was noteworthy that the rickets was cured and growth became normal when at the thirteenth month codliver oil was added. On the other hand the five children in whom rickets did not develop, although their food was presumed to be highly deficient in the fat soluble vitamine, were given a diet of an extremely high total caloric value, containing, together with a vegetable fat, a large daily ration of a skim milk powder. Hopkins was of the opinion that to contrast the nutritive effects of skim milk, fortified with vegetable fat, with those of whole milk, was doubtless a legitimate method of testing the influence of the fat soluble vitamine, so long as both milks were administered in normal amounts. But he drew attention to the fact that skim milk was by no means free from the so-called fat soluble substance. He had experimental evidence to show that highly separated milk contained an amount decidedly in excess of what the residual fat would seem to indicate. When, then, so large an amount as 180 grams of a milk powder, equal to

nearly two litres of the original milk, was daily administered, as in Hess and Unger's experiments, in infants aged from four to nine months, the supply of the fat soluble vitamine was far from being negligible. Therefore, Hopkins deemed that valuable as this clinical study might be, he did not think it brought evidence that was final.

It does seem certain, that the more investigations undertaken to determine the causation of rickets, the clearer it becomes that more than one factor is concerned in its causation. Too great stress has been laid on the vitamine element, just as too much emphasis has been placed on defective hygiene in the etiology of rickets. Each plays a part, and the dietetic factor is not confined to the vitamine content of the food. The point that requires study now is the relative importance of each factor.

 PHYSICIAN-AUTHORS: DR. OLIVER
GOLDSMITH.

It requires a stretch of the imagination, perhaps, to include Oliver Goldsmith in a list of author-physicians, for the truth is that Goldsmith's medical skill was of a low grade, and as for patients, the records show he never was able to get any worth mentioning. "I do not practise," he once said; "I make it a rule to prescribe only for my friends." "Pray, dear doctor," said Beauclerk, "alter your rule and prescribe only for your enemies." Goldsmith took up medicine only after he had failed at several other professions—including the ministry, the law and teaching. He spent eighteen months at the medical school of Edinburgh University and about the same length of time at Leyden University. As an indication of how much of that time he devoted to study it need only be mentioned that some time later when he presented himself at Surgeons' Hall for examination for the humble position of "mate to an hospital" he was unable to pass. Goldsmith laid claim to having received a medical degree somewhere on the Continent—but not at Leyden. If so, no one has ever been able to find a record of it. When he left Leyden he rambled through Flanders, France, Switzerland and Italy playing a flute for his meals. When he returned to London he tried to build up a practice but failed miserably. Instead, he became a strolling player, and the life of a strolling player in those days was a dog's life indeed. Later he pounded drugs and ran errands for chemists. A friend once got him a medical appointment in the service of the East India Company, but this was speedily revoked when it was found that he was incompetent and wholly unfitted to do the work.

And yet, in spite of all this, Oliver Goldsmith prided himself on his medical knowledge and, even after his literary successes, preferred to be known as a physician. He invariably signed himself "Dr. Oliver Goldsmith" and had such confidence in himself that for several weeks at the beginning of his last illness he prescribed for himself and refused to let a real physician take charge of his case. After his first failure as a physician in London Goldsmith had worked for a short period as a bookseller's hack, and when he failed to qualify as a hospital mate there was nothing for him to do but return to this lowest form of literary drudgery. So, at the age of thirty, Macaulay tells us, he sat down amid squalid surroundings to toil like a galley slave. And in time he became perhaps the most beloved of English writers, a position he held for many decades, and comes mighty near holding it even today.

During these and later hack days Goldsmith wrote a little of almost everything—several volumes of translations, innumerable essays, many poems, a *Life of Beau Nash*, histories of England, Rome and Greece, a *History of the Earth and Animated Nature* in eight volumes, and other writing of various sorts. In the compilation of his histories he was a master of selection and condensation. His style was pure and easy, his humor rich and joyous, and his descriptions picturesque. Practically all this work was published anonymously, but in spite of this Goldsmith was becoming a popular author. A series of lively sketches of London life and narratives of his Continental rambles, in particular, aided in attracting attention to him. Then, too, he was doing at intervals during this period some of the work which made him famous and prosperous. But prosperity didn't help Goldsmith much; it merely served to hasten his demise, and when he died he was ten thousand dollars in debt. He has been described as vain, sensual, improvident and frivolous. Horace Walpole called him "the inspired idiot" and Samuel Johnson said: "No man was more foolish when he had not a pen in his hand or more wise when he had. But let not his frailties be remembered. He was a very great man." Goldsmith was one of those men of whom we say, "He was his own worst enemy." He was a curious compound of absurdity and folly. He spent lavishly, gave freely and was an unlucky gambler. His average income for the last seven years of his life was more than four hundred pounds a year, which was opulence in those days, but he squandered it as fast as he got it and died in debt. He had to sell *The Vicar of Wakefield* to pay his room rent and got only three hundred dollars for this novel which charmed all Europe and is still a big favorite.

Goldsmith's poem, *The Traveler*, was his first signed work. It is one of the finest poems in English literature. While the fourth edition of *The Traveler* was being published *The Vicar of Wakefield* appeared and rapidly attained immense popularity. Critics says it is one of the worst stories ever constructed, but its faults are offset by its vivacious comedy. After its appearance Goldsmith turned to the drama. His first effort, *A Good Natur'd Man*, was actually too funny to succeed, for that sort of comedy was unfashionable at the time. His second great poem, *The Deserted Village*, appeared next, and this was followed by his second play, *She Stoops to Conquer*, an incomparable farce which marked the high tide of his prosperity and popularity. Goldsmith's other notable work includes his poems, *The Hermit* and *Retaliation*, both replete with humor and charming imagery.

Goldsmith was born in Ireland, of English parents, in 1728. A relative taught him his A B C's and for two years he attended a school kept by a retired soldier. Thereafter he attended some grammar schools and was the butt of ridicule of both pupils and teachers because he was so homely and such an incorrigible dunce. Later he went to Trinity College, Dublin, where he was invariably at the foot of his class but managed to get a bachelor's degree in 1749. His father, who had died while he was at Trinity, was a minister; the son applied in a scarlet coat for a ministerial berth, and was turned out. He next tried his hand at tutoring and failed, and his despairing relatives tried to pack him off to America. They gave him one hundred and fifty dollars and a good horse and started him off to Cork. He spent the one hundred and fifty in revelry and the ship sailed without him, and Goldsmith turned up again like a bad penny. He next tried the law, in Dublin. An uncle gave him two hundred and fifty dollars to start with. He gambled the money away in a few days. And then he went to Edinburgh. Goldsmith died on April 4, 1774, in London, of a nervous ailment brought on by those habits of life which made him such a conspicuous failure in everything except as a writer.

MILK

Milk is such a dangerous food, or has the possibility of being such, that some of our best sanitarians hesitate, in their own households, to use that furnished by the finest dairies in the country without its previous pasteurization. In the light of some epidemics that have been traced to the doors of these dairies, they are justified in this attitude of distrust of the raw product. Happy is the consumer of milk

who knows nothing of bacteriology, but the one who has tasted of the fruit of the tree of the knowledge of such forms of life, must have a damper put on his appetite for the lacteal fluid. At best it is a contaminated, if not a dangerous food. When the high proportion of tuberculous cows resident in some of our states is considered, the number of cases of tuberculosis in children which may have been derived from milk is truly alarming. We know little indeed of the sources of tuberculous infection at a later age, but if, as has been suggested, the disease in the adult is due to infection in early childhood the food supply of that period comes in for close scrutiny.

A prominent English physician, Campbell, has proposed that, after the period of infancy, milk should be dropped from the diet as no longer needed and because of the high element of danger in its use. He has excellent example for this in that the young of animals get along without, or can get along without, milk after their early days. Certainly man, before he learned to take advantage of the cow, had no milk after his first year or so.

On the other hand there is much outcry, on the part of food specialists, about the need for vitamins which are contained in milk. There is no question about the presence and the value of these substances, but is it so essential that they be obtained from milk? If so it would seem as if we had lost the ability to utilize these substances from other sources. Considering the danger of infection which exists in even the best of milk we are much in need of the real facts in the case as to whether it is essential for the human being in other than the earliest months. At least, however, we can feel assured that milk which has been carefully pasteurized or has been boiled is above suspicion of danger, and all efforts to improve the milk supply of a community should receive the heartiest support of all concerned in the promotion of health.

FREE USE OF MEMORY.

Repression is manifest in a timid reluctance to engage in health stimulating pursuits. It is not the distinct positive phobia alone which shows the effect of the choking back of psychic energy. The acute distress, the vaguer pain that realizes itself only in restless inaction, these are familiar marks of repression. And repression builds itself upon the want of courage to seize knowingly upon one's memory store. Because of the cutting out of the latter there is no vigor with which to turn to action, no flaming energy to outleap the ashbed of despair.

More and more the duty of discovering the reasons for such cutting off of the larger part of the self presses itself as a primary one of medical

practice. This is psychoanalysis. Bergson in *Mind Energy* hints at the hidden material which "in reality" lies "concealed in the depths of memory." He is not interested, however, in this book in the inner pathological aspect of the problem of unavailable memory material. He rather pours illumination upon the final end and goal of psychoanalysis, the gain to life if memory is free. Access to unconscious material is power and quickening inspiration where once was listlessness or active despair.

Bergson's conception of the brain in its higher areas is that of an organ at the service of conscious choice interposed as a screen against a flood of unconscious intruders, but at the same time a machine through which selective admission is gained. Thus memories obtain egress to enrich the situation in hand. This selection and admission must not be hindered by such weighting down of these memories that they cannot emerge.

The man of action is the opposite of the timid soul who dares not act, or the possessor of such positive fear, projected result of the unconscious weight, that there is no room for endeavor. Energy released no longer drives tortured nerves to forbidden and therefore impossible action. Such action would be only anyway a repetition of past conceived desires which memory stores. Free of admission to a constructive consciousness these memory images become reshaped to newly created uses. With such freedom therefore the man of action goes out to leave "his mark on the events in which chance has called on him to take part." Free behind his conscious present moment, free ahead of it, he is able to guide his action through a "momentary vision which embraces a whole course of events within one purview." His ability, his stimulus toward the future owe themselves to this wholeness of his mental life—and wholeness is also healthy exuberance. "The greater his hold on the past in his present vision, the heavier is the mass he is pushing against the eventualities preparing. His action, like an arrow, flies forward with the greater force the more tensely in memory his idea had been strung."

SIMULATION AND THE CAMERA.

Clever simulation requires a larger amount of selfcontrol and study of the emotions than the average faker possesses. A little faradic psychotherapy, restriction of food, isolation, generally bring the man to confession. At one war clinic where simulations of mental deficiency, deafness, and other conditions were common as an excuse to avoid military service, frequent photographs were made; every mood, every attitude was recorded; the pictures, if simulation was present, bore

no consecutive likeness to the symptoms asserted. In the first the man would be worried, confused; in another indifferent, melancholy; in a third expectancy would be betrayed as to the success of his simulation. On being shown the many photographs and the impossibility of so many mental conditions being coexistent, the expected confession was nearly always forthcoming.

News Items.

Nobel Prizes Awarded.—The Nobel prizes in medical science for 1919 and 1920 have been awarded to Dr. Jules Bordet, of Brussels, and Professor August Krogh, of Copenhagen.

California Health Officers to Meet.—The state, county, and municipal health officers of California will hold their annual conference in Chicago, on November 8th to 11th, under the presidency of Dr. Ernest H. Pape, of Berkeley.

Gift to Red Cross Society.—By the will of Emma Chambers Jones, of New York, who died in Grafton, Mass., on September 18th, the American Red Cross Society will receive \$10,000. The Charities Organization Society will also receive \$10,000.

Gift to Presbyterian Hospital.—By the will of Adèle Emilie Flint, of Larchmont, the Presbyterian Hospital of New York will receive \$100,000. Another beneficiary is the Society for Improving the Condition of the Poor, which receives \$25,000.

Bronx Maternity Hospital Dedicated.—The new \$100,000 building of the Bronx Maternity Hospital, at 168th street and the Grand Concourse, was dedicated with suitable ceremonies on Sunday, October 30th. The institution is now open for the reception of patients. The building will accommodate forty beds.

Public Health Lectures.—The School of Hygiene and Public Health of the University of Pennsylvania announces a course of ten lectures on public health problems, at the University of Pennsylvania during the coming term, which will be open to the public. The first lecture in the course will be given Saturday evening, November 6th, on the Objects, Aims, and Results of Medical Inspection of Schools.

Clinical Congress of American College of Surgeons.—The tenth annual session of the Clinical Congress of the American College of Surgeons was held in Montreal, October 11th to 15th. Dr. John B. Deaver, of Philadelphia, was elected president, to succeed Dr. George E. Armstrong, of Montreal, and Dr. Harvey G. Mudd, of St. Louis, and Dr. Charles E. Sawyer, of Marion, Ohio, were elected vice-presidents. The secretary and treasurer were reelected.

American Hospital Association.—At the annual meeting of this association, held in Montreal, October 4th to 8th, the following officers were elected: Dr. Louis B. Baldwin, of Minneapolis, president; Dr. George O'Hanlon, of New York, president-elect; Dr. Malcolm T. MacEachern, of Vancouver, B. C., Mr. S. G. Davidson, of Memphis, and Miss Alice M. Gragg, of Louisville, Ky., vice-presidents; Dr. A. R. Warner, of Chicago, secretary, and Mr. Ara Bacon, of Chicago, treasurer.

Red Cross Establishes Health Centres in New York.—According to reports issued by the Red Cross Society, substantial headway has been made in the health program of the organization, eighteen health centres having been established in the Metropolitan District of New York and in New Jersey and Connecticut.

Hahnemann Hospital Association.—A meeting of homeopathic physicians and others was held in New York, Thursday evening, November 4th, for the purpose of considering how best to carry on the work of the hospital as was originally planned when the institution was established. The Hahnemann Hospital Association was organized with this object in view.

Civil Service Examination for Anesthetists.—The United States Civil Service Commission announces an open competitive examination for anesthetist, to fill a vacancy in Freedmen's Hospital, Washington, D. C., at \$1,200 a year, plus increase granted by Congress of \$20 a month, with board. Freedmen's Hospital is an institution for the treatment of colored patients. Applications will not be received after December 7th.

\$3,000,000 Police Hospital Planned.—It is announced that one of the largest and best equipped hospital buildings in Greater New York will be erected shortly in the Eastern Parkway district of Brooklyn for the benefit of the Police Department of New York. It is estimated that \$3,000,000 will be required to erect and equip the necessary buildings and a drive to obtain the money is contemplated.

Faculty Changes at Yale Medical School.—Dr. George Blumer, formerly dean of the faculty, has accepted a temporary appointment as clinical professor of medicine at Yale Medical School. Dr. Wilder Tilleston, of New Haven, has been named assistant to Dr. Blumer, and Dr. Edward H. Hume, dean of the medical school of Yale-in-China, home on leave of absence, will serve as visiting professor of medicine. Dr. John E. Lane and Dr. Alfred G. Nadler have been appointed clinical professors of dermatology.

Coming Meetings.—The fourteenth annual meeting of the Southern Medical Association will be held in Louisville, Ky., Nov. 15th to 18th, under the presidency of Dr. Edward H. Carey, of Dallas, Texas.

The eighth annual meeting of the North Pacific Surgical Association will be held in Spokane, Wash., December 10th and 11th, under the presidency of Dr. John H. O'Shea, of Spokane.

The Western Surgical Association will meet in annual session in Los Angeles, December 3d and 4th, under the presidency of Dr. Arthur T. Mann, of Minneapolis, Minn.

The Southern Surgical Association will hold its annual meeting at Hot Springs, Va., December 14th, 15th, and 16th, under the presidency of Dr. Willard Bartlett, of St. Louis, Mo.

The Medical Association of the Southwest will meet in annual session in Wichita, Kan., November 22d, 23d, and 24th, under the presidency of Dr. E. F. Day, of Arkansas City, Kansas.

Personal.—Dr. Casey A. Wood, of Chicago, has gone to British Guiana, where he will conduct research work in comparative anatomy of the eye, with special reference to birds.

Dr. Thomas R. Brown, of Johns Hopkins University, has returned from Europe, where he spent a year as director of the department of medical information for the League of Red Cross Societies.

Dr. William B. Cornell, diagnostician of the New York State Department of Education, is conducting a survey of mental deficiency in Maryland, under the direction of the National Committee for Mental Hygiene.

Dr. Ludwig Hektoen and Dr. Peter Bassoe, of Chicago; Dr. Lewellys F. Barker, of Baltimore, and Dr. Warfield T. Longcope and Dr. Rufus I. Cole, of New York, have been elected foreign associate members of the Swedish Medical Association.

Dr. Jules Bordet, director of the Pasteur Institute of Brussels, delivered the Herter lectures at the Johns Hopkins Hospital, Baltimore, on October 26th, 27th, and 28th.

Hospital for Shell Shocked Soldiers.—The new Government hospital at Perryville, Ind., where the United States Public Health Service will provide special care and treatment for shell shocked soldiers, was opened on September 24th, and over 100 patients were transferred from the temporary hospital at Cape May, N. J., to the new institution, where Surgeon E. H. Mullan is in charge. In addition to the main hospital building, there are numerous individual cottages where special care and a homelike environment can be provided where necessary. At the present time the Public Health Service has under treatment over twelve thousand discharged soldiers suffering from shell shock and other mental disorders. Of these 5,578 are in hospitals operated by the Service, and the remainder in other hospitals where proper care and treatment is provided under contract.

Public Health Service Takes Over Army Hospitals.—Two army hospitals, one in North Carolina and the other in New York Harbor, were taken over by the United States Public Health Service during the past week. The North Carolina hospital (O'Reilly Hospital), which is at Oteen, eight miles from Asheville, will be continued as a tuberculosis hospital with about one thousand beds; Dr. W. M. Foster will be in temporary charge.

The buildings were erected by the army for that particular purpose and are superior to most of those in base camps. Two of the wards will be remodeled, and some additional buildings will be erected for the use of the staff. The present patients will probably remain, if the hospital equipment can be taken over with them.

The hospital in New York, variously known as the Hoff General Hospital and the U. S. Debarkation Hospital, is at Fox Hills, Staten Island. It will be continued as a general hospital with a capacity of about five hundred beds. Dr. J. O. Cobb, recently in charge of Public Health Service activities at Chicago, will be in charge. By reason of its proximity to New York this hospital has available the best consultation facilities in the country.

Meetings of Local Societies.—The following medical societies will meet in New York during the coming week:

MONDAY, November 8th.—Society of Medical Jurisprudence; New York Ophthalmological Society; Yorkville Medical Society (annual); Williamsburg Medical Society, Brooklyn.

TUESDAY, November 9th.—New York Academy of Medicine (Section in Neurology and Psychiatry); Manhattan Dermatological Society; New York Obstetrical Society; Clinical Society of the Hospital for Deformities and Joint Diseases.

WEDNESDAY, November 10th.—Medical Society of the Borough of the Bronx; New York Pathological Society; New York Surgical Society; Alumni Association of the Norwegian Hospital, Brooklyn; Brooklyn Medical Association.

THURSDAY, November 11th.—New York Academy of Medicine (Section in Pediatrics); West End Clinical Society; Brooklyn Pathological Society.

FRIDAY, November 12th.—New York Academy of Medicine (Section in Otology); Eastern Medical Society of the City of New York; Flatbush Medical Society, Brooklyn; Society of Externs of the German Hospital in Brooklyn.

Died.

BROOKS.—In Auburn, Wash., on Thursday, October 21st, Dr. Frank Brooks, of Seattle, aged seventy years.

CAMPBELL.—In Cohoes, N. Y., on Wednesday, October 20th, Dr. William M. Campbell, aged fifty-nine years.

DROWNE.—In Roxbury, Mass., on Sunday, October 24th, Dr. Edwin Lewis Drowne, of Boston, aged forty-three years.

GARDNER.—In Philadelphia, Pa., on Tuesday, October 19th, Dr. Charles H. Gardner, aged eighty-two years.

GERHARD.—In Philadelphia, Pa., on Wednesday, October 27th, Dr. George S. Gerhard, aged seventy-one years.

HOYT.—In Concord, N. H., on Thursday, October 21st, Dr. Adrian H. Hoyt, aged fifty-nine years.

HORNING.—In Collegeville, Pa., on Wednesday, October 20th, Dr. Samuel B. Horning, aged fifty-eight years.

HUDSON.—In Yonkers, N. Y., on Saturday, October 30th, Dr. Walter Guy Hudson, aged fifty-one years.

KINNEY.—In Easton, Pa., on Tuesday, October 26th, Dr. Charles S. Kinney, aged sixty-six years.

LAMONT.—In Hazleton, Pa., on Saturday, October 23rd, Dr. Robert B. Lamont, aged seventy-two years.

McGINTY.—In Olyphant, Pa., on Friday, October 22nd, Dr. James McGinty, aged thirty-nine years.

MANN.—In Brockport, N. Y., on Saturday, October 23rd, Dr. William B. Mann, aged eighty-two years.

NEWMAN.—In New York, on Monday, October 26th, Dr. Charles F. Newman, of Brooklyn, N. Y., aged sixty-six years.

O'BRIEN.—In Orange, N. J., on Monday, October 18th, Dr. Daniel Jerome O'Brien, aged forty-five years.

RADIN.—In New York City, on Thursday, October 28th, Dr. Maurice L. Radin, aged forty-eight years.

RODGERS.—In Mifflintown, Pa., on Sunday, October 17th, Dr. W. H. Rodgers, aged seventy-five years.

STEPHENS.—In Mansfield, Tex., on Friday, October 15th, Dr. J. P. Stephens, aged seventy-one years.

THOMAS.—In Rochester, N. Y., on Thursday, October 21st, Dr. Cornelia White Thomas, aged fifty years.

THOMPSON.—In Cambridge, Ia., on Friday, October 22nd, Dr. Frank Thompson, aged sixty-two years.

WESTBROOK.—In Rock Island, Ia., on Wednesday, October 20th, Dr. Edwin Westbrook, aged sixty-three years.

WHITE.—In Sandwich, Mass., on Wednesday, October 20th, Dr. George E. White, aged seventy-one years.

Book Reviews

TREATMENT OF WOUNDS OF LUNG AND PLEURA.

The Treatment of Wounds of Lung and Pleura. Based on a Study of the Mechanics and Physiology of the Thorax. Artificial Pneumothorax Thoracentesis Treatment of Empyema. By Professor EUGENIO MORELLI, Assistant in the Medical Clinic of the Royal University of Pavia, Maggiore Medico, Field Hospital No. 79. Translated from the Italian by LINCOLN DAVIS, Formerly Lieutenant Colonel, M. C., U. S. Army, and FREDERICK C. IRVING, Formerly Major, M. C., U. S. Army. Illustrated. Boston: W. M. Leonard, 1920. Pp. xvi-214.

The work which Morelli did in connection with the treatment of wounds of the lung and the pleura places him among the men who devised ingenious measures for the treatment of the wounded in war. He takes his place with Gillies, of England, who gave us the pedicle tube, with Carrel, of France, who gave us a new method for the treatment of infected wounds, and Willems, of Belgium, who gave us the most radical method—one which seemed to be at variance with all we had been taught in regard to injuries involving articulations.

Much opposition was developed against Morelli, especially in regard to his doctrine of noninterference as far as foreign bodies were concerned. This was contrary to the teachings of the French school. In France great skill was shown by certain surgeons in the removal of foreign bodies by means of direct fluoroscopic examination and through a minute opening in the skin, an opening just large enough to admit a specially constructed forceps, the jaws of which were skillfully maneuvered to the point of contact with the foreign body and then opened to close again, this time grasping the body firmly and not releasing it until it was well outside the body of the patient. Great success attended the use of this method and the patients would be sitting up within a day or two and up and about within a week. Infection was seldom encountered. The only untoward results occurred when the region of the hilum was invaded. But let us get back to a discussion of Morelli's book. Of course he was enthusiastic about his methods and no doubt frequently used them when others would have served. For this reason his statistics are extremely good. In spite of all this, however, it seems as though the methods devised by Morelli, the perfection of his technic, and the many modifications which he so skillfully provided, should make the work which he did so enthusiastically during the war of far greater importance for the operation of pneumothorax in civil practice.

There will be many opportunities to test Morelli's methods under conditions identical with those he encountered during the war. For many of the injuries of peace simulate the more numerous injuries of war. And it would be well for the surgeons in civil practice to take advantage of the findings of men like Willems and Morelli and take them over into their work; apply them fearlessly and energetically to the cases they encounter. The great drawback is that there is felt a lack of familiarity with the technic and the older methods;

the methods they have become skillful in applying are frequently employed rather than an attempt made to adopt the newer and more radical procedures which have come into existence through the war. For just this reason it is to be urged that surgeons, or clinicians for that matter, in the case of Morelli's work, attempt to familiarize themselves with the details of his technic. This he has outlined with great care and elaboration in his section on treatment.

He gives many indications for the use of his method. Among the more important are: acute pleural eclampsia, interference with healing of the wound and difficulty of encystment of the projectile; acute hemorrhage; continuous oozing. By the production of a pneumothorax immobilization is obtained, compression of the lung is favored, and thereby both the healing of the wound and encystment of the projectile is hastened; through the pneumothorax the movement of the lung and suction ceases and hemorrhage can be prevented or checked; in case hemothorax existed it should be evacuated, and the danger is lessened if the blood is substituted by the air as it is removed and if done so as not to dilate the lung.

The principal opposition that Morelli has found to the treatment are summed up in the following assertions: The air put into the pleural cavity will escape either into the chest wall or lung; the air may be a source of infection; the establishment of a pneumothorax and the evacuation of a hemothorax with the substitution of air may cause embolism; and finally the hemothorax should not be evacuated because it serves for the compression of the lung and therefore checks the hemorrhage. These assertions are analyzed and each one carefully answered.

In this country where pneumothorax is a common procedure, questions of this kind would not be likely to occur. The question of the possibility of an embolus would seem to warrant the most serious consideration, but Morelli states that in over a thousand cases he has not caused a single embolus. This seems satisfactory enough but the question comes up if one less skillful could show a similar record. The last point of allowing the hemothorax to remain so that it may serve to check hemorrhage seems rather pointless as the presence of a quantity of material which would serve as an excellent culture medium is not a situation that should be defended. Morelli admits that there is danger in the removal of clots of blood when this is done carelessly or too rapidly, for hemorrhage may again be started; for this reason firm clotting should be allowed to take place and then the clot removed slowly and carefully. Then Morelli goes into the physiodynamics of having the blood used to cause compression of the lung. He shows that the effusion of blood is little fitted for this task.

Then we are taken into the details of the technic and this is worthy of most careful study. Many case histories are given, with numerous x ray photographs portraying the character of the work done.

DIFFICULT LABOR.

Herman's Difficult Labor. Sixth Edition, Revised and Enlarged by CARLTON OLDFIELD, M. D. (Lond.), F. R. C. S. (Eng.), Honorable Obstetric Surgeon to the General Infirmary, Leeds, etc. Illustrated. New York: William Wood & Co., 1920. Pp. ix-573.

Few changes have been made in Oldfield's revision of Herman's standard textbook, *Difficult Labor*. The principal change has occurred in regard to the advisability of the Cæsarean operation. The advice is given that the operation be a more frequent one in cases of contracted pelvis and in antepartum hemorrhage. The reasons for the advisability of this are fully explained. For a small and concise book of this character the illustrations are exceptionally good. They do credit to a textbook of much greater size and one covering the ground more extensively. Many revisions in technic are also noted. These, however, are not of a radical nature and not as extensive as some which have appeared recently in textbooks devoted to the surgical aspect of gynecology. From the mechanical point of view there is little to criticize, but it seems as though more attention might have been given to the chapters on infection and kidney diseases. Nevertheless the subject of labor, both normal and abnormal, is presented in a practical fashion.

ANALYSIS OF THE UNCONSCIOUS

Man's Unconscious Passion. By WILFRID LAY, Ph. D. New York: Dodd, Mead & Co., 1920.

An ancient preacher sighed, "Of the making of books there is no end." We have reason to suspect, however, from other of his words that he had lost enthusiasm for the active phases of life. There are two sufficient reasons for refusing to heed the weary preacher's complaint. Any new book can be accepted if it fulfills them. Is it the result of an effort to rise above the accepted level of thought and attainment? Does it introduce a new insight into old conditions which has all the stimulus of newly created thought? Or as the other suitable condition does the book fulfill a need of the writer's own, a healthful expression of his energized impulses. The latter can be really known only by the author himself, but at the same time such true outlet is possible only if the first condition also is met, if the work is creative. Then the effect upon the author is one shared with all his readers.

It is only fair to ask the author of this book, the third in a series of which he promises more to come, to consider whether he is entering deeply enough into the contemplation and investigation of the unconscious to give the public in each new book fresh stimulus. Lay has presented some of the cardinal facts which psychoanalysis has discovered in the unconscious in a manner to win the general reader's attention. He has presented these with special reference first to the actual existence of unconscious factors and the mechanisms by which these work. Second he has applied these facts to the problems of the child mind and its education.

In this present volume he definitely studies them in their relation to the mating of men and women, the necessity in marriage of union in both conscious and unconscious points of contact. He has pointed out the infant fixations upon the parent which present

such complete union. This brings the more complete view of the marriage relation to the attention of men and women who have thought little about the real reasons why marriages fail or who know little of the full basis of lasting union. He has also again included simple expression of fundamental psychological truths in an instructive manner with the force of everyday language and frequent apt illustration. Yet complaint must be made of confusion of thought and some uncertainty of expression. Most glaring is the introduction and attempted explanation of the division of the emotional life into affection and passion. We thought that for professed psychoanalysts at least Freud had reduced the consideration of this life to a simpler unified basis. To find Lay's restatement and his elaborated insistence upon it gives not only confusion but a sense of strained uncertainty of position on the writer's part.

DENTAL HYGIENE.

Hygiene, Dental and General. By CLAIR ELSMERE TURNER, Assistant Professor of Biology and Public Health in the Massachusetts Institute of Technology; Assistant Professor of Hygiene in the Tufts College Medical and Dental Schools. With Chapters on Dental Hygiene and Oral Prophylaxis, by WILLIAM RICE, Dean, Tufts College Dental School. Illustrated. St. Louis: C. V. Mosby Company, 1920. Pp. v-400.

Again we hear about dental hygiene from the New England States, the home of Fones and Forsythe, where no doubt more work is being done to stimulate the importance of hygiene of the mouth than anywhere else in the country. Dr. Turner, although he has written his book for the dentist, concerns himself most with a consideration of the general hygiene of both the functional and organic diseases of the individual and his relation to the community, touching carefully enough on the necessity for proper nutrition and the expenditure of sufficient energy through exercise or work. An important point is made in attributing disease or arrested development of parts of the body to a lack of proper functioning as much as to infective organisms. Dr. Rice, who has written the chapters on dental hygiene, gives the dentist a much needed warning when he says that "each tooth performs its function as a dependent unit in a perfect machine," for in truth the dentist still sees the tooth as an independent structure having no relation to what is really a most delicately constructed mechanism.

GERSTER'S AUTOBIOGRAPHY

Recollections of a New York Surgeon. By ARPAD G. GERSTER, M. D. Illustrated. New York: Paul B. Hoeber, 1917. Pp. xi-347.

It is often a matter of regret to a family that they did not pay more heed to and preserve the stories told them by the ancient grandparents who welcomed a listener to while the hours which were so long. Their experiences, touched by emotion, were infinitely more interesting than bundles of dusty letters often undated, or files of papers. Doctor Gerster's forbears evidently listened to and kept all records faithfully, so he greets us first from his own cradle in Hungary in 1848, then presents us to his Swiss ancestors back in 1378, returning

to Hungary and telling of the family circle and the political and social conditions which prevailed during his childhood, school days, and his being influenced by Robert Ultzmann, the urologist, to become a doctor. The scene changes to Vienna in 1864, and the youthful Gerster is listening to Hyrtyl in the University. Rakitansky, Skoda, Billroth figure in his student life, then followed army service and after that a determination to come to New York, a bold step for a youth. On the ship there was a certain Anna Wynne, returning to Cincinnati from musical studies in Stuttgart, who shortly after became the wife of this adventurous physician.

Owing to his letters of introduction, and, presumably, a certain amount of genius he is too modest to mention, he is well received, notably by a Doctor Krachowitz, who, better than his jaw-cracking name, takes much pains to launch young Gerster. The latter noticed at once something which struck English doctors and soldiers during the late war—the informality between doctor and patient, the absence of the Harley Street manner, and the greater cheeriness in the hospitals. He is delighted too with the clean, well lighted wards and operating rooms and the cordiality of the doctors, not being one of those who take all they can get in a foreign land and slang the givers. The German Hospital; Mount Sinai, the Polyclinic School knew him as a worker, the various medical societies and the Charaka Club know him as a member; some hundred medical and historical papers show him as a writer. Part three is a little account of his ways and habits, early inclinations, sports, and his joy in travels. There will be no need for his biographer to hunt for material; he himself has furnished enough, though in selecting, the biographer may unconsciously wound an inarticulate ghost by ignoring important points, but the man who really wants to know can always consult the *Recollections* as a volume which gives not merely one man's life but things of international interest in the medical world.

ROCKWELL'S RECOLLECTIONS.

Rambling Recollections. An Autobiography. By A. D. ROCKWELL, M.D. Illustrated. New York: Paul B. Hoeber, 1920. Pp. ix-332.

A pleasant book of men and things is this which Doctor Rockwell has prepared. He had designed it, he states, originally only for his family but has now given to a wider circle of readers these pleasant reminiscences. There are incidents of childhood in abundance, pleasant tales of healthy country life. The scenes in which they take place give a charming glimpse back into the simpler aspect of localities since greatly changed. There are reminiscences of old acquaintances of fellow physicians as well as of patients who have been well known in various walks of life. References also to members of other professions with whom his medical life has been associated, all these give many human points of interest. The narrative of the author's experience in the Civil War presents also much of this general anecdotal personal matter. There is but little even here, however, of his real surgical experience, as

there is very little throughout the book of the actual professional activity which he maintained.

Those of every age still in active service, no less than those at the very entering threshold look to one who has passed further for a number of vital things: They expect some revelation of the conflicts through which progress has been achieved. They expect a record of victories, of discoveries and achievements to give impetus to still undeveloped possibilities. They look for the stimulus of faithful endeavor which realizes that its only partial fulfilment is the opportunity to those following. Thus the aged worker flings out a stirring battlecry to those following. Pleasant as are these rambling recollections one listens in vain for this note. One cannot believe the author's long active life has failed to realize such an inspirational attitude for himself or others. He forgot, however, in writing that the younger generations are listening for its challenge. Or if they are not listening so much the more should they be startled by its utterance.

New Publications Received.

[We publish full lists of books received, but we acknowledge no obligation to review them all. Nevertheless, so far as space permits, we review those in which we think our readers are likely to be interested.]

PRACTICAL VACCINE TREATMENT. For the General Practitioner. By R. W. ALLEN, M. A., M. D., B. S., Late Captain, N. Z. M. C. New York: Paul B. Hoeber, 1920. Pp. xii-308.

UNTERSUCHUNGEN UBER DIE MYELOMKRANKHEIT. Von Dr. ARVID WALLGREN Fruher 1:ster Assistent der Med. Klinik. Uppsala and Stockholm: Almqvist & Wiksellsboktryckeri-A.-B. 1 Distribution. Sid. 151.

COMMISSIONE PER LO STUDIO DELLE OPERE DI PICCOLA BONIFICA. Seconda Relazione della Lotta Antimalarica A Fiumicino (Roma) Diretta dal Prof. B. GRASSI. Roma: Tipografia del Senato di Giovanni Bardi, 1920. Pp. vii-314.

RETRAINING CANADA'S DISABLED SOLDIERS. By WALTER E. SEGSWORTH, M. E., Formerly Director of Vocational Training Department of Soldiers' Civil Reestablishment, Canada. Illustrated. Ottawa: J. de Labroquerie Taché, 1920. Pp. 193.

DIE PARTIGENGESETZE UND IHRE ALLGEMEINGULTIGKEIT. Erkenntnisse, Ergebnisse, Erstrebniisse, Allgemeinverstandlich dargestellt von HAND MUCH, Universitatsprofessor in Hamburg. Mit 2 Tafeln. Leipzig: Verlag von Curt Kabitzsch, 1921. Seiten 70.

TASCHENBUCH DER MAGEN- UND DARMKRANKHEITEN. Von Dr. WALTER WOLFF, dirig. Arzt der inneren Abteilung am Konigin - Elisabeth - Hospital, Berlin - Oberschoneweide. Zweite, vermehrte und verbesserte Auflage. Mit 18 Textabbildungen und einer farbigen Tafel. Berlin-Wien: Urban & Schwarzenberg, 1920. Seiten vii-199.

MATERNITAS. A Book Concerning the Care of the Prospective Mother and Her Child. By CHARLES E. PADDOCK, M. D., Professor of Obstetrics, Chicago Post-Graduate Medical School; Assistant Clinical Professor of Obstetrics, Rush Medical College; Attending Obstetrician, St. Luke's Hospital. Chicago: Cloyd J. Head & Co., 1920. Pp. 210.

THE LINK BETWEEN THE PRACTITIONER AND THE LABORATORY. A Guide to the Practitioner in His Relations with the Pathological Laboratory. By CAVENDISH FLETCHER, M. B., B. S. (Lond.), M. R. C. S., L. R. C. P., Director, Laboratories of Pathology and Public Health, London, and HUGH McLEAN, B. A., B. C. (Cantab.), D. P. H. (Camb.), M. R. C. S., L. R. C. P., Assistant Pathologist, Laboratories of Pathology and Public Health, London. New York: Paul B. Hoeber, 1920. Pp. 91.

Practical Therapeutics and Preventive Medicine

A Compendium of Treatment and Prophylaxis, Original and Adapted

X Ray in Fibromyomata of Uterus.—L. Martindale (*Archives of Radiology and Electrotherapy*, September, 1920) discusses the use of intensive x ray therapy versus hysterectomy in the treatment of fibromyomata of the uterus and presents the following conclusions:

As long as one's diagnosis necessarily remains faulty, there is a danger in using intensive x ray therapy for any but those cases in which we are fairly certain we are dealing with a straightforward uncomplicated case, e. g., a fibroid uterus well under the size of a six months pregnancy, interstitial rather than subperitoneal, and in which the chief and only symptom is excessive menorrhagia. In such a case it seems to me to be the treatment *par excellence*. Also in cases of grave heart disease, where no surgeon would like to operate, it is an ideal treatment, and the marked improvement in general health of such patients is wonderful. In all cases where diagnosis is doubtful, an exploratory laparotomy, followed by hysterectomy where necessary, is the only right treatment. It seems that x ray treatment may be looked upon as the treatment *de luxe* for all small uterine fibroid tumors associated with hemorrhage. It improves the health of the patient without interfering with her usual mode of life. It causes a great reduction in the size of the tumor, and therefore does away with pressure symptoms. It eliminates the nervous shock of an abdominal operation and the inconveniences of an anesthetic, and, as I said before, it brings about a climacteric involving less disturbances even than a natural one. Lastly, and most important of all, it is a treatment eminently successful in suitable cases—according to Gauss in ninety-nine per cent. of cases, and even according to my own series in ninety-seven and four tenths per cent. of the cases—and it is a treatment free from any mortality.

Maternal and Fetal Blood.—Stander and Tyler (*Surgery, Gynecology and Obstetrics*, September, 1920) give the following conclusions from their studies of the ash content in the fetal and maternal blood: 1. During pregnancy the water content of the blood is usually found to be between seventy-seven and eighty-two per cent., the accepted normal limits. The tendency is toward the upper extreme, and in one third of our cases this was slightly exceeded. 2. Examined month by month during pregnancy characteristic fluctuations in the blood moisture become apparent. It increases gradually until the seventh month and subsequently remains stationary or slowly decreases. At the onset of labor it is approximately the same as in the early weeks of gestation. The act of labor has no constant influence upon the blood moisture. 3. The water content of the blood and the corpuscular count vary inversely. 4. The plasma moisture, examined month by month, presents the same type of variation as that characteristic of the whole blood. 5. Quantitatively the blood ash and the plasma ash

are found to remain normal during pregnancy. 6. Eclampsia may not be distinguished from nephritis on the basis of blood moisture. In either complication, the percentage of water may be great enough to constitute a true hydremia, which is usually presented by cases with marked general edema. 7. identical values for the ash in maternal and fetal plasma indicate that a free exchange of their inorganic constituents takes place through the placenta in accord with the laws of osmosis. 8. The moisture of whole blood is appreciably higher in the mother than in the fetus. 9. The plasma moistures approach each other closely, though by the method employed a difference of one per cent. in favor of the fetus is found constantly. Some unrecognized factor, physical or chemical, maintains osmotic equilibrium between the two circulations, and water passes the placental partition equally well in either direction.

Aspiration and Pressure Treatment of Unopened Mammary Abscesses.—John P. Gardiner (*American Journal of Obstetrics*, November, 1919) states that the aspiration and pressure treatment is superior to the ordinary radial incision and drainage method in that drainage is better maintained, practically no scar remains, and the breast heals more quickly. In none of the eight cases he reports, did the treatment extend over nine days, from the first aspiration until no more pus from the cavity was obtained. The instruments used consist of two glass syringes, one an ordinary hypodermic syringe with a sharp needle of twenty-four gauge and the other a ten mil or larger syringe with a needle of seventeen gauge and at least two inches in length. The skin is first washed and painted with seven per cent. tincture of iodine. A 0.5 per cent. solution of novocaine, with three drops of adrenalin added to the ounce of solution, is then injected as an anesthetic at the site of election, down to and into the abscess cavity. The left hand now steadies the breast, and with the syringe in the right hand, the initial puncture is made with a quick stab into the skin. The solution is distributed equally along the proposed track for the aspirating needle. After a few minutes the latter is inserted, and the syringe filled and emptied repeatedly until the cavity is thoroughly evacuated. Upon frequently repeated aspirations plus constant pressure on the breast with a binder depends the success of the method. The second aspiration is performed four to six hours after the first, and the amount of fluid then obtained determines the frequency of the subsequent aspirations. Each succeeding needle puncture is made through the original one and is always preceded by local anesthesia. Abscesses contiguous to the original abscess are not difficult to locate because the pressure exerted by the bandage prevents any excessive edema, so that any induration between the skin of the breast and the chest wall is readily recognized by palpation. It is usually easy to drain by aspiration these con-

tigious abscesses through the original cavity. During the acute stages, before the abscess has localized, it is essential that the pressure bandage should not be removed from the breast except for the briefest possible time; the bandage should be continued for several days after a dry tap. Cold should be continuously applied unless pus is present, when heat is substituted. The author also has an autogenous vaccine made and administers a dose of five hundred millions on the fourth or fifth day after the first tap as a preventive against recurrent abscesses. Prenatal care of the nipples does not prevent the occurrence of sore nipples or breast abscesses. Care of the lactating breasts and nipples involves the following: Cleanliness; avoidance of prolonged and frequent nursings during the first days before the milk comes in; early recognition of a failing milk supply and the immediate institution of supplemental feedings, and temporary cessation of nursing on the first sign of local trouble, the lymphangitis being meanwhile combated by pressure and cold to the breast.

Generative Organs Treated by X Ray.—I. Seth Hirsch (*American Journal of Electrotherapeutics and Radiology*, August, 1920) presents the following findings from his use of the x ray in the gynecological field:

Advantages: 1. The treatment is painless. 2. It takes six to nine weeks, and if it fails the operation may be carried out under the same conditions as before. 3. If successful the menopause is not usually attended by any severe nervous symptoms. 4. The general systemic disturbances present after the operation are not present with this treatment. 5. There are no failures in the properly selected cases. 6. There is practically no mortality from this treatment, while the operative mortality varies from one to four per cent.

Disadvantages: 1. There is a definite time period before the cure is effected. 2. The fibroid may only partially disappear after several months, and in rare cases a recurrence may occur. 3. Malignant changes in fibroid tumors of the uterus may be present and overlooked, or malignant changes may take place in the fibroid under treatment. The last is the most important objection to the use of radiotherapy. It is true that a sarcoma may, except in the case of a rapidly growing tumor, be overlooked in determining the proper treatment. But sarcoma is very rare and occurs in less than a half of one per cent. of cases. Greater stress is laid on the coincidence of carcinoma or epithelioma with fibromyoma. It may occur in about five per cent. of the fibroids. Though it is obvious that an undiscovered cancer of the uterus will lead to fatal results, in spite of radiotherapy, it is also obvious that the discovery of cancer in the specimen after hysterectomy has been performed, presents the problem of surgical treatment in a new aspect.

Just as any form of treatment outlined for the fibroid is altered when the cancer is discovered, so the röntgen treatment must be altered if after the treatment is begun carcinoma is discovered. This phase of the case is in the hands of the gynecologist, whose constant scrutiny will minimize the possibility of an erroneous diagnosis.

Copper Sulphate in the Local Treatment of Inoperable Uterine Cancer and in Vaginal Recurrences.—D. Pamboukis and G. Berry (*Presse médicale*, May 22, 1920) remove any extensive fungous outgrowths by curettage, apply local pressure for a few moments to arrest bleeding, and then cover the surface with a powder consisting of one part of copper sulphate in twenty-five parts of powdered talc. To maintain contact of the powder as well as protect the surrounding vaginal mucosa a tampon or sterile compress is inserted. At subsequent dressings, the following paste is generally used: Copper sulphate (forty per cent.), one gram; magnesium oxide, ten grams; adrenalin solution, ten drops; glycerin, enough to make a pasty fluid. This preparation is painless and should be left in contact with the parts for one or two days. After its removal, an injection of one spoonful of sodium bicarbonate in two litres of warm water is administered. Internally, the following combination is simultaneously prescribed: Quinine bihydrochloride, 0.25 gram; magnesium oxide, 0.50 gram. Three such doses are taken in cachets each day. The local dressings are renewed at least three times a week at first, later less frequently, according to the extent of improvement of the lesions. Where there is a tendency to exuberant proliferation, copper sulphate crystals are applied directly, an attempt even being made to force them into the depths of the prominent vegetations while the rest of the vegetating surface is dusted with powdered copper sulphate crystals. Plenty of sterile petrolatum should be used on the tampon or compress, to protect the remainder of the vaginal mucosa. The pure salt should never be allowed to remain in contact longer than twenty-four hours, and should be alternated with the diluted powder or the paste.

Treatment of Menorrhagia with Radium.—S. W. Budd, (*Virginia Medical Monthly*, April, 1920), holds that in radium we have a remedy which in a large measure obviates the difficulties associated with successful termination of an intractable case of menorrhagia. Among the fifty cases of menorrhagia unassociated with cancer or fibroids, treated by the author with radium, some of the patients had to return for two or more radiations before they obtained relief, but in no instance did removal of the uterus become necessary. A simple dilatation and curettage is first done, the uterine cavity swabbed with iodine, and the radium then applied in a silver capsule, screened with one millimetre of brass. In short radiations the author does not screen with rubber, as do some other operators. The amount of radium to be used depends largely on the age of the patient and the condition under treatment. In young women under thirty-five years of age more than three hundred to four hundred milligram hours is seldom given in a single treatment. Application of twice this dose might bring about sudden termination of the menses. Three months are allowed to elapse and if the menstrual flow has not then returned to normal a second application is advised. The first period after radiation is often associated with menorrhagia, but the flow during the third period is usually not excessive, and at the third period a normal state is

reached. In women over thirty-five years of age a slightly larger dose is used, and more than one treatment is seldom required. Where there is no fibroid and the menorrhagia results from a hypertrophic endometritis or chronic metritis, five hundred to seven hundred milligram hours are usually given. In cases of menorrhagia with fibroids, the latter sometimes entirely disappear as a result of the treatment. After a radiation symptoms of intoxication such as nausea and slight fever may develop, but these subside within twenty-four hours. When the menorrhagia ceases the patient soon regains her hemoglobin and health.

Late Hereditary Syphilis.—Custex and Del Valle (*Surgery, Gynecology and Obstetrics*, August, 1920) state that:

1. Hereditary syphilis is a very frequent cause—perhaps the most frequent—of membranous perienteritis and analogous conditions.

2. Its pathogenesis is complex as several factors operate, which set down in chronological order are: defects of conformation in the intestinal walls because of the faulty endocrine function which presides over and governs their development. These malformations on the one hand, and the abnormal function of the nervous system (sympathetic and autonomous), owing to the endocrine deficiencies, produce defects in the gastrointestinal statics and dynamics. As a consequence of the latter we have intestinal stasis which brings on chronic inflammation of the colon. From the wall of the colon the inflammation spreads to the surrounding serous membrane, aggravating the existing congenital lesions. The primary cause of all this is hereditary syphilitic infection.

3. These patients, first of all, should be given mixed antisiphilitic treatment with mercury chiefly.

4. The surgical treatment is not to be abandoned, but is to be restricted to cases in which definite indications confirmed by clinical and radiological diagnoses point to mechanical alterations of importance (kinks, adhesions, etc.); or to coexisting inflammatory lesions of adjacent organs: ovaries, tubes, appendix, gallbladder, duodenum, and stomach. Surgical treatment should consist in separating membranes and in molding and mobilizing the peritoneum, together with careful peritonization and removal of the adjacent affected organs.

5. There is the group in which the patient suffers from the chronic abdomen and yet there is no anatomical lesion of importance. These should be considered as types of "sympathicopathy," owing to the particular deficiencies, more or less marked, of the endocrine glands as suprarenal capsules and thyroids, principally. It is important to know this type of chronic abdomen, for it involves a prognosis and a therapeutic management very different from the membranous perienteritic type.

6. The prognosis depends on the anatomical and clinical type, and the period or stage of the affection; good, in cases of early diagnosis and rational treatment; less favorable, in those of late diagnosis where rational treatment is impotent in modifying chronic lesions already well developed. In these a more or less pronounced improvement is to be obtained by carrying out suitable surgical treatment.

Amniotic Hernia.—Emanuel Friend (*Surgery, Gynecology and Obstetrics*, September, 1920) gives the following treatment for amniotic hernia: It is obvious that operation immediately after birth is imperative in order to save the child's life. Sanderson states that the time to operate is immediately after birth, before there is any drying out of the thin membrane covering the abdominal wall and before the hernial protrusion has been increased in size by accumulation of fluid in the stomach. The only cases which are amenable to treatment by operation are those which are small enough so that their contents can be reduced into the abdomen and a closure of the abdomen effected. When resection of liver or other abdominal contents is required the child usually dies. The Olshausen method has been effective in small protrusions of this type. The method consists in separation of the skin around the sac, removal of Wharton's jelly, and reduction of the hernia *en masse* without opening the sac and suture of the skin. Small protrusions can be treated by carefully cleansing the parts, keeping them as nearly aseptic as possible and applying pressure to the hernial tumor by means of adhesive plaster, and encircling the entire abdomen. Amniotic hernia is a rare condition. The treatment, when resection of abdominal organs is not indicated, is operative immediately after birth; for small protrusions or in case of failure to recognize the condition until late, the treatment is palliative.

Empirical Results of the Treatment of Cancerous Tumors with Radium.—S. A. Heyderdahl (*Acta Chirurgica Scandinavica*, June 12, 1920) gives a statistical summary of cases, 252 in all, treated by him during a period of five years in his capacity of senior physician to the Röntgen Radium Institute of the Riks Hospital, Christiania. While rodent ulcer and skin, mammary and uterine cancers comprised the majority, there were also cancers of the lip, cornea, mouth, maxillæ, neck, rectum, thyroid gland, axillary glands, bladder, penis, vagina, vulva, ovary, prostate, as well as leucoplasia oris. Of these eighty-eight were free from symptoms at the time of writing, eighty-one were improved, eighty-three not cured. Both tube and surface preparations were employed. In the former pure radium salts (radium-barium sulphate) were used, enclosed in platinum tubes with walls one-half mm. in thickness, this tube being enclosed in a case of silver one-tenth mm. thick. A description of his technic follows, including the use of Kerr's paste, which he considers an indispensable aid in radium therapeutics. The individual history and treatment of a large number of cases is given. The author points out the necessity of destroying the malignant tumor quickly by the aid of the largest possible doses of radium, as too small doses only irritate the more deeply situated parts to increased growth. Also prolonged treatment with small doses, he believes, weakens or renders impossible reaction from the surrounding tissue of the tumor, by causing degenerative changes in the blood vessels and lymphatic ducts, while the resorptive processes are more likely to be stimulated by acute irritation with radium rays.

Miscellany from Home and Foreign Journals

Functional Menstrual Disturbances.—Florence L. Meredith (*Surgery, Gynecology and Obstetrics*, October, 1920) states that mental hygiene and general hygiene, including general and special exercise, seem to be the treatment of choice in most cases of menstrual disturbances in young girls, and in many cases in older women. These disturbances are largely due to faulty muscular development and faulty circulation within the power of the individual to correct.

Physiology of Ovulation.—S. S. Schochet (*Surgery, Gynecology and Obstetrics*, August, 1920) gives the following as the results of his observations:

1. Ovulation is due to a specific enzyme, its nature being similar to the enzyme erepsin. Apparently there are other proteolytic enzymes in the liquor folliculi; also a lipase.
2. Atresia of the follicles is due to this proteolytic enzyme or enzymes.
3. That the experiments which were made offer a rational explanation for the use of thyroid extract and corpus luteum in sterility.

Relation of Pregnancy and Reproduction to Tumor Growth.—Maud Slye (*Journal of Cancer Research*, January, 1920) reports the results of five years' investigation of the behavior of tumor growth in its relation to pregnancy and reproduction. The experimental animals were mice bearing alveolar tubular carcinoma of the mammary gland. The conclusions arrived at are that reproducing females grow much less tumor than nonreproducing females of approximately the same age and general state of nutrition; reproducing females also grow much less tumor during the period of reproduction than when they are not pregnant. The various factors entering into the problem, such as the age of the mouse, and complicating causes of death, are given consideration.

Primary Spontaneous Tumors of the Ovary in Mice.—Maud Slye, Harriet F. Holmes, and H. Gideon Wells (*Journal of Cancer Research*, July, 1920) review the literature of ovarian tumors in animals, and state that among 22,000 mice of the Slye stock, dying natural deaths at all ages, forty-four mice had primary ovarian tumors, twenty-six having tumors in other parts of the body. Thirty-eight of the tumors were simple benign solid papillary adenomas, only occasionally with slight cyst formation. Nineteen, or fifty per cent. of these, were bilateral, so that there were fifty-seven tumors of this class. There was one typical papillary cystoma and one typical solid teratoma. Four unquestionably primary malignant tumors of the ovary, all showing the mesothelioma type of growth characteristic of malignant tumors derived from the sex glands were seen, one of which produced perirenal metastases. One other tumor of the same type was primary either in the ovary or the adrenal. Two round cell sarcomas arising either from the ovary or some other organ are described, and two other sarcomas had produced secondary growths in the ovary.

Icterus in Ectopic Gestation.—Edgar H. Norris (*Surgery, Gynecology and Obstetrics*, July, 1920) presents the following conclusions from a study of icterus in ectopic gestation: 1. Jaundice is a not uncommon symptom of ectopic gestation. 2. The presence of jaundice is of great importance and may frequently be the symptom which determines the differential diagnosis. 3. The jaundice in these cases is probably due entirely to the absorption of blood derived pigments produced by the hemolysis of the extravasated blood. 4. The blood serum often contains considerable quantities of blood pigment (hemoglobin, hematin, hemochromogen, hematoïdin). 5. In the progress of the differential diagnosis the blood serum should be studied both grossly and with the aid of the spectroscop.

Leucoplasia of the Bladder and Ureter.—Herman L. Kretschmer (*Surgery, Gynecology and Obstetrics*, October, 1920) presents the following conclusions from his extensive study of leucoplasia. 1. As far as a review of the present literature shows, the conclusion seems justified that leucoplasia is a rare condition. 2. The etiology is unknown. 3. The histopathological findings appear to be uniform and constant. 4. There is no symptom or symptom-complex by means of which the condition can be diagnosed. 5. The presence of large quantities of squamous epithelial cells in the urine from the bladder, or from the kidney after ureteral catheterization, and the passage of pieces of membrane or flakes of squamous epithelial cells, are very valuable findings in making the diagnosis. 6. By means of careful cystoscopic examination leucoplasia of the bladder can definitely be recognized.

Neonatal Mortality.—A. Newsholme (*Lancet*, May 22, 1920) discusses this subject, giving several charts representing the conditions in England and Wales. He states that a high infant mortality does not indicate that there is a selection of the fittest to survive, for it is shown that the communities with the high infant death rate have also a higher death rate in the later periods of life than communities with a low infant mortality, and concludes that the high early mortality rates point out some fundamental hygienic weakness of the locality. Moreover, he maintains that since there is a wide variation between the neonatal mortality rates of different communities there must be some removable cause in the places where the rate is high and that by discovering the cause we may appreciably reduce the deaths of newborn babes in the communities where the rate is now high. In a comprehensive survey of the possibility of improving the conditions he considers the following steps: 1. Continuous medical and nursing supervision during pregnancy, parturition, and infancy, perhaps through antenatal and postnatal clinics. 2. Skilled care during parturition. 3. Provision of maternity homes and hospitals. 4. Raised standards of the practice of midwifery. 5. Further research in antenatal pathology.

Heat and Infant Mortality.—Albert Jobin (*Canadian Medical Association Journal*, July, 1920) asserts that poor elimination of the body heat, food in excessive amount, and the depressing influence of a prolonged high atmospheric temperature, are three great reasons why infant mortality is so high during the summer. To eliminate these causes we must watch the temperature of the child's room and cut down the food to about two thirds of the ordinary allowance, making up any loss in fluids by giving water in sufficient amount. The child should also be lightly clothed and kept in the coolest and best ventilated room. During the heat of the day windows should be closed and opened during the night, in order to store as far as possible the cooler air of the night.

Toxicity of Mustard Gas to the Human Eye.—C. I. Reed, (*Journal of Pharmacology and Experimental Therapeutics*, March, 1920), reports investigations made to determine the minimum concentration of mustard gas that will produce effects on the unprotected eye of man. Thirteen subjects were exposed for periods varying according to the relative degree of skin sensitiveness in each individual, previously determined by a special method. Each man wore a respirator and nose clip to protect the respiratory tract, and one eye was protected as a control with one half of a close fitting rubber rimmed goggle. The experiments showed that the eyes are the structures of the body most sensitive to mustard gas. Concentrations of 0.0005 milligram of mustard gas to the litre of air—one part in ten millions—will produce visible eye reactions from less than one hour of exposure in individuals whose skin resistance is relatively high.

Acute Encephalitis in Children.—J. Comby (*Bulletins et memoires de la Société médicale des hôpitaux de Paris*, February 26, 1920) directs attention to the acute nonsuppurative variety of encephalitis in children, a condition already described and emphasized by him in 1906. The onset is sudden, sometimes with fever, vomiting, convulsions, and paralytic or comatose manifestations. The duration of the affection is variable. After a stage of restlessness or somnolence—lethargy, as it would now be termed—with or without ocular disturbances, secondary disorders, such as chorea, athetosis, paralysis, convulsions, insanity, idiocy, or epilepsy may follow. The prognosis is likewise variable. In the diagnosis, lumbar puncture, showing absence of lymphocytosis is important. The somnolence of lethargic encephalitis was absent in seventeen out of the twenty-five cases of acute encephalitis in children seen by the author since 1894. In six of the eight cases with somnolence, the condition followed influenza, and in one each, whooping cough and vaccination. The seventeen non-lethargic cases showed such etiological factors as influenza, one case; whooping cough, two cases; vaccination, one case; adenoiditis with otitis, one case; enteritis, six cases; carbon monoxide poisoning, one case, and unknown factors, five cases. In all these cases the provisional diagnosis had been tuberculous meningitis; from this they were soon distinguished by lumbar puncture and the course of the disease.

Tetany in the Adult, Due to Thyroid Apoplexy.—Cordier, (*Presse médicale*, April 3, 1920), reports the case of a man in colonial service in whom tetany of the upper extremities developed, with the usual clinical and electrical signs of this condition. Glandular therapy was followed by almost complete recovery, but the attacks then recurred, cachexia and acidosis set in, and the patient died in the midst of intense tetanoid spasms and violent prelaryngeal pain. At the autopsy a hematoma of the laryngopharyngeal region was found. Serial sections revealed destruction of one external parathyroid gland by the hematoma and the presence of large areas of hemorrhage in the other. The internal parathyroids could not be located. The tetany must undoubtedly be ascribed to the parathyroid injury. The case would seem to shed light on the cause of many cases of spontaneous tetany in adults. The acidosis was analogous to that noted by Morel in experimental parathyroidectomy, but whether it was actually the result of a parathyroid insufficiency is uncertain.

Fibrous Tumors of the Palm.—R. Ducastaing (*Paris médical*, March 20, 1920) states that the cause of fibrous tumors of the palm of the hand is as yet unknown. Care should be taken not to confound them with cysts, the result of traumatism and epidermal inclusion. Small fibromas, independent of any local irritative cause, often mark the first stage in retraction of the palmar fascia. The fibrous nodules develop insidiously. There is no manifest tuberculous family history, but a familial arthritic and rheumatic tendency is sometimes elicited. Pathological study of such a nodule revealed many new-formed vessels with endovascular inflammation; the centre of the tumor was infiltrated with numerous hemoglobin granulations. Clinically, the nodules cause little discomfort. There occur all transition stages between camptodactylia, palmar nodosities, and retraction of the fascia. In one of the author's cases the nodules did not seem to have any tendency to extend; in another, nodules and camptodactylia were simultaneously present, and in the third, the patient passed gradually through the various stages of fibrous infiltration, leading eventually to Dupuytren's contracture.

Common Origin of Chickenpox and of Some Cases of Herpes Zoster.—A. Netter (*Bulletin de l'Académie de médecine*, June 29, 1920) reports two instances in which a case of herpes zoster was manifestly secondary to one of chickenpox and itself manifestly gave rise to another case of the latter disease. In the first instance the child who had herpes zoster had been in a hospital for forty-three days, but had been transferred to a ward in which chickenpox had prevailed for nearly two months, just thirteen days before the herpes zoster came on. In the second instance a child contracted herpes zoster ten days after being transferred to a hospital from a boarding school in which chickenpox had been epidemic. Fifteen days later another child, who had been in this hospital seventy-nine days with lethargic encephalitis, contracted chickenpox. Feer recently reported a similar instance from a hospital in Zürich. Netter reviews other cases in the literature, illustrating a relationship of

chickenpox to some cases of herpes zoster, and concludes that in these cases of zoster the eruption arose through the localized action of the chickenpox virus upon the corresponding intervertebral ganglia. Sixteen cases of chickenpox closely following herpes zoster in the same person have been reported. The small number of persons contracting chickenpox from cases of herpes zoster is to be ascribed to the fact that a large proportion of individuals before exposure have already been immunized by a previous attack of chickenpox. The possibility should be borne in mind that a case of herpes zoster may be followed by the appearance of chickenpox in the same ward or family.

Action of Chloral on the Pupil.—Hyatt, McGuigan, and Rettig (*Journal of Pharmacology and Experimental Therapeutics*, July, 1920) point out that the pin point pupil in many cases of chloral poisoning may be responsible for the mistaking of chloral for morphine poisoning. One should remember that toxic doses of many drugs may give a pin point pupil, and that in the diagnosis other symptoms must be observed, the great difference between morphine and chloral poisoning being the condition of the reflexes. With chloral the reflexes and muscle tone are lost, while with morphine most of the reflexes are either normal or exaggerated. Small doses of chloral, such as one gram, produce in man a slightly contracted pupil resembling that of normal sleep. The authors' experiments show that large doses may produce a pin point pupil. No part of the mechanism of the eye peripheral to the ciliary ganglion is directly acted on by the chloral, and neither the ciliary nor the sympathetic ganglia are involved. The action is therefore central, and due to removal of inhibitory influences which normally are active. Strychnine, caffeine, atropine, and other centrally acting drugs are antagonistic to the action of chloral on the pupil.

Mechanism of Fever Reduction by Drugs.—H. G. Barbour and J. B. Herrmann (*Proceedings of the National Academy of Sciences*, March, 1920) note that dextrose taken by mouth has been found frequently to exert a mild antipyretic action. The experimental work of the authors showed that various antipyretic drugs—sodium salicylate, quinine hydrochloride, or antipyrine subcutaneously, or acetyl salicylic acid by mouth—increase the blood sugar in both normal and fevered dogs. In the latter this effect is accompanied by a dilution of the blood—indicated by diminished hemoglobin percentage—and a fall in temperature, neither of which occur in healthy animals. The authors' theory of the action of antipyretics is, therefore, that in fevered animals these drugs produce a dilution of the blood or plethora, hyperglycemia probably contributing largely to this effect. The plethora promotes dissipation of heat both by radiation—peripheral vasodilatation—and by water evaporation from the surface of the body. The occurrence of the plethora, with its resulting antipyretic effect, is apparently limited to fevered animals. This fact should probably be attributed not so much to a greater degree of hyperglycemia as to the relative water retention by the tissues which is said to accompany febrile conditions.

Major Trigeminal Neuralgias.—Harvey Cushing (*American Journal of the Medical Sciences*, August, 1920) describes five types of facial neuralgia capable of being mistaken for trigeminal neuralgia; those ascribed to the sphenopalatine ganglion, those secondary to zoster, those attributed to the geniculate ganglion, those accompanying certain cases of convulsive tic, and those due to an involvement of the trigeminus by tumors. Finally, an attempt is made to describe what are considered minor trigeminal neuralgias as distinguished from major trigeminal neuralgias, for which the Gasserian operation is the proper therapeutic procedure. Though the difference is merely one of degree, it is important to have some basis for separating them. In the case of the five types of pseudotrigeminal neuralgia which may be mistaken for trigeminal neuralgia, there is every reason to refrain, if possible, from a trigeminal neurectomy.

Functional Insufficiency of the Pulmonary Orifice in Association with Mitral Stenosis.—Vaquez and Magniel (*Bulletin de l'Académie de médecine*, March 9, 1920) report three cases presenting the usual manifestations of mitral stenosis together with a diastolic murmur with its maximum intensity on the left, along the sternal margin, and apparently originating in the second interspace. This murmur is believed to have been that already described by Graham Steel in 1886. Such a murmur may arise in one of two different ways. In one instance it is due to mechanical conditions and the rise of pressure in the lesser circulation, which results in distention of the pulmonary artery and its orifice. In other instances it is due to a pulmonary endarteritis, rather similar to the superadded, slowly progressive infectious endocarditis so frequently met with in valvular disease. Its localization in the pulmonary artery may be accounted for on the ground that this artery is particularly exposed to stress in these cases. The disturbance of the pulmonary artery entails additional danger chiefly through the infection associated with it; often it disappears when the infection is recovered from. Where it is due to mechanical distention of the vessel, the prognosis is much less serious, and it may even constitute a favorable factor, affording some degree of relief as regards the primary mitral disturbance.

Chemical Disinfection of Tuberculosis Sputum.—E. Arnould, (*Presse médicale*, April 3, 1920), recommends highly for this purpose a solution already used with success by Küss for several years. It consists of soft, potash soap, eight grams; crystalline sodium carbonate, ten grams; thirty-five per cent. formaldehyde solution, forty grams, and water, enough to make one litre. This soapy, alkaline solution, containing four per cent. of formaldehyde, liquefies the sputum thoroughly and certainly kills the tubercle bacilli in from fifteen to twenty hours. The solution is, moreover, odorless, gives off no irritating fumes, is of low toxicity, is easily handled, facilitates cleansing of sputum cups by its liquefying property, and can be prepared by any one at slight expense. The practitioner is urged to use this solution whenever circumstances do not permit of disinfection of sputum either by boiling water, steam, or incineration.

Proceedings of National and Local Societies

AMERICAN ASSOCIATION OF OBSTETRICIANS, GYNECOLOGISTS, AND ABDOMINAL SURGEONS.

Thirty-third Annual Meeting, Held at Atlantic City, N. J., September 20, 21, and 22, 1920.

The President, Dr. GEORGE W. CRILE, in the Chair.

Interesting Surgical Conditions of the Liver and Biliary Tract.—Dr. JOSEPH H. BRANHAM, of Baltimore, said that a healthy gallbladder should never be removed, nor should it be subjected to operation. When symptoms were severe enough to warrant operation, in most cases the organ was so diseased as to be of little or no value and was a menace to future health. For several years he had removed the gallbladder by a method that was almost subperitoneal. After the abdomen was opened the ducts and neighboring organs were carefully examined. This could usually be done by palpation. If the disease was confined to the gallbladder, an oval incision was made over the lower anterior surface of the organ, and the peritoneal coat was dissected from the deeper tissues. When the duct was reached it could always be known by the well marked sphincter. A considerable margin of the peritoneal coat was left at the liver attachment; the duct was severed, and after being explored and emptied of stones, a large catheter was fastened to it by a twenty day catgut suture; the peritoneal coat from each side was stitched together, and then to the ventral peritoneum. This left the catheter outside the peritoneal cavity and gave a smooth serous surface over the entire wound, thus preventing adhesions. By confining the incision to the accessible part of the organ, the suturing was made easier. A small cigarette drain left in for one or two days was all that was needed in most cases. After operations were done in this way, there were few adhesions, and the patients were left usually in good condition.

Dr. ORANGE G. PFAFF, of Indianapolis, Ind., in discussing the subject, said that all aimed to be conservative in the treatment of gallbladder diseases, but in the last few years the statement had been made that a gallbladder once diseased always diseased. This, however, was not always the case. If the abdomen was opened and no stones found, a gallbladder that could not easily be emptied by pressure should be drained, but in most instances, instead of draining the gallbladder that was grossly diseased, all were now agreed that the thing to do was to remove it.

Where the Rubber Glove Is Behind the Times.—Dr. ROBERT T. MORRIS, of New York, said that discarding the rubber glove represented one of the best advances of surgery in general. It interfered with the sense of touch in some kinds of work. In abdominal work the rubber glove was not necessary if the hands of the operator were otherwise well prepared. It made a longer incision necessary, and consequently was not in accordance with the principles of modern surgery.

Dr. HERMAN E. HAYD, of Buffalo, N. Y., said he thought that Dr. Morris had done the profession a great service in teaching them to do surgery through small incisions and to develop tactile sense. He was rather surprised that a man with a judicial mind like Dr. Morris's should have put before the association so strongly the results of the work of Kennedy without the use of rubber gloves. It was hard for him to believe that in ninety-nine per cent. of the cases in which other surgeons who wore gloves had operated there were adhesions, while those operators who did not wear gloves only had seven per cent. adhesions. To him this was ridiculous. Out of one hundred cases, probably sixty to seventy-five per cent. were the simplest kind of operations and would have taken but a short time to accomplish. He did not believe it was possible that such results could take place in the hands of ninety-nine men with adhesions and Dr. Kennedy had only seven per cent. adhesions from operating without gloves.

Dr. CHARLES L. BONIFIELD, of Cincinnati, Ohio, could not believe that the rubber glove in and of itself caused adhesions. He could conceive of a man with rubber gloves being rough, and a man without rubber gloves scratching tissues with his finger nails. One thing that induced him at an early age to wear rubber gloves was the fact that his finger nails were very hard to keep clean, and he seldom knew whether he had them clean or not, and he felt it was better to cover them up with something that he could boil. While rubber gloves might impair tactile sense a little, still they should be used in operating.

Dr. GORDON K. DICKINSON, of Jersey City, stated that Dr. Morris wanted to standardize surgery by discarding gloves. Why were gloves worn? To prevent infection. Why was infection likely? In one went the rounds of the clinics one would see the most incongruous things perpetrated, such as putting on soap and washing it off again. If one wanted to get his hands free from germs he must not wash the soap off and must not scrape it off. It did not do any good. Put soap on, rub it in, and one would kill the germs, and there was no germicide more potent than potassium soap.

Dr. JOHN W. KEEFE, of Providence, R. I., said that a surgeon's tactile sense was not as acute with a rubber glove on as it was without it. When rubber gloves first came into use he used them in nearly all cases in which he operated. Now and then he slipped the rubber gloves off because he thought he could feel better without them. At one time he was in the habit of going to see Dr. McBurney, who was one of the greatest surgeons America had ever produced. He told him about his difficulty, and he said that was exactly where the mistake was made. The rubber gloves should be kept on in a difficult case and the fingers ought to be educated as to how differently things felt with the gloves on. He went home and had practised that ever since.

Dr. JAMES N. WEST, of New York, said that Dr. Morris had spoken of the great tendency to standardization, with the result that it stifled originality. There were times when the surgeon could operate to greater advantage without the use of gloves than with them, particularly if he was very careful in the preparation of his hands.

Dr. ABRAHAM J. RONGY, of New York, said in a large city like New York it was not only unsafe to operate without gloves, but unsafe to examine patients in the office without gloves, and as a measure of protection the use of gloves was one of the best things for the physician.

Rupture of the Bladder during Labor.—Dr. JOHN W. POUCHER, of Poughkeepsie, N. Y., reported a case, stating that rupture of the bladder during labor was very rare. It might be caused by instrumentation or spontaneously by an overdistended bladder. The immediate symptoms simulated those of rupture of the uterus. It was important that the bladder be frequently emptied during severe and protracted labor. Recovery of the patient depended on prompt operative treatment.

My Method of Performing Version.—Dr. IRVING W. POTTER, of Buffalo, N. Y., stated that for the year ending August 31, 1920, he had personally delivered 1,113 women, 920 of whom were delivered by version. Of the 920 versions, 400 were in primiparæ, and 520 in multiparæ. He showed lantern slides demonstrating his method of performing podalic version. He emphasized the importance of proper preparation of the patient for delivery, the condition of the bladder, cervix, and vaginal canal. He laid stress on the position of the patient during delivery, and the degree of anesthesia necessary.

Dermoid Cysts of the Ovary; Etiology, Diagnosis, and Treatment.—Dr. BENJAMIN R. McCLELLAN, of Zenia, Ohio, gave a brief review of dermoid cyst of the ovary, saying that recent research into the etiology of these strange neoplasms, especially the work of Goodall, had added new interest and emphasis to the parthenogenetic theory. As to the diagnosis, the question of possible infection and malignant potentiality in these growths demanded more careful study of all tumors arising from the pelvic basin. The x ray should be more generally utilized. In the treatment the utmost care should be exercised in removing the tumor *en masse*, without the use of trocar or aspirator. The case reported by the author only added another example to prove the fact that these tumors did not prevent pregnancy nor interfere with parturition as long as the pedicle remained untwisted.

Certain Procedures in Vaginal Surgery.—Dr. SAMUEL W. BANDLER, of New York, described an operation for cystocele and prolapse of the uterus, modified by partial hysterectomy and complete perineorrhaphy. He exhibited numerous lantern slides and made a running comment on them.

Case of Congenital Absence of the Vagina with Other Abnormalities.—Dr. DAVID HADDEN, of Oakland, Cal., reported the case of a girl of eighteen with absence of menstruation. The symptoms were indefinite. Examination showed external parts nor-

mal with unperforated hymen. A body felt through the rectum occupied the position of the uterus. Operation revealed the absence of a vaginal canal, the pelvic mass being the right kidney fixed in position. The cecum and appendix were undescended and located in the right kidney fossa. A general consideration of the factors involved was discussed.

Luteum Extract.—Dr. ADAM P. LEIGHTON, JR., of Portland, Me., spoke of the necessity for combining thyroid extract with luteum in many cases. He spoke of the use of these extracts in cases of menorrhagia, dysmenorrhea, functional amenorrhea and obesity. The climacteric symptoms and others were due to ovarian insufficiency. He pointed out the great necessity for prolonged administration of luteum extract in order to obtain results.

Submucous Adenomyomata.—Dr. OTTO H. SCHWARZ, of St. Louis, Mo., stated that submucous adenomyomata were comparatively rare, only a few cases having been described in the literature. The condition was primarily a localized adenomyoma in the uterine wall. These tumors were usually diffuse in character and their tendency to become submucous was quite unusual. He described a very large submucous adenomyoma, unusual in structure, with marked cystic dilatation and intracanalicular projections. A subserous tumor, described by Robert Meyer, arising from the Wolffian duct or the parovarian tubules, was mentioned. The submucous tumor in the author's own case, although identical in structure with the tumor described by Meyer, was definitely of Müllerian origin.

Endocrine Influence, Mental and Physical, in Women.—Dr. JAMES E. KING, of Buffalo, N. Y., pointed out that the endocrine system supplied stimuli for the fulfillment of the two fundamental laws of nature. The secretions prompted in the human being many mental attributes. In women, both the physical and mental phenomena associated with reproduction were the result of glandular secretion. There was some fact and much theory bearing on this. Woman would be better understood when we had further knowledge of the complicated operation of her endocrine system.

Case Reports.—Dr. GEORGE VAN AMBER BROWN, of Detroit, Mich., reported, 1, papilloma of the bladder in a woman forty-five years of age; 2, a case of advanced carcinoma of the uterus in a woman of thirty-eight; 3, fibrosarcoma mucocellulare carcinomatodes (Krukenburg type of tumor) in a woman fifty-seven years of age; 4, chorioepithelioma malignum with multiple fibroid tumors in the uterine tissue, in a woman thirty-five years of age; 5, lymphoblastoma primary in the parovarium of a child five years of age.

Accidental Hemorrhage; Cæsarean Section; Hematuria in Pregnancy.—Dr. JAMES K. QUIGLEY, of Rochester, N. Y., reported two cases, one of accidental hemorrhage in which a Cæsarean section was done. The interesting points in this case were: 1. Of the several causes advanced as factors in the etiology of accidental hemorrhage, this patient presented three, viz.; trauma, a marked pregnancy toxemia, and a short umbilical cord (seventeen cm.) 2. Extreme intrauterine pressure. 3.

Gross appearance of the uterus *in situ*, corresponding to that described by Wing and by the author in a previous publication. 4. Relatively large amount of free peritoneal fluid. 5. Leucocytosis and clinical improvement following the two transfusions. The second case was one of hematuria in pregnancy in a primipara aged thirty. Of the various causes offered for hematuria, it seemed that the most plausible etiological factor was toxemia of pregnancy, as evidenced by increased blood pressure and edema.

Hernia of the Ileum Through a Rent in the Mesentery.—Dr. WILLIAM EDGAR DARNALL, of Atlantic City, N. J., reported the case of Mrs. D., aged forty-six, married, one child, weight two hundred pounds. She had never been seriously sick, family history was negative. She was well developed, with splendid physique, and the picture of health. She had had no symptoms until recently when she noticed a lump in the abdomen and had suffered from menorrhagia. Examination revealed a fibroid tumor of some size freely movable and uncomplicated and there was a very slight laceration of the cervix. On July 18, 1918, he performed a supravaginal hysterectomy, from which she made a perfect recovery and in due time was sent home.

On August 12th, a month afterward, she ate a large dinner, and the next morning, about six o'clock, she was seized with an agonizing pain in the epigastrium and vomited. The pain was so severe that morphine was administered. Her bowels were irrigated, producing a copious stool. The next day her pains were considerably improved but distention appeared. During the afternoon there was an absence of peristaltic sounds on auscultation, her pulse was increasing in rapidity and her temperature had risen to 101° F. Dr. Hobart A. Hare, of Philadelphia, saw her with Dr. Darnall in consultation and was of the opinion that in spite of the temperature there was some form of obstruction, although enemas still brought away some feces and gas. Operation was decided upon and performed at 5 p. m. The findings were as follows: Through an opening in the mesentery of the second convolution of the ileum there had slipped a loop of the ileum belonging to the first convolution high up on the left side under the spleen. There was a volvulus of this loop and it was gangrenous and perforated. There was an abscess in the left kidney pouch and foci of pus at various locations in the upper abdomen. The whole abdominal cavity was filled with fluid and intestinal contents.

The hernia was released and the rent in the mesentery closed. Twelve inches of ileum was resected and a Murphy button used for anastomosis. Drainage and counterdrainage were used. Proctoclysis with Locke-Ringer solution was instituted and the Fowler position ordered. An opportunity was afforded of inspecting the lower abdomen and pelvis which were found in perfect condition with no adhesions or constricting bands. He was unable to account for the rent in the mesentery so far away from the site of the pelvic operation, which made this unusual hernia possible. She had led a very quiet and well ordered life since her first operation and seemed in perfect health. The patient succumbed to shock in about five hours.

An Unusual Abdominal Cyst.—Dr. ORANGE G. PFAFF, of Indianapolis, Ind., on March 20, 1920, was consulted by a young married woman on account of a large abdominal cyst which had been tapped ten days previously, twelve quarts of thin fluid having been drawn off at that time, according to the statements of the patient and her husband. Her first menstruation occurred at the age of fourteen and this function had always been normal. She has passed through three normal pregnancies, the last one three years ago, which was followed by phlebitis affecting both legs. This had, however, practically disappeared when he first saw her. She had noticed some abdominal swelling about four months before she came to him. This had not given her much trouble until about six months before she consulted him, when she began to suffer severely from pressure. Her appetite was also impaired and she had lost a few pounds in weight in that time. The abdomen was greatly distended and fluctuation was readily elicited in every part. Dullness on percussion was general with the exception of a slight indistinct resonance at the epigastrium.

The case was considered one of large ovarian cyst, and on March 22d she came into the hospital and the following day was operated upon. Through the usual median incision Dr. Pfaff said that he came directly upon the sac, which was so densely adherent to the parietal peritoneum that it required some care to form a line of cleavage, the further separation, however, being accomplished with only moderate difficulty, and he was then able to pass his hand freely in every direction, widely on either side and almost from the diaphragm to the pelvic brim. Retracting the lower angle of the abdominal incision the bladder came into view and appeared to be normal and was free from adhesions. Its healthy color contrasted strongly with the dark, purplish red of the cyst wall, which was firmly adherent across the brim of the pelvis, in front of the uterus on a line corresponding to the vesicouterine fold. Upon separating the sac along this line a gush of several quarts of water occurred. He continued the separation and lifted up a flap of the material constituting the anterior wall of the cyst, which was now recognized as a perverted and greatly thickened omentum being in places more than half an inch thick. With the lower omental flap up he came upon a number of peritoneal cysts varying in size from that of a walnut to a large grapefruit which filled up the pelvis on both sides. The intestines were held down and away from the anterior abdomen wall by innumerable strands of adhesions, so that even when distended by gas there would be no note of tympany elicited on percussion. This was one of the puzzling elements in diagnosis. The laboratory report on the specimen removed for examination stated that the condition was one of proliferating tuberculosis with much newly formed fibrous tissues. Dr. Pfaff said that the case was unique in his experience. The great thickening of the omentum, the extensive fibrinous formation, and the restrained viscera were unusual and the resultant absence of tympany regardless of posture constituted a complex which was very puzzling indeed and very misleading in diagnosis.

Obstruction of the Superior Mesenteric Vessels from Bands, with Threatened Gangrene of the Greater Part of the Small Intestine; Recovery.—Dr. JAMES N. WEST, of New York, stated that gangrene of the small intestine, due to thrombosis of the superior mesenteric vessels, might have been cases of this kind. The distribution and anastomosis of the superior mesenteric vessels was such that, if they were destroyed, death must necessarily ensue. In a case reported by Dr. West, the patient, a female, aged twenty, had general abdominal pain for three days, when suddenly violent and uncontrollable pain developed, with elevation of temperature, increase of pulse rate, and moderate distention. Abdominal section revealed the small intestinal tract in a state approaching gangrene, with a firm band, which proved to be a cecal mesentery, extending across the superior mesenteric vessels. In the inflammatory process of the appendix the cecal mesentery undoubtedly became tightly constricted across the superior mesenteric vessels, obstructing them completely, and resulting in a swelling, edema, and bloody effusion in the mesentery of the small intestines. Appendectomy was performed, and the abdomen closed without drainage. Protracted recovery ensued. Union was by first intention. Collapse on the second and third days was successfully combated by intravenous saline infusions with adrenalin. On the fourth day there was a mild septic temperature, and on the sixth day there was diarrhea, continuing violently until the sixteenth day. Malpositions of the cecum were frequent, and might be hypodescent and hyperdescent. In hyperdescent volvulus of the cecum was favored and at times necessitated operation. The collapse, diarrhea, and septic temperature were probably due to autolysis.

The Toxic Thyroid; Its Treatment by Ether Oil Colonic Anesthesia.—Dr. GORDON K. DICKINSON, of Jersey City, N. J., said that mental stress required a strong thyroid, adrenal and liver. One or more might fail and produce symptoms. To handle such a case skillfully required a careful surgeon and an adept at applied psychology. Excessive action of thyroid was always associated with an overactivity of adrenal and glycogenic function of liver, and a mental state analogous to fright. Surgery of the thyroid under these conditions demanded recognition of component states. A slight affront to the mind overreacted on thyroid and adrenal. Proper technic demanded elimination of such possibility. An anesthesia cone to the face and a surgeon working at the neck were mental traumatism. In ether oil colonic anesthesia we had the ability to anesthetize patients safely without their knowledge.

Gehrung Pessary.—Dr. EDWARD J. ILL, of Newark, N. J., drew attention to the value of the Gehrung pessary. He urged its use in those who were old and decrepit, and for those with decompensated heart disease, diabetes, and serious renal disease; also for those with a pulmonary affection that contraindicated anesthesia and for timid patients. The use of the pessary, however, was by no means to take the place of the Watkins operation, of which Dr. Ill spoke in the highest terms.

Enuresis.—Dr. JOHN W. KEEFE, of Providence, R. I., said that, viewing the subject of enuresis broadly, he had arrived at the following conclusions: 1. Considering the multiplicity of measures that had been found to assist in the cure of enuresis, it seemed that underlying them all there must be some common factor, which he believed to be a psychophysiological impression made upon the brain. 2. Heredity undoubtedly played an important rôle. 3. These patients had a neurotic, unstable nervous system accompanied many times by mental retardation. 4. Psychotherapy, mental suggestion and education of the subconscious mind should supplement other forms of treatment to the end that involuntary or voluntary micturition might be anticipated. In a word his contention was that the cure was the result of the mental awakening and stabilizing of the brain cells that controlled the act of micturition.

The Female Pelvic Ureters.—Dr. DAVID W. TOVEY, of New York, said that palpation of the ureters should be a part of every vaginal examination. Ureteritis, because of the nerves irritated, might simulate disease of any of the abdominal organs. Palpation would make the diagnosis. There was nothing between the palpating fingers and the ureters but the anterior vaginal wall. They were marked on the anterior wall by the ureteral ridges and could be felt from their entrance into the bladder to the pelvic brim. They were felt as flattened cords the size of a leather shoe string, and could be displaced in the loose cellular tissue. In ureteritis, periureteritis, stone, pyelitis, and tuberculosis, the ureter was thickened and tender. Ureteritis and periureteritis were commonly due to infection from the cervix, and it might follow hysterectomy. It was a condition often mistaken for cystitis. Palpation showed a thickened tender ureter with intense desire to urinate. Treatment should be applied to the cervix and parametrium and not to the bladder, as cystoscopic examination showed the bladder to be normal.

Pathological Leucorrhea and Its Treatment.—Dr. FRANCIS REDER, of St. Louis, Mo., stated that all pathology had its basis in physiology. A leucorrhea which was physiological must be differentiated from one which was pathological. To gain an exact knowledge of the condition of the genital tract it was well to take an existing leucorrhea as a starting point. The character of the discharge and the various states upon which the discharge depended, might reveal the seat of the disorder. The term leucorrhea grouped together a large number of lesions, and although it was the most common and prominent symptom in the majority of uterovaginal cases, the fact that certain constitutional disorders had important relations with the different forms of leucorrhea must not be overlooked. Under such conditions it was not merely the expression of a symptom but of the disease itself. Different periods of female life presented different kinds of leucorrhea. Forms of leucorrhea which were not pathological were easy to diagnose and readily yielded to proper treatment. A pathological leucorrhea often presented great diagnostic difficulties.

THE PLACENTAL GLAND AND PLACENTAL EXTRACT.

BY SAMUEL W. BANDLER, M. D.,
New York.

Professor of Gynecology, New York Post-Graduate Medical School and Hospital.

In the discussion of glandular interrelations, even though we leave out of consideration the possible element of altered character of the secretions, and concentrate our attention only on the thought of oversecretion or undersecretion, we have a markedly complex problem, owing to the numerous, in fact, almost innumerable variations which may exist. If to this already complex situation are added the variations in balance between the so-called vagus system on the one hand, and the sympathetic on the other, with their intimate and purposed association with the endocrine structures of the body, diagnosis and especially the reactions to endocrine therapy become still more uncertain. If we add further, what must not be omitted, the psychic factor in each individual patient, and the give and take dependence on physical states, on the autonomic nervous system and on the endocrines, we are led into a maze of problems sufficient to prove to the most unobserving that there can be few fixed and definite rules except such as serve to furnish an outline or a basis from which to proceed. Whether purposed or no, one may logically state that the outstanding sign posts of endocrine aberrations, such as acromegaly, Graves's disease, myxedema, Addison's disease, tetany, dystrophia, adiposogenitalis, diabetes, and other disturbances, were given to us to form or to help develop an outline or basis for the understanding of some of the vague factors in endocrinology. And even after years of observation and study, after years of surgery and clinical observation, after the close study of the changed metabolism, we are beginning to recognize more clearly the association of the thymus, the adrenals, the posterior pituitary, and the parathyroids with the numerous symptom complexes of the states known as Graves's disease and myxedema. Myxedema too is a pluriglandular disease, cretinism is a lack not only of thyroid but of other endocrines essential to physical, organic, and mental growth. While the administration of thyroid activates the other endocrines, some of them are not able to respond and these must be substituted by gland extracts themselves. And we also must, of neces-

sity, recognize the numerous deviations from the cardinal symptoms as expressed by what has been called vagotonia and sympathicotonia. And with all this, we have not yet solved the questions as they relate to the thyroid itself, for it is probable that the thyroid is related to both the vagus and the sympathetic systems and that in the thyroid we may have more than one hormone.

The fact that the thyroid affections tending towards the symptom complex myxedema and to the symptom complex Graves's disease, with their numerous degrees of intensity, are more frequent in women than in men, points to the sex organs and to the gonads as being the central point from which originate those differences in psyche, in the autonomic system and in the endocrines, which render the female more susceptible to the psychic, bacterial, functional or environmental causes responsible for these diseases. And if in searching more closely for the finer distinctions implied in so general a statement, a gynecologist centres his attention on the ovary, he must of necessity go back to physiology and the physiological processes as a starting point. The very fact that the major forms of thyroid abnormalities come into the sphere of observation after menstruation has been well established, and that the minor forms are extremely frequent at puberty and adolescence would furnish a suggestion of the relation of the menstrual endocrine interrelation to thyroid aberrations. That the menstrual life of women of itself proves endocrine interrelation to be less stable and settled than in the male, is self evident. Therefore endocrine instability or imbalance constitutes a predisposing factor. But this lack of stability involves other endocrines than the thyroid. It concerns the pituitary, the parathyroids, the mammæ, the adrenals, and other glands.

Pregnancy makes demands on these endocrine structures and the so-called male endocrine glands are brought into increased activity by substances thrown off by the ovum designed, of course, for this special purpose. The sequelæ of abortion, the asthenia postpartum, the psychic disturbances postpartum, are only factors which we take into consideration. Lactation, the responsibilities of motherhood, changed or altered sexual procedures add hugely to the accentuating predispositions. While all these numerous and diverse sustaining arguments may be brought into the field of discussion we must in the first instance go back to the normal

physiological process, in order to get a proper start, and therefore the relation of the endocrines to normal menstruation is brought to our attention.

The instinct of curiosity lies at the root of science and religion. Suggestibility is the quality which implies the acceptance of opinions without question. Contr suggestion signifies a tendency to accept the opposite of what is stated or implied. A judicious mixture of these elements in any individual is responsible for ordinary incredulity.

As I recall my earliest studies in medicine two points connected with gynecology stand out quite plainly. One was the hesitation, rather decided, to accept the then current theory that the ovum given out from the ovary entered into the fallopian tube when the outer end of the latter partially enveloped the ovary before the rupture of the graafian follicle. It was difficult for many of us to understand how, in a case in which the ovary of one side had been removed and the tube of the other side had been removed, the fimbriated end of the fallopian tube could make this extensive excursion to the other ovary, this apart from the marvellous mechanism implied in the timing of such a process. It was not long before the knowledge of the action of the ciliated epithelium of the fallopian tubes made clear the manner in which ova enter the uterus. The other point which constituted a puzzle, was the amenorrhea of pregnancy; in other words, why does menstruation cease when fecundation takes place? Some years later the work of Von Spee and others on extremely early nested fecundated ova showed that the ovum buried itself in the decidua and that a digestive action is exerted by the trophoblast upon the surrounding decidual cells and capillaries of the now decidua of pregnancy. The question was, then, why does menstruation cease when embedding takes place? Implantations of thyroid gland furnished not only the physiological but the therapeutic tests of the existence of its internal action. Thyroid extract, in myxedema, gave the final touch that was needed in the demonstration of the hormone action going on in the body.

It was Knauer who, by his transplants of ovaries in animals, clearly demonstrated that the ovaries, too, produced their effects by means of an internal secretion, and not by any mechanically stimulated reflex acting through the autonomic nervous system. Then came the wonderful observations of the pathologists, who showed that in the various months of pregnancy, syncytial cells and chorionic epithelia were being continually thrown off into the circulation, dissolved and absorbed. This made easy the interpretation of these processes as a secretory function; in other words, it showed that we were dealing with what was truly a secretion produced by the outer shell of the ovum—that is, the placental secretion, for the placenta is only an exaggerated development of the chorion. In those days, when the ovary was considered the sole factor in the premenstrual and menstrual functions, a step forward was taken in the demonstration by these syncytial processes of what was later recognized as the antagonistic or inhibitory action of one secretory structure upon another in the performance of a normal physiological process.

While later the ovary and thyroid were recognized as of almost equal significance to the female sex organs, supporting each other in certain phases and probably antagonistic in others, yet at this time no direct proof of any relation or balance between ovary and thyroid was clearly disclosed. It did seem clear, however, that the ovary in its turn possessed the power of influencing thyroid activity and, therapeutically, ovarian extract was used in hyperthyroidism. The thyroid develops at puberty and adolescence, it swells before each menstrual flow, it develops noticeably in the early months of pregnancy, and numerous experiments on the thyroid and the results of its failing or diminished functions during the years of development, prove it to be intimately related, not only to growth and to mental development, but quite specifically related to the early and later development of sex organs. In other words, the thyroid activates the other endocrines and exerts a trophic effect on tissues and cells. As regards the ovaries and the progressive change of the corpus luteum of menstruation into the true yellow body of pregnancy, nothing then but the external envelope of the nidated ovum, its trophoblast, syncytium, and chorionic epithelium could be held responsible. The reaction and stimulation of the corpus luteum by the tiny ovum, and by the offthrow from the cells invading the maternal capillaries, is an evidence of unity of action designed to accomplish a definite purpose.

As a broader understanding of endocrine action on menstrual function became more clear, it was apparent that while the ovaries initiated menstruation, the corpus luteum aided in changing the endometrium into the decidua menstrualis and, by limiting the tendency to rhexis and diapedesis was concerned in perpetuating the decidua menstrualis into the decidua of pregnancy. But other of the internal structures are also concerned in this function whereby the nesting of the ovum is favored. This relation of the thyroid was not recognized early but its action on the decidua, trophic in character, was later readily granted. One effect is to prevent any myxedematous change in the decidual cells and structure and to limit bleeding. Thyroid activity, we believe, first exerts a trophic effect on the decidua, and second, aids in the nidation of the ovum.

Later came the understanding that the adrenals, and particularly the pituitary body, were involved in the cyclic process, called menstruation. If this were so, then activity by what might be called placental secretion was limited, not to the ovary alone, but concerned other glands. Since its relation to the corpus luteum is of a stimulative nature, the corpus luteum and placenta have then a somewhat similar function.

The study of the action of the pituitary gland, and its relation to uterine processes during menstruation, the not infrequent occurrence of dysmenorrhea, the realization that menstruation was a miniature labor, turned our thoughts more directly to the study of the relations of the posterior pituitary to menstruation and to the interrelation between the various endocrines on the one hand, and the posterior pituitary on the other. Since the

thyroid is stimulated before and during menstruation, the natural thought is that corpus luteum rouses part of the thyroid and stimulates the posterior pituitary. Since overactivity of the posterior pituitary is a stimulus to the onset of menstruation, the suggestion becomes more relevant, that the placental secretion inhibits the posterior pituitary. Such a notion would make the placenta and another part of the thyroid and corpus luteum partners, so to speak, in their antagonism to one and the same endocrine.

The production of menstruation is initiated by the ovary, not forgetting the interstitial structure. Cooperation is evidenced by the corpus luteum and thyroid and the posterior pituitary. Unless the posterior pituitary is inhibited, menstruation takes place. I may say that the effect of the posterior pituitary in aiding the onset of menstruation is evidenced by its therapeutic application. It would seem as if all these endocrine activities suggested and started in each premenstrual phase are then accentuated and made into a definite balance for nine months, by the introduction of the placenta. The balance in the autonomic nervous system which takes on the form of a crisis at menstruation is altered by placental action and is postponed to the day of labor. In pregnancy the entrance of the anterior pituitary and particularly of the adrenal cortex is assumed as produced by the placenta.

That the ovary contains elements differing in their degree of influence and even in the character of their influence seems to be fairly well established. While extract of the hilum and ovarin diminish uterine contraction and lengthen the coagulation time, corpus luteum contracts the uterus and shortens coagulation time. While all the elements further uterine hyperemia, the corpus luteum does so less markedly. While the interstitial tissue and the corpus luteum favor dilatation of the peripheral vessels, the follicle tissue and the liquor folliculi do not dilate the peripheral vessels and do not postpone the coagulation of blood, ovarin and lutein and placenta are trophic in their action on the uterus and favor its growth and hypertrophy. But they, too, appear dependent on an associated activity of the thyroid so that their normal functions may be carried out. Even though the contractile function of the posterior pituitary is normally nullified during pregnancy, its trophic effect is still exerted and through a normal relation and cooperation of these glands, assisted by the stimulated activity of the anterior pituitary, and the suprarenal cortex, we have a growth of the uterus, especially in the early months, which can by no means be attributed to any mechanical stretching action by the ovum. It seems as if the placenta which, of course, is partly male in origin, brings into the sphere of activity what might be called the male glands, meaning thereby, the anterior pituitary and the adrenal cortex which functionate in a relative degree, more in the male than they do in the female. Menstruation is not a process which Nature wishes. Instead of thinking of menstruation as the normal picture and pregnancy as a new process, let us think of the matter in the reverse manner. Let us view menstruation as a process to which Nature yields un-

readily, hoping each month to see use made of the preparatory steps and readjustments taking place in the uterus and in the endocrine system. If a nest for the awaited impregnated ovum is prepared, if nidation is favored by certain endocrines, if other endocrines which favor menstruation are to be checked, then the fecundated ovum must bring its own material for the preservation of the balance essential to continued growth. The inability to preserve this balance, the inability to hold the interstitial ovary, the posterior pituitary, and probably the adrenal medulla in check, accounts very readily then for many cases of so-called sterility and for many cases of repeated miscarriage.

Before going further, let us review the premenstrual constitutional phenomena. We speak of premenstrual cyclic changes, but they are, as stated above, changes which anticipate nidation, and menstruation is simply to be viewed as an evidence that nidation has not taken place. Stated in simple language, ovary and thyroid, pituitary and adrenals and probably other endocrines increase their functions. A balance exists in the endocrines and in each endocrine awaiting nidation. Nidation introduces a new secretion and one end of the balance becomes stronger and the crisis known as menstruation is postponed for ten lunar months, when the postponed crisis does occur in a magnified form, known as labor. Therefore premenstrual phenomena of a constitutional nature and their variations depend greatly on the interglandular relations of that period and may concern interstitial, ovary, corpus luteum, thyroid, adrenal cortex, adrenal medulla, anterior pituitary, posterior pituitary, and other glands.

Of the various endocrines, little is generally known or established concerning the pineal, the adrenal cortex, and concerning posterior pituitary overactivity. It was the study of this latter condition, and the belief in its frequent occurrence and its probable relation to many premenstrual annoyances, and possibly to many psychic disturbances, that attracted me to the study of the effects of placental extract administered by mouth and by hypodermic injection. My belief is that in the premenstrual rearrangement of the endocrine relations, the thyroid, adrenal, medulla, and the posterior pituitary are responsible for the largest number of annoying symptoms. Placental extract is therefore used with judgment in selected cases, for the very fact that it delays menstruation constitutes a bar to its use in cases of relative amenorrhea with or without dysmenorrhea unless given in combination with ovarian extract.

When pregnancy takes place, the placental extract aids by throwing its weight into the balance against part of the thyroid, posterior pituitary, and adrenal medulla. For months the constitutional annoyances, which so often occur before menstruation, disappear and even though the nausea and vomiting of pregnancy may be severe, these are of a different nature. The soothing effect, the quieting effect, the stimulating effect in the vast majority of cases of pregnancy should of itself make a silent plea for the powerful influence of the placental secretion and its allies, the anterior pituitary and the adrenal

cortex, and if by reason of an unusual power in the glands to be inhibited, this soothing effect is not in evidence, we may point to some of the annoyances, especially in the later months, as an evidence of endocrine rebellion and dysbalance and to other annoyances, as probably related to anaphylaxis.

If cyclic premenstrual constitutional phenomena are an index to the endocrine relations of the moment, then the premenstrual psychic phenomena may be judged by the same token. And in the study of the premenstrual psychic upsets, we get a glimpse of the various mental aberrations dignified, when sufficiently gross by the term psychosis. And it is from a study of the question from this angle, as it were, that the view is fixed in my mind, that, whatever may be the exciting and contributing causes, abnormal and altered endocrine action should be given an important place in discussing and treating the so-called mental diseases. The annoyances of pregnancy are physical and rarely psychic. But in the postpartum period, we do observe the onset of melancholia, mania, or other manifestations. These two facts are mentioned again as proof of the quieting psychic action of the placental element and of the disturbed relationship (which sometimes occurs) in the attempt at endocrine rearrangement after the termination of pregnancy. And since we are still discussing pregnancy we may step back a distance and call attention to the fact that while sterility, in some cases, is due to a lack of proper function on the part of the ovary or the thyroid, or the pituitary, yet, excessive action of the posterior pituitary is a very frequent cause of sterility, of extremely early miscarriage, often not recognized as such, of miscarriage at periods when it is readily recognized, and of repeated or habitual miscarriage.

A notable action of placental extract is the production of what the patient calls "a sleepy, dopey feeling," and this is often noted, even though thyroid extract and placenta are administered together. Only rarely is a result observed in regard to the pulse rate. A few patients have complained of paroxysmal tachycardia even though thyroid was not given. Therefore there occasionally take place either a thyroid or an adrenal stimulation, but this influence is only transitory, for I have given placental extract in hyperthyroid cases without production of tachycardia, or an increase in tachycardia, and not rarely with great benefit.

The therapeutic test is supplied by the results obtained on the administration of placental extract. What is its effect on menstruation? As a rule the normal rhythmical menstruation function is delayed thereby several days. This action is likewise evidenced in many individuals whose menstruation, while regular, comes on at periods three to five days before the normal interval is reached. Going further into the field of pathology and considering cases of menorrhagia or even metrorrhagia, it is found that placental extract tends to diminish bleeding. Therefore, judging by my own experience, I take it that placental extract not only inhibits those regular processes whereby blood is lost from the uterus, but does likewise in many conditions

simulating menstruation, even though the flow is profuse or the interval shorter than normal.

Placental extract has an effect second only to mammary extract, in diminishing excessive menstruation, though it lacks entirely the power often evidenced by mammary extract, of diminishing the size of the uterus as in myomata, and it does not have a like influence in aiding involution. Carrying the therapeutic effort over into the field of pregnancy, I find that threatened early miscarriage or abortion is often averted by the administration of placental extract and thyroid extract. The various processes going on in the uterus, which are typical of normal menstruation, are practically the steps which occur in many miscarriages. Therefore placental extract, by inhibiting these processes, furnishes added proof that it delays or inhibits the processes tending to menstruation. During pregnancy many patients are sleepy, drowsy and tired, without a suggestion of nausea, and we presuppose here that the placenta has put the posterior pituitary to sleep.

The premenstrual rousing action which the corpus luteum exerts upon the thyroid and the important relation between the corpus luteum and the thyroid during pregnancy emphasize the place of these two glands in the scheme of endocrines as sensitized allies in a process that concerns opposition to the posterior pituitary. This sensitization, designed for aid to the processes of procreation, is one of the factors which makes thyroid aberrations so frequent in women. It is this uncertain balance between thyroid and corpus luteum and posterior pituitary which tends to make pituitary aberrations so frequent in women.

The effect of placental extract in frequently relieving the psychic symptoms of restlessness, marked irritability and physical and mental *wanderlust*, which I attribute, in many cases at least, to overactivity of the posterior pituitary, has led me to think that deviations in the activity of the posterior pituitary may be responsible, not only for alterations in the amount and character of the cerebrospinal fluid, but for changes in certain cerebrospinal areas which cannot, as yet, be defined, and for changes in the autonomic nervous system, and consequently for changes in behavior.

Judging from the quieting effects of placental extract in those cases where the symptoms are seemingly due to posterior pituitary overactivity, I translated my observations to the realm of that phase of human instinct called the libido sexualis. If we take the libido into consideration, we must grant the relation of the endocrines to this element in the human being. In the female, the pituitary plays an extremely important part not only so far as concerns the physical but likewise as regards the psychic association. I consider this condition to be an urge with an endocrine basis, and for that reason its variations in intensity are numerous and the variations at different periods of life are often noteworthy. Placental extract is, so far as I know, the most valuable of the endocrines administered for the purpose of controlling or modifying this human instinct. Though Freud would have us believe that the neuroses and psychoses are related

almost entirely to the instinct of sex, it requires little experience and little study to prove that this is certainly not the case. But many of the endocrines are related to growth and to the preservation of function, and most of the important ones are naturally related in part to the development and preservation of the organs of sex and of the instincts and emotions associated therewith. Hence among the neuroses and psychoses there must of necessity arise symptoms and phenomena, often overexaggerated as to their importance, which bear an intimate relation to the physical or psychic processes associated with the sex side of man. In many of these aberrations the balance in the glands and between glands which stimulate and those which inhibit is lost, most often through a physical endocrine predominance and not as a matter of will or even desire. I find the thymus and the placental extracts valuable when our purpose is that of anesthetizing or modifying the so-called libido sexualis.

Many factors of an apparently unrelated nature may influence cerebrospinal pressure. Thus the injection of duodenal mucosa extract exercises an effect on the cerebrospinal fluid. Hypertonic and hypotonic solutions injected into the veins or introduced into the gastrointestinal tract or into the rectum lower and raise the cerebrospinal pressure (Weed and McKibbin). The therapeutic effect of spinal puncture in some cases of eclampsia is remarkable, and so in many severe as well as in mild conditions this factor must be taken into consideration. For this reason, but without the support of results furnished by animal experimentation, I have used placental extract when headaches, stiffness of the neck, and other disorders, seem by their location to be possibly connected with variations in pressure or possibly qualitative complications in the cerebrospinal fluid.

It is stated that the normal escape from the cerebral chamber is by way of the arachnoid villi direct into the dural sinuses, and along perineural spaces about the cranial and spinal nerves. The cell membrane of Gley is believed to be concerned by osmosis with the amount and character of the cerebrospinal fluid. Dr. A. Goodman is more than ever convinced by his more extensive work of the beneficial effect in chorea of injecting the serum of the patient to take the place of the withdrawn cerebrospinal fluid. It was for these reasons that I have noted the action of placental extract by mouth and by hypodermic injection because it seemed possible that it might be influential in promoting osmosis or exchange. I have to this day no proofs that it in any way alters pressure within the cerebrospinal canal, either raising or lowering it. But the very gratifying relief of many of the typical headaches makes me lean to the notion that it probably diminishes pressure.

The study of gland modifications in pregnancy divulges the thyroid as an all important structure designed for the protection of the pregnant woman and for the preservation of a normal state. The pituitary, however, by its interference with this normal balance, is of the greatest importance in the production of pathological conditions. Many con-

siderations have entered into the study and observation of these phenomena and I have come to the conclusion that in thyroid minus and posterior pituitary plus we have a very frequent combination, associated in many cases with the toxemia of pregnancy in its various well known manifestations. Not the least noteworthy is the increase in blood pressure, the headaches, and the excess of the cerebrospinal fluid. In this latter condition the cell membrane of Gley is apparently involved and by reason of its very location and its relation to the cerebrospinal fluid this posterior pituitary gland may well be related to the processes of osmosis and exchange. That this should be the case in a secretory structure like the cell membrane of Gley is a natural deduction, since we know the relation of the posterior pituitary to renal function and to renal excretion.

The great and complex metabolic changes of the body in its normal state yield to important metabolic alterations in the pregnant individual, and without attempting to solve or even explain the intricate processes which have yet to be discovered, we are therapeutically depending more and more on our conception of endocrine aberrations to aid in the solution; and as the thyroid gland is, to my mind, one of the important protecting organs, especially over the renal epithelium, it is only necessary to conceive of a myxedematous change in the renal epithelium and in altered kidney function produced by the posterior pituitary, to furnish ourselves with at least an outline of some of the changes occurring in the so-called pregnancy kidney. A like change in the cell membrane of Gley would serve to explain many of the cerebrospinal symptoms in the pre-eclamptic and eclamptic states. It was a study of this condition that attracted my attention to that form of headaches so peculiarly typical in women, the headaches in the occipital region radiating behind the ear and down the cervical spine, associated with soreness and stiffness. I set out with the idea that these changes—which are so often premenstrual, but not always—may be due to altered activity of the posterior pituitary (though possibly in part to a swelling or hyperemia of this structure), but more probably due to some interference with osmosis, the cell membrane of Gley, and the spinal nerve roots.

While some were helped by thyroid and some by corpus luteum, I have found that in a number of cases placental extract gives surprisingly effectual results; and when with peculiar headaches of this type we find not infrequently psychic disturbance characterized by restlessness and inability to be physically or mentally quiet—a typical mental *wanderlust*, as we might call it—it is the first thought to attribute both to the same cause, and if this be true, what stretch of the imagination is it to conclude that mental *wanderlust*, without these typical headaches, may be due to the same cause? Only by dissociating associated phenomena can we lay the finger of investigation on many of our puzzling problems. Furthermore, when by the therapeutic application of placental extract the physical manifestations disappear and the psychic peculiarities often improve noticeably, the test of

therapy justifies the conclusion that the primary conception was correct.

Since in many of these cases the blood pressure was above normal, a test was made concerning high blood pressure in general, and it became apparent that a number of the endocrines enter into the causation of high blood pressure in many cases, and metabolic changes occurring in the body serve as an explanation for the apparently contradictory basic theories. Hence it is apparent to me that there are no one, two, or three endocrine causes of high blood pressure, but that each individual with this symptom must be viewed as a distinct entity and the gland aberrations of that individual must be sought for and disclosed, of course first taking physical states into consideration.

Pursuing this plan from the basis of menstruation alone, and treating the conditions of amenorrhea, menorrhagia, metrorrhagia, and dysmenorrhea by endocrines, not infrequently I noticed a reduction of the blood pressure, even though no attempt at a solution of the primary cause was in mind at the time; and taking a large number of patients at the climacteric period and noting their symptoms after this basic experience, the fact was likewise disclosed that in many cases the blood pressure was noticeably reduced.

Considering this material, the fact stands out that thyroid minus and pituitary plus explain a certain proportion of cases of high blood pressure. When this is traced back to the domain of physiology, it suggests the influence which the thyroid and the pituitary probably have on the cerebrospinal fluid, and on the kidneys and their excretory function; but to state that a pituitary minus may not be associated with high cerebrospinal fluid pressure is to disregard entirely the metabolic changes associated with endocrine activities and to overlook the relation of either plus or minus pituitary to the osmosis and interchange in the cerebrospinal fluid. For while diabetes insipidus is attributed to pituitary minus, I am inclined to believe that in some cases pituitary plus increases the urinary output. So, reviewing the theoretical, the physiological and the therapeutic conditions, I have become satisfied that we have in placental extract a substance which should be ranked among our therapeutic agencies as worthy of study. If posterior pituitary does half the harm for which, in my opinion, its overactivity is responsible; if placental extract does only half as much as I have gleaned from my therapeutic endeavors, I may still safely suggest that the important factor concerning placental extract is its ability to influence the posterior pituitary and to stimulate the anterior pituitary and the adrenal cortex.

134 WEST EIGHTY-SEVENTH STREET.

Rhabdomyoma of the Ovary.—H. E. Himwich (*Journal of Cancer Research*, July, 1920) reports a case of rhabdomyoma of teratomatous origin of the ovary in an infant. Cells were discovered in the tumor which are found exclusively in rhabdomyoma of the heart, and the fact that there was branching in some of the fibres led the author to conclude that the tumor described arose from the heart muscle.

NEW ASPECTS OF MENSTRUATION

Based on an Analysis of the Menstrual Fluid.

BY JAMES OLIVER, M. D., F. R. S. (Edin.),
London, England,

Gynecologist to the Hospital for Women.

The menstrual fluid, amounting to seventy ounces, of which an analysis was kindly made for me by Dr. Francis Goodbody of University College, London, was preserved for examination with thymol and was obtained from a girl of eighteen who had never seen her menses because the hymen was imperforate. This girl for eighteen months before coming under my care had complained of periodical attacks of pain in the abdomen and back which had recurred regularly every month and had on each occasion continued more or less severe for five days. The pain was always worse in the abdomen but was never accompanied by sickness and sometimes she stayed in bed two days out of the five on account of the pain which was always greatly relieved by hot applications to the abdomen. For six months she had remarked that her abdomen was getting larger and for this same length of time she had a more frequent desire to pass urine. On March 1st and during the four succeeding days she had one of her usual attacks of pain and when I examined her seven days later the physical signs then noted were the following:

As the patient lies on her back the anterior abdominal wall in the hypogastric and umbilical regions is pushed markedly forward by a large and somewhat ovoid swelling which extends out of the pelvis and reaches to two inches above the umbilicus. From it there can be elicited an ill defined feeling of fluctuation. The vagina is completely closed by a bulging membrane of apparently great thickness and on the surface of this membrane in the centre is a deficiency of material which looks like the spot where the perforation of the hymen should have been exhibited.

On March 15th, ten days after what undoubtedly was the last menstruation, I made a crucial incision through the thick and tough imperforate hymen and collected seventy ounces of menstrual fluid. Without further interference—no douching even—the patient was returned to bed and from six hours after the operation there was no discharge whatever until April 13th, when without pain the menstrual discharge made its appearance and continued in evidence for five days. This discharge, during the first four hours, was rather watery and of a pale red color, but thereafter and until it ceased it was of a dark cherry red hue. Judging from the patient's records of confinements to bed on account of pain before the hymen was incised, the menstrual cycle was one of about thirty-one days, but it will be observed that the first menstruation after the evacuation of the retained menstrual fluid was twelve days late. This I attribute to the fact that the uterus which was somewhat hypertrophied, took, after the evacuation of the retained fluid, ten days to return to a normal size.

DESCRIPTION AND ANALYSIS OF THE FLUID.

The fluid as it flowed through the incised hymen presented from first to last the same appearance

and was throughout of a uniform consistence. These are noteworthy points because fresh menstrual fluid must have been poured out ten days before the retained fluid was evacuated and because quite as much of the fluid had been pent up in the uterus itself as had actually accumulated in the vaginal sac. It is truly remarkable that the fluid as it escaped showed no evidence that the portion which must have been in contact with the imperforate hymen for two years or more was of a different character or different age from that which came from the cavity of the uterus. It was thick like treacle and tenacious and diffusion could have played no part in establishing its homogeneity. It exhibited no free fluid and there was not a trace of blood clot to be seen. It was of a dark reddish brown color with light nut brown streaks through it. The nut brown strata were probably due to hematin. After the fluid had been kept thirty days the nut brown streaks had disappeared and the color was uniformly dark reddish brown of a slightly deeper hue than when fresh. The fluid showed a faintly alkaline reaction. It gave markedly the spectrum of hemoglobin and on qualitative examination it was found to contain a large quantity of albumin. The fluid poured sluggishly but on the addition of water it became perfectly fluid.

Quantitative examination disclosed the following: specific gravity 1031, water 87.13 per cent., and solids 12.87 per cent., consisting of organic material 95.02 per cent. and ash 4.98 per cent. Further analysis showed: serum albumin 12.49 per cent., serum globulin 16.56 per cent., mucin 3.37 per cent., and fat 0.0051 per cent.

The inorganic ash contained sodium, potassium, calcium, magnesium, phosphorus and iron and the salts present were principally sodium chloride and sodium carbonate with small amounts of phosphates and sulphates. It is extremely doubtful whether the fluid contained iodine and after repeated testings it was determined that if iodine was present the amount was so small that it could not be estimated. It contained no arsenic.

Microscopically large numbers of red blood corpuscles and some leucocytes were seen together with small crystals of hemoglobin enclosed in a colorless matrix.

Judged by its physical characters we have no reason to believe that the retained menstrual fluid had ever at any time behaved as blood poured out from broken down capillary vessels would or should have done. Its consistence like that even of menstrual fluid retained in the uterus alone was such that diffusion could not possibly have played any part in establishing its distinctive glutinous character. Moreover, the pressure exerted by seventy ounces of fluid, which after distending the vagina had so accumulated in the uterus as to form an abdominal tumor almost as large as an adult head, must necessarily have prevented the periodical degenerations and disintegrations of the endometrium and the concomitant capillary hemorrhages to say nothing of the recuperation and healing month after month of such devastated structures. As a matter of fact the continued recurrence of menstruation in marked cases of retained menstrual

fluid is only conceivable on a secretory hypothesis.

Again on scrutinizing the analytical findings there cannot be the least shadow of a doubt that the retained menstrual fluid was not and never had been blood poured out by broken down capillary vessels. We can at the outset banish from our minds the question of the probability of any admixture of vaginal secretion modifying or affecting the fluid, since there could have been to all intents and purposes no secretion from the vaginal mucous membrane as otherwise, because the vagina had never been anything but a closed sac, the secretion would have been accumulating for at least thirteen years before menstruation set in and that secretion could not possibly have diffused through the fluid of the recurring menstrual periods. It will be remarked that the specific gravity of the fluid, 1031, is much below that of normal blood, the specific gravity of which averages from 1055 to 1060 and that the quantity of serum albumin in 12.49 per cent. is half as much again as that found in blood serum. The mucin content, 3.37 per cent., is remarkably high and no doubt the viscous character of the fluid—homogeneous in this respect—was largely if not entirely due to the presence of that substance, and there can be no gainsaying the fact that the mucinogen which is the precursor of mucin was secreted simultaneously with the menstrual fluid and was not added afterwards, for as I have already observed diffusion could have played no part in establishing the homogeneity of the fluid. By the hypobromite test, moreover, there was no evidence that the fluid contained urea, neither was there any evidence of the presence of sugar nor of cholesterol.

It is noteworthy that there was in the fluid an abundance of hemoglobin and hemoglobin products. Regarding the presence of hemoglobin crystals I would remind my readers that in the laboratory it is an extremely difficult matter to obtain oxyhemoglobin or hemoglobin crystals from human blood. That hemoglobin in some remarkable way plays an all important rôle in the phenomena of menstruation and in the function of gestation is certain. In cases of pronounced anemia and chlorosis, for example, it is common knowledge that menstruation is often suspended for a greater or less length of time and only becomes reestablished under such circumstances when the hemoglobin content of the red blood corpuscles has been adequately improved and increased. That hemoglobin plays a most important part in starting and carrying on gestation there can be no doubt, for the oxidative processes and powers of the uterus must be enormously increased at this time and from the hemoglobin the fetus derives the iron it stands in need of for its immediate and future requirements.

Confronted with such facts as I have here detailed there clearly is no justification for clinging to the belief that menstrual fluid is purely and simply blood poured out by vessels which have been opened into in consequence of a degeneration and disintegration of the mucous lining of the uterus. On a secretory hypothesis alone is it possible to account for the great variation in the amount and in the physical characters of the menstrual fluid,

not only in different individuals but in the same individual at different times and even during the same menstrual period.

In dealing with the question of the mechanism whereby the different bodies entering into the composition of menstrual fluid are produced we are dealing with a problem vastly more difficult than that concerned in the production of milk but by careful clinical observation valuable light may eventually be thrown on this all important matter.

123 HARLEY STREET.

DIFFERENTIAL DIAGNOSIS BETWEEN DISORDERS OF THE PELVIC ORGANS IN WOMEN AND OF THE ABDOM- INAL VISCERA.*

BY E. E. MONTGOMERY, M. D., LL. D., F. A. C. S.,
Philadelphia,

Professor of Gynecology, Jefferson Medical College; Gynecologist to
Jefferson and St. Joseph's Hospitals.

An accurate diagnosis of abdominopelvic conditions is of the utmost importance for the proper treatment of disease. An inaccurate or careless study of such conditions will result in unnecessary or improper operative procedures. Certain groups of subjective and objective symptoms are often associated with diseased conditions in such a fashion as to present an almost absolute physiognomy of the disorder. I once heard a prominent surgeon say, "A woman, fair, fat and forty belching; gallstones." This diagnosis may be found true in the majority of such cases but it is a dangerous assumption, and capable of much harm. The surgeon who operates on such a conclusion is executing sentence on the victim on circumstantial evidence.

Gastric distention, discomfort after eating, dyspepsia, frequent and ineffectual efforts to yawn, frequent eructations, are all indications of gastric, duodenal and hepatic disorders, and with the exception of jaundice may arise from the pressure on the sigmoid or rectum of a large retroverted uterus or one with a fibroid in the fundus. Such pressure by interfering with the transmission through the tract of its contents through reversed peristalsis refers the discomfort to the upper abdominal portion of the alimentary canal. Such pressure, by interfering with the pelvic circulation, is also a frequent cause of hemorrhoids, fissure and pruritus ani. It must become evident, then, that no woman should be subjected to operation on either end of her gastrointestinal canal or the adjacent structure at the upper end, the gallbladder, until a careful bimanual investigation of her pelvic viscera has been made. I recall a sister, who came to this hospital from Baltimore and was referred to me for treatment of hemorrhoids, in whom an examination disclosed that the cause of the hemorrhoids was the presence of fibroid growths filling up the pelvis. The hemorrhoids were in evidence but operation on them alone would have been unsatisfactory as the injured rectal structures under such circumstances are slow in healing.

The recognition of retrodisplacements and enlargement of the uterus from whatever cause is readily determined by careful bimanual examination. While the evidence of such a condition does not preclude the simultaneous occurrence of abnormal conditions in the upper abdomen, the procedure necessary for its relief affords an opportunity to explore the entire abdomen and determine abnormal conditions affecting gallbladder, duodenum and stomach, and possibly save the operator from the mortification and discredit of knowing that he had subjected the patient to an unnecessary operation.

Probably a more frequent cause for error in diagnosis is the presence of pain or discomfort in the right lower quadrant of the abdomen. In the female, the gallbladder, kidney, ureter, appendix and uterine appendages must all be kept in mind as possible causes of discomfort in the right side. Inflammation of any of these structures may cause such discomfort. That the general surgeon often errs is shown by the frequency with which women are subjected to operation for removal of the appendix, without obtaining relief from the discomfort for which the surgeon was consulted, subsequent examination disclosing evidence of tubal inflammation from which relief is obtained only by another operation for the removal of the offending structures.

Such experiences demonstrate very clearly the necessity of a careful study of the individual patient; nothing should be taken for granted. Disease of the adnexa is too easily excluded by abdominopelvic examination to justify the operator in overlooking its existence and thus subjecting the patient to an unnecessary operation upon the appendix or an inadequate one in the sense that equally serious conditions are overlooked. Lesions of the urinary tract should be suspected when the kidney is palpable as an enlarged, tender and dragging organ. The urine is likely to contain pus and blood and the frequency of micturition points to irritation of this tract. Rarely, an appendiceal abscess will involve the peritoneum over the ureter to such an extent as to simulate ureteral disease. I had a case of carcinoma of the appendix in which the carcinoma had infiltrated the peritoneum and through it the wall of the ureter. The patient died from a recurrence of the disease.

Malignant disease of the ovary, or of the intestines, may present conditions rendering difficult a definite diagnosis previous to abdominal incision. Malignant disease of the ovary presents no distinctive symptoms from an ordinary ovarian cyst, until it has infiltrated the wall and extended to the surrounding structures, or has ruptured, producing a more disseminated spread of the disorder attended with ascites. In addition to the mass which can be palpated in the pelvis, such patients present palpable evidence of secondary nodules through the peritoneum and especially marked infiltration of the omentum. It seems a part of the function of this structure to aid in covering up and assist in forming a guard against the spread of infection. I have seen the omentum, having wrapped up within its folds a suppurating appendix, closing

*Read before the St. Joseph's Hospital Clinical Society, June 8, 1920.

every avenue for the further spread of the infection; so it is also seen enveloping a threatened rupture of a malignant ovary and itself receiving the charge which led to its infiltration. In the majority of cases of malignancy originating in the intestine the cell infiltration leads to early constriction and obstruction of the intestine before there is infiltration of the surrounding structures. Here the signs of obstruction and reversed peristalsis soon occur. The natural tendency of all enlargements of the adnexa and intestines is to drop into the retrouterine pouch and as the disease progresses they become adherent and sooner or later lead to infiltration to the adjoining structures forming a mass which adds to the difficulty of diagnosis.

The progress of the condition originating in the ovary may be much slower in its progress and be attended with greater accumulations of ascitic fluid and not infrequently great distention of the intestines with gas. Many cases illustrating these conditions which have occurred in the last few years come to mind, three of which I will present.

CASE I.—Mrs. S., aged forty-eight, referred February 22, 1919, by Dr. Goldberg, had been pregnant twice, delivered at full term with natural labors. A curettage followed the last. Menstruation was regular, lasting four to five days; no leucorrhœa. Bowels had always been regular, but she was unable at the time to have a movement because of some obstruction. Her abdomen was greatly distended especially at the upper part. She gave a history of having had an operation last June when, her daughter informed me, it was necessary to suture the bowel in two places. Examination revealed a mass in front of the rectum which pressed upon it and was evidently the cause of the obstruction. On February 27, 1919, she was operated upon in St. Joseph's Hospital. A median incision discharged a large quantity of ascitic fluid and the pelvis was found filled with a mass of cancerous growth involving both ovaries with secondary nodules in the peritoneum of the bladder and other points. The omentum was extensively infiltrated. The uterus contained fibroid growths. I pulled the mass out of the pelvis, removed both ovaries and the fundus uteri; covered the raw surfaces with peritoneum and closed the abdomen after having irrigated the belly with hot saline solution. Her condition was so bad that we resorted at once to intravenous injection. The patient recovered from the operation and was first seen at my office doing fairly well, on April 18th, and again on June 23rd and July 17th, feeling quite uncomfortable. There was evidence of a return of the mass in the pelvis. On July 22nd I tapped her in my office and drew off about a gallon of fluid. I tapped her again on August 4th, when nearly as much fluid was withdrawn. Dr. Richards subsequently attended her at her home and I saw her with him October 17th. I believe she lived over the end of the year but was uncomfortable all the time.

CASE II.—A colored woman at the Jefferson Hospital had undergone operation nearly a year before when Dr. Bland removed the fundus of the uterus for fibroids. Her abdomen was quite distended and a mass could be felt in the pelvis. The

abdomen was opened which revealed carcinoma of the ovaries. The mass was removed and the patient recovered and left the hospital. Two months later this woman returned with ascites. Examination revealed that there was a recurrence of the growth in the pelvis. After an evacuation of the fluid by trocar this patient was lost sight of.

CASE III.—On October 1, 1919, Mrs. G. came under observation. She was forty-seven years old, pregnant three times, in all of which she went to full term. She had not menstruated for a year, and did not show leucorrhœa. She had been obstinately constipated and without urinary disturbance. She had pain in the lower abdomen. My notes say that the examination disclosed a fibroid in the posterior wall of the uterus and hysterectomy was advised. The obstruction was ascribed to the pressure of the mass on the sigmoid.

On November 13, 1919, it was noted that the patient had had no movement of the bowels since I last saw her, which made the necessity for relief very urgent. At St. Joseph's Hospital, the abdomen was opened in the median line which revealed that the mass was a tumor between the rectum and the uterus adherent to both. The principal mass was found to be a carcinomatous involvement of the ileum which had dropped down and become adherent and infiltrating the tissues with which it lay in contact. Both the posterior wall of the bladder, the fundus and posterior surface of the uterus and the anterior surface of the rectum were involved. I resected the ileum and made an end to end anastomosis, cut away the peritoneal surfaces of the rectum and fundus of the bladder and removed the uterus. Proctoclysis was instituted at once. She had some distention on the second day but was given fractional doses of calomel every fifteen minutes and saline following. She had five movements of the bowels the next morning and improved steadily. A week after the operation she had a very offensive discharge from the vagina. It was so foul that the intern attributed it to a fecal fistula, but it was evidently due to colon bacillus infection and soon cleared up. She soon had a recurrence of the disease and although she lived some months her condition was so uncomfortable that one could not but regret that she had not been permitted to die without the first operation.

These cases are not reported on account of the successful result of the operative procedures, but for the purpose of illustrating the difficulties of diagnosis. A proper diagnosis is of importance to determine not only the condition but to be able to advise as to whether any operative treatment should be employed.

Pregnancy often affords a cause for error in diagnosis of supposed appendicitis. If the tumor is a fibroid, a subperitoneal one, as the uterus increases in size such a tumor may be squeezed between the developing uterus and the bony pelvis or abdominal wall and the pressure thus induced lead to its being pressed into the uterine wall like a cork in a bottle until its circulation is cut off and it begins to set up inflammation as a foreign body. The pain, tenderness and muscular rigidity frequently lead to the diagnosis of appendicitis. I have seen three

such patients, two of whom were subjected to operation for supposed appendicitis. In the third case, recognizing the condition, I attempted to carry the patient along by pushing up the uterus to release the pressure but the condition caused an abortion and the condition had become so disturbing as to later require an abdominal hysterectomy.

Ordinarily in acute appendicitis complicating pregnancy, the cecum generally being somewhat fixed, the gravid uterus lies in front of it and consequently the pain may be aggravated by making pressure over the uterus or in pushing behind the uterus. In a fibroid causing the condition the pressure and pain are more anterior to the position of the appendix.

1426 SPRUCE STREET.

RECENT ADVANCES IN OBSTETRICAL PRACTICE.*

BY JOHN OSBORN POLAK, M.Sc., M.D., F.A.C.S.,
Brooklyn,

Professor of Obstetrics and Gynecology, Long Island
College Hospital.

Obstetrics has become a specialty. The obstetrician is no longer a medical man, but an obstetrical surgeon. We have passed out of the period of the midwife; the public demands a specialist, and he must be fully equipped with a training in the fundamentals of the science and art of obstetrics, general and special diagnosis, and an appreciation of the principles underlying obstetrical surgery.

The existence of the trained obstetrician is justified, if he is able to produce a living child with a reasonable certainty of life, with less mortality and morbidity to the mother, and has the ability to restore the parturient woman to the proper economic state of health, and as perfect anatomically as before she was delivered.

Prenatal care is the right of every prospective mother. This does not mean an occasional examination of the urine when we happen to remember to make one, and a record of the expected date of confinement, but a searching and painstaking examination of the individual. This investigation should not only include an examination of the heart, lungs, kidney, and other general condition, but of the thyroid and kidney function, repeated estimations of the phthalein elimination and its relation to the blood pressure, and a routine blood Wassermann test, together with careful observations as to the development of the pregnancy, inquiry into the character of the discharges, and a bacterial examination of these discharges; and finally, the diagnosis of the presentation, position, posture, and pelvic mensuration of both the pelvic brim and outlet. For not only has the child to enter the bony pelvis, but it has also to pass through it and get out of it, and this can only be determined by a proper appreciation of the relative size of the child to the mother's pelvis.

This prenatal investigation permits us to discover syphilis; prevents the occurrence of eclampsia; allows the recognition of malpositions and dispro-

portion, and thus minimizes the difficulties of labor. Being thus forewarned, we are forearmed for any emergency, and consequently we know how to conduct the labor in the best interests of both the mother and the child.

Nothing has done so much to improve both maternal and fetal mortality as accurate prenatal work. In our clinic at the Long Island College Hospital, in over five thousand consecutive cases in which there had been done the most careful antepartum work, including routine salvarsan treatment of all syphilitics, there were but two per cent. of stillbirths. No case of eclampsia occurred in this series, and the operative procedures were reduced to a minimum; while the mortality and morbidity were both lowered.

Next in importance is the prevention of infection, and no one procedure has contributed so much to the diminution of this serious complication, which alone causes over ten thousand deaths annually in the United States, as the routine employment of abdominal diagnosis and a rectal examination following the course of ordinary labor.

While it has been contended by those who are making routine vaginal examinations that it is safe under proper precautions to enter the vagina at will, or at least as freely as is necessary to follow the advance of labor, our experience has shown us that not only the morbidity but the mortality has actually been reduced by the adoption of routine rectal examinations. The vulva and vagina are the constant habitat of bacterial flora which are readily carried into the uterus by vaginal examinations. This can be absolutely prevented by confining our explorations to the rectum. One can follow the course of labor by rectal touch after very little experience, and determine the dilatation of the cervix, the descent of the head, the rotation of the vertex, with almost as much accuracy as by vaginal feel. Only when the progress of labor has become arrested, is it our custom to make a vaginal examination. When this is necessary it should be made a surgical procedure. The patient's vulva is clipped, scrubbed, and sterilized. The examining hand is scrubbed and gloved, and with the patient under an anesthetic, a careful examination is made and the cause of the dystocia determined. Besides this, an accurate knowledge of the physiological processes of labor is essential, for labor is a mechanical process.

In the ordinary obstetrical case when the woman falls into labor, if she is a primipara and there is no disproportion, the head should be in the pelvis; while in the multipara, during the stage of dilatation, or shortly after dilatation is complete, the head either engages in the pelvis or it does not. This is fundamental. It would engage if it could, and if it does not, there is some defect in the power, the passage or the passenger. Consequently every labor must be studied and conducted in such a way by our knowledge of the presentation, position and posture, the preservation of the membranes, the maintenance of absolute asepsis, and the conservation of the nervous energy of the patient by rest.

Should intervention be demanded in the interest of mother or child, such operation can be done with

*Read at the Centennial Meeting of the Oswego County, N. Y., Medical Society, October 13, 1920.

the greatest margin of safety. Anodynes and analgesics are absolutely necessary for the patient's comfort in every prolonged labor; for certain mechanical processes must be effected in order that the child may pass through the pelvis, and these take time to accomplish and require active labor pains; and pain exhausts. The steps of the mechanism occur after there is dilatation of the cervix and the presenting part passes the brim and reaches the pelvic floor; this in turn is followed by dilatation of the vulva outlet. When the head passes out of the cervix, the uterus moulds itself about the child, and this interferes with the uteroplacental circulation, hence the importance of an accurate record of the fetal heart, its action under the influence of uterine contraction, and its reaction during the periods of uterine rest, are essential in order to estimate the effect of labor on the child.

With this knowledge, should the necessity for operative intervention arise, the woman is reasonably safe, for the child is in good condition, the woman's strength is not exhausted, infection has been minimized, and sufficient time has been given to accomplish the opening up of the soft parts by Nature's processes, consequently it may be deduced that every obstetrical case unless the delivery is spontaneous, will fall into one of two general classes, namely, either the child will come into the pelvis and providing the outlet is ample allow of infravaginal delivery, or it will fail to enter the pelvis when supravaginal delivery will be necessary.

In the first class, where infravaginal delivery is possible, certain essentials must be observed in order to have a favorable outcome. First of all, the cervix must be fully dilated and this takes time; to give this time to the patient, and yet conserve her nervous energy requires the use of anodynes. Here morphine and scopolamine used judiciously have given the greatest comfort to the woman, and have accomplished much which could not have been done without their aid.

Secondly, the membranes should be preserved until complete cervical canalization has been accomplished. The patient's comfort may be further advanced by keeping both bladder and rectum empty. A tight abdominal binder aids materially in crowding the head into the pelvis besides maintaining flexion, and it further maintains a better driving axis for force of the pain. Not until the head has reached the spines or has passed them should forceps be resorted to, for in good practice today median and high forceps are seldom if ever used. Both of these procedures have a high fetal mortality. On the other hand, low forceps is a life saving operation, and should be frequently employed, more frequently, perhaps, than at present, when the head is at the spines or below them and the cervix is fully dilated, and the outlet is ample; for many children lose their lives after they have reached the pelvic floor by too long delay in the perineal stage. Furthermore, the fascial sheets become overstretched and pelvic relaxation follows. Both Pomeroy and DeLee have called attention to this and have suggested prophylactic forceps and perineal section in the interest of the child. This perineal section may be done through the median

raphe or laterally, and so remove the soft part dystocia which is jeopardizing the fetal life.

Probably no advance in obstetrics has been so great as the recognition of danger to the child by routine auscultation of the fetal heart done at regular intervals throughout the entire perineal stage, as by this means we are able to recognize cord complications as coils, short cord and shoulder cord, by the arrhythmias and souffles and so terminate labor promptly in the interest of the child. Only in funnel pelvis where the outlet is contracted, namely, when the bischial and posterior sagittal diameters total less than fifteen, is infrapelvic delivery of the engaged head by forceps absolutely contraindicated. It is here with a contracted outlet, with the head well in the pelvis, at or below the spines, and a living child, that pubiotomy has its principal indication. Hebosteotomy is also permissible in occipitoposterior positions of the vertex arrested at the pelvic outlet by contracted hard parts.

Again, in mentoposteriors impacted in the pelvis with a living child, by increasing the size of the pelvis by pubic section the chin may be successfully rotated. Pubiotomy is not fraught with the serious dangers that we have been told about, and, while the field is limited, it has a distinct place in obstetrics, and in certain outlet contractions we may frequently be able to save a child without excessive trauma by its adoption. Do not for a moment understand that we place pubiotomy against Cæsarean section. To make pubiotomy successful, the head should be well in the pelvis and arrested at the outlet, while Cæsarean section has its chief indication in arrest of the head at the brim. In the past few years, indications for Cæsarean section have been broadened; not only is suprapubic delivery done for contracted pelvis, but for many relative conditions in the interests of the unborn child.

Davis has successfully used it in the treatment of placenta prævia. Occasionally it is of value in prolapse of the cord. Peterson has recommended it in eclampsia, and many operations have been done because of soft part dystocia. Many of these dystocias have been brought about by the procedures used for the correction of retroversion, such as the so-called suspension of the uterus, and have contributed a very large percentage of these dystocias which have necessitated the delivery of the child by the suprapubic method.

Cæsarean section is not without danger. In the collective records of two thousand cases of various operators in America, almost all of whom are recognized as obstetrical surgeons, we found that there was a mortality of over eight per cent., with a morbidity of between thirty and thirty-five. This high percentage of mortality and morbidity should not be credited to Cæsarean section, but to the results of not knowing what class of patients would need section before we started.

In our own service, where the prenatal work is exacting, we know practically from the very beginning in what case Cæsarean section will be required. Consequently, our mortality has been lowered as well as the maternal morbidity. If the labor has been conducted along aseptic lines, and the progress watched by rectal and abdominal examinations, the

suprapubic transperitoneal operation may be done at almost any time during labor with a mortality of less than one per cent. Primiparous labors are always trial labors, while in multiparæ we have a history of past performances, consequently these trial labors should be given the trial on aseptic lines and every precaution we can take in the interest of the mother and child is justified.

What runner, what athlete, what horse, what crew goes into the supreme contest without preparation and training; yet many women go into labor without training or even knowledge of what is before them. Potter, of Buffalo, arbitrarily shortens labor by the election of version in every case with no disproportion. While we cannot agree that his teachings are sound, he has certainly succeeded in what he started out to do. Potter is an artist, but who of us can duplicate his record without increasing our fetal and maternal mortality, and we question the advisability of deliberately disengaging the engaged and moulded head and bringing down the feet as a routine, just to relieve the woman of the pain and exertion of the second stage of labor, when by the employment of morphine and scopolamine in the first stage and anesthesia with gas and oxygen or ether and oxygen in the second stage—together with the judicious use of forceps when the head is below the spines supplemented by perineotomy—we can have a fetal mortality of between three and four per cent. or about half of that reported by Potter.

287 CLINTON AVENUE.

THE COMPLETE FORCEPS OPERATION.

BY EDWARD P. DAVIS, M. D., F. A. C. S.,
Philadelphia,

Professor of Obstetrics, Jefferson Medical College.

If the histories were taken of patients who had had bad deliveries followed by worse recovery, usually in private practice, and if these histories were analyzed, it would be found that in many cases the circumstances were essentially as follows: There may have been slight disproportion between mother and child, or failure in the development of the natural forces of labor. From whatever cause the mother failed to deliver herself and assistance was required; with the help of a trained nurse only or possibly without such assistance, the attending physician anesthetized the patient and delivered her by forceps. There was more or less laceration, for which an attempt was made at repair. The circumstances were such that this was not done in a manner satisfactory to the physician, for a tendency to postpartum hemorrhage developed in the patient, and it was necessary to check that as soon as possible. The child was injured somewhat, but apparently no permanent results followed these injuries.

Convalescence in this case was prolonged, temperature was higher than normal, and, while the mother nursed her child, her recovery was not complete. Some time afterward, it was found upon examination that considerable tear of the cervix had occurred which had not completely healed, and that

the repair of the pelvic floor and perineum had not been completely successful. For this, secondary operation was required, and in all between one and two years passed before the woman recovered something like her previous health. In other cases there is the distinct history of postpartum hemorrhage after such delivery, or of well defined puerperal septic infection.

If these histories are analyzed, it is found that the primary cause of the unsatisfactory result did not lie with the inefficiency or neglect of the attending physician. He possessed such average knowledge and operative skill as the law demands; he took such precautions as he could to make his operation aseptic. The nurse had been properly trained and did her work as carefully as circumstances permitted. Two factors caused the bad result. One was delay in delivery, for the general practitioner frequently does not recognize symptoms of threatened exhaustion, but waits until the patient is thoroughly tired before interfering. The second factor was insufficient appliances and assistance and an incomplete and a nonsurgical operation. The circumstances were such that an aseptic technic could not be thoroughly carried out and efforts at checking hemorrhage and repair were not carried out in a thoroughly efficient manner.

How can better results be obtained? Must the profession be content with such procedures? The most important factor in all discussion relative to obstetrical practice is the question as to whether obstetrical practice should be put on the same professional level as surgical practice. So long as obstetrics is considered essentially the practice of midwives, and so long as complications in obstetrical cases receive adequate attention as a last resort only, no improvement can be expected. When cases of abnormal labor are treated by obstetricians in properly equipped hospitals, or when the obstetrician takes to the private house the necessary equipment for good work, then, and then only, will substantial improvement occur. In suggesting what can be done in this matter, I advance no theory. I merely state what has been done in my personal experience and observation.

It is most important that signs of approaching exhaustion be detected by nurse and physician before the patient reaches a point where haste may be necessary. Medical teaching should emphasize this fact. When interference is imperative, it must be remembered that a vaginal operation, whereby hands or instruments are passed from without into the uterus, cannot be a strictly aseptic procedure. In the present state of our knowledge, or ignorance, it is practically impossible to invade the uterus through the vagina without introducing bacteria. In carrying out the principles of surgery, the operator must remember that in such cases drainage cannot be neglected. Normally the genital track drains after labor by intermittent uterine contraction and by gravity. When interference is practised, these factors must be more than usually developed and additional precautions must be taken.

No more efficient cause exists for the development of septic infection than hemorrhage preceding or accompanying an operation. Hence, to conduct

an obstetrical operation upon surgical principles, the operator must see to it that precautions are taken to avoid hemorrhage and to secure necessary drainage. To bring these observations into a concrete form, the following technic has been successfully practised for a considerable period of time:

A thorough examination of each patient and as careful and complete a history as possible will show the shape and size of the birth canal, the strength and development of the mother, and approximately the size of the child. With these data symptoms of exhaustion in labor are carefully watched for and recognized as soon as possible. The forceps delivery is never attempted unless the head is well engaged and the birth canal dilated or practically dilatable. It is unnecessary to give details of hospital technic. In operating in private houses a portable sterilizer is necessary. Gowns, dressings, and other appliances may be sterilized in a hospital and taken to a private house, carefully protected from contamination. Boiled water and antiseptic fluids can be procured. A kitchen table, suitably prepared, makes a good operating table. Such matters of aseptic technic as are necessary can readily be managed, provided the operator is willing to take the trouble and give the attention to the problem.

It is especially important that a competent anesthetist, who has had obstetrical experience, and an additional nurse be at hand. Ether-oxygen is the anesthetic of choice, and in giving anesthesia for such an operation, obstetrical experience will indicate when the anesthetic is to be pushed and when its administration may be relaxed. Furthermore, the obstetrical anesthetist must be competent to observe with his hand the contractions of the uterus and the downward passage of the child. He must also be able to take charge of the patient immediately after delivery, watch her general condition, and recognize symptoms of threatened shock or hemorrhage.

The additional nurse should have had experience with the individual operator. She should have charge of his instruments and appliances, be responsible for their condition and sterilization, and be able to assist in the operation. The nurse who has charge of the patient will have enough to do in the general care of the mother and the infant.

Elaborate appliances are unnecessary. The legs of the patient can be held in position by the use of a folded sheet, and it is not the number or elaborate character of instruments or appliances which is of value, but the judgment and skill of the operator, the fact that he places his patient under the best possible conditions for operation and that, in justice to himself, he has adequate assistance.

It is not my purpose to describe delivery by forceps. Attention is directed, however, toward what should be done after the delivery of the child. The uterus, having been invaded, may be considered as possibly infected. Sufficient time should elapse after the birth of the child before an attempt is made to deliver the placenta. Should hemorrhage begin, this should be done at once by the introduction of the gloved hand. If conditions are favorable, the operator may wait from ten to twenty minutes with the

patient partially anesthetized before delivering the placenta. If the hand is introduced, it is well to note the location of the placenta as a guide for further procedure.

The uterus having been emptied, strychnine and aseptic ergot should be given by hypodermic injection. The uterus should be irrigated with one per cent. lysol solution and thoroughly packed with ten per cent. iodoform gauze. After trying various ways, I have discarded specula and tenaculum forceps and introduce the gauze with the left hand, while the right hand places the gauze in the fingers of the left and, by pressure on the uterus, aids in placing the gauze accurately. We have found by observation that the recently emptied average uterus will contain and retain a strip of gauze nine inches wide and four yards long. Where relaxation is threatened, more may be required; in rare cases, less is used. The advantage of this procedure is its tendency to prevent postpartum hemorrhage and the fact that the gauze acts as an efficient antiseptic drain.

Following the introduction of the gauze, the cervix is drawn down by tenaculum forceps, inspected, and, if torn, the lacerations are closed. No. 2 chromicized catgut is employed. The cervix is then released, the uterus carried forward in the pelvic cavity, the cervix pressed backward by aseptic gauze packed in the upper vagina and the uterus is watched by the hand of the anesthetizer. The pelvic floor and perineum are then inspected. The lacerations are closed. In the majority of cases in primiparæ the median incision will greatly lessen injury to the pelvic floor and perineum. The gauze is then removed from the vagina and a vaginal douche of one per cent. lysol is given. A strip of bichloride gauze is then tied to the end of the iodoform gauze within the uterus and the cervix is carried backward and the uterus put in normal position by this moderate vaginal packing of bichloride gauze. If the patient requires stimulation, this should be given by hypodermic injection before she leaves the operating table. In cases where it is desirable to leave the patient undisturbed so long as possible, she should be catheterized twice, just before the operation and at its conclusion.

It may be urged in criticism that this is meddling midwifery; that in many cases all that is needed is to extract the head and that such a procedure is more dangerous than beneficial. So long as human beings remain as they are now, it will always be possible to say that if a physician had not interfered, a different result might have occurred. We can only reason from a considerable experience and avail ourselves also of the recorded experience of others. Meddlesome midwifery consists in repeated vaginal examinations, infrequent and futile attempts to dilate the cervix and in unsuccessful application of the forceps.

A very practical question would indicate that such a procedure might be followed by the development of septic infection. After a considerable personal experience, both in private and hospital practice, and with the accumulated experience of those who work with me, it has been shown that this is not the case.

We have yet to find a case in which it could be shown that septic infection has developed in the patient following this procedure. Our experience indicates that this is beneficial and successful in preventing relaxation, hemorrhage and infection and in securing primary union of lacerations and in promoting complete recovery of the patient. It is also of some importance that under such precautions an accurate and proper application of the forceps to the child's head is more readily made than when the operator is at a disadvantage and also that those precautions which protect the mother from infection, give like protection to the child.

In after-treatment the gauze is removed in from thirty-six to forty-eight hours. If the upper gauze is dry and clean on removal, it is unnecessary to irrigate the uterus. If there are particles of decidua or membranes on the gauze, it is well to irrigate the uterus with one per cent. lysol solution. No other douching is practised. After the operation tonic doses of strychnine are given, to which some form of digitalis is added, if needed. In our experience, after-pains are caused by faulty contraction of the uterus and the presence of clots. It has been interesting to observe that under this method pain after delivery is rare. After the removal of the gauze, strychnine and ergot, in moderate doses, are given for a week or ten days. External stitches are removed in from seven to ten days; internal catgut stitches are absorbed.

An interesting and natural question arises. Will patients pay for the trouble, attention, skill and expense which such a procedure involves, in hospital or in private houses? The anesthetist must receive compensation, and the whole procedure calls for more expense than the public expect in an ordinary case. Under the usual circumstances, physicians realize that they will receive for their services only such compensation as the profession asks and as people under ordinary circumstances are willing to give. For years the profession has held obstetrical practice to be the cheapest sort of medical work, and the public have held that as the production of the child is thought to be a natural process, therefore it should be cheap. Much of the injustice and negligence of the present can be traced to these two causes. At present the majority of patients on first confinements go to hospitals. All of them should do so. All patients, whether in first or other labors, in whom there is any reason to suspect complications, should be sent to hospitals for their confinement.

If it is necessary to operate in private houses, it should be distinctly made clear that the operation is as difficult, responsible, and expensive as the removal of the appendix or the removal of a complicated ovarian cyst would be in a private house. Payment will be made for the removal of an appendix or cyst because it is not believed the appendix or cyst will return. If a higher value can be placed on human life, the public may be brought to believe that it might be well to pay adequately for the safe removal from the body of a mother of a child, although there may be others later. The mother's health is also of value.

250 SOUTH TWENTY-FIRST STREET.

SEVERE PELVIC INFECTION FOLLOWING HYSTERECTOMY.

*Report of a Case Where Radium Had Been Used
Two Weeks Before Operation.*

BY FRANCIS WARD LANGSTROTH, JR., M. D.,
New York.

Consulting Gynecologist to the New Jersey State Hospital, Trenton.

The time when the report of a single case history could have any interest to the medical profession is long since passed. We think in big figures these days, and do things in a large way. However, it would seem that an intensive study of a case illustrative and suggestive of so many diverse aspects might be a source of fruitful thought not only to those who devote their time so largely to gynecology and obstetrics, but also to those in general practice. The case here reported seems to bring before us clearly the following gynecological needs and problems:

1. The extreme importance of surgical judgment at the time of the first operation, so that gynecology is not subjected to disrepute and ill fame, by the unnecessary need of an almost immediate secondary operation for conditions which existed, and whose cause existed, at the time of the first operation.

2. That a focal infection of the cervix will always continue to be the cause of further trouble until it is completely eradicated, as has been pointed out by Sturmdorf (1 to 5), myself, and others.

3. The importance of a more careful diagnosis of cancer before much dependence can be placed upon reported cases of improvement from the use of radium treatment.

4. Can the use of radium cause the lighting up of a subacute or chronic pelvic inflammation into an acute one, as Graves (6) suggests?

5. How long should we wait before operating after radium has been used in cases of pelvic infection?

CASE.—Miss W., aged thirty-seven; past history and family history were negative, except for appendectomy twelve years ago. Present trouble started about a year ago, and consisted of severe pain in the abdomen at times, which the patient said was not always in the same place. About six months ago the patient was operated upon for some pelvic condition at a hospital in St. Paul. She was better for about two months and then the pain returned. The history of the previous operation was not very complete, but the diagnosis from that hospital was "right ovarian cyst and double hydrosalpinx." The report of the operation was "double salpingectomy, ovariectomy and removal of cyst." After this first operation the patient had a slight amount of fever for several days without a wound infection. This rise in temperature was probably due to a mild pelvic infection. The patient was referred to me in May, 1920, by her physician, Dr. Thelberg, on account of the return of the pain in the right side. This pain was worse at the time of her menstrual period. Pelvic examination disclosed an irregular, firm mass rather low down in the right pelvis, which was only moderately sensitive to pressure. The uterine body was normal in size and consistency,

but was displaced, either by this mass or from adhesions, to the patient's left side. Inspection of the cervix showed a nonlacerated but markedly infected cervix from which an almost mucopurulent discharge was issuing. A diagnosis was made of cystic right ovary which had been left at the time of the previous operation, and an infected cervix. Operation was advised and good prognosis offered. The patient did not act upon this advice but consulted several other surgeons who, I understand, considered the condition a recurrent cystoma. She then had one application of radium to the right external abdominal wall. About two weeks later the patient returned and again sought my advice, and was again advised to allow me to operate upon her. The patient entered the hospital on May 4, 1920. Physical examination was negative except for the patient's pelvic condition. The uranalysis showed: Color yellow, appearance slightly cloudy, reaction acid, specific gravity 1,032, no albumin, no sugar, no indican, no acetone, no crystals, no casts, many squamous cell epithelium, few pus cells. Repeated examinations of her urine all showed similar findings, except for slight trace of albumin after the operation.

Operation: Surgeon, Dr. Langstroth; anesthetist, Dr. Coburn; anesthetic, gas-oxygen-ether q.s. nitrous oxide-oxygen. Hysterectomy, begun at 9.15 a. m. and finished at 11.15 a. m. The left tube and ovary were missing and a peculiar thickened inflammatory condition of all the pelvic tissues was noted. The appearance of the tissues while hard to describe, differed from that of ordinary subacute inflammation of these tissues. A multiple cystic right ovary was found. This was bound down, back of the uterus, with inflammatory adhesions. The tube and uterus were involved in adhesions so it was thought best to remove the whole mass, supravaginally. The cysts contained what appeared to be clotted blood, but may possibly have been corpus luteum cysts. The endometrium of the cervix was cored out from above in order to remove this infected tissue, and a drain was left through the cervical stump. The abdomen was closed in the usual manner. The condition of the patient at the end of operation showed respiration 20, and pulse 120.

REMARKS.

The case was not inoperable in the sense that there was any outgrowth of malignant tissues into the pelvic tissues and there was no reason to expect any return of the trouble. An examination of the specimen showed the tube to be thickened and inflamed, otherwise negative, and the uterus normal. In the rest of the mass there was nothing to suggest a malignant condition. It was not malignant in the sense of being a solid sarcoma, or carcinoma of the ovary; however, as many of these cysts are of an adenocarcinomatous type, a specimen was sent to the laboratory for microscopical diagnosis. A report of the microscopical examination showed that there was no reason to expect any second or malignant growth in this case.

This patient started to show a septic temperature almost immediately after the operation. The first day at 4 p. m. it reached 100.1° F., the following afternoon at 4 p. m., 102.1° F. On the fourth af-

ternoon, however, it was only 100.2° F., and on the morning of the fifth day it was 98.2°. The packing was removed at this time, and the temperature went up to nearly 102° in the afternoon. At this time the patient complained of some pain in the lower abdomen. Examination disclosed rigidity of the abdominal muscles. The following day the temperature in the afternoon was again 101.5°. A mass was now discernible above the pelvic brim and it was seen that we had to deal with a large pelvic abscess. The patient's condition remained about the same, and it was thought best to allow the abscess to become well walled off before operating. On May 17th, thirteen days after the first operation, the dulness had reached above the umbilicus, and it was decided to operate at this time.

Operation: Surgeon, Dr. Langstroth; anesthetist, Dr. Coburn; anesthetic, gas-oxygen-ether q.s. (grams iv). The abdomen was opened and a cervical drain inserted, and a large amount of pus was evacuated from both the abdomen and the cervix. Rubber drains were inserted in the abdomen. Immediate operative recovery was good.

The patient from this time on made a tedious, but progressive, recovery, the only real setback being a slight pleurisy with effusion which cleared up without drainage being necessary. On June 16th the patient was examined by Dr. Satterlee, who reported her to be normal except for a few râles at the right base posteriorly and some dulness in the same area. On June 18th, according to the hospital record, there was a very moderate discharge from the wound and the patient was greatly improved in every way. On June 30th, the patient, who had been walking about the ward for nearly a week, went home. At the present time of writing the patient is in the best of health.

The first point which we wish to consider in studying this case is the importance of correct surgical judgment in connection with gynecological operations, in order that secondary operations may become necessary less frequently, and at the same time we shall consider the second point of importance in this case, i. e., that infections of cervical endometrium are responsible for most of the diseased conditions in the tubes and ovaries.

As has been pointed out by Sturm Dorf (1) and others, cystic conditions of the ovary follow infective endocervicitis very frequently. In fact, the writer is now convinced that this condition is the usual, if not the only, cause of simple follicular and corpus luteum cysts of the ovary. We do not yet know if these infections act in causing cystoma of the ovary, either the simple multilocular cystoma or papilliferous cystoma, which are probably due to an epithelial hyperplasia, although it is reasonable to suppose that the endocervical infection may act as the chronic irritant which induces this epithelial proliferation. The infection from an endocervicitis spreads up through the lymphatics of the cervix, uterus and broad ligament, thus reaching the ovary. There it may cause a thickening of the tunica albuginea delaying or preventing the rupture of Graafian follicles, thus producing cystic conditions of the ovary and causing many of the menstrual disorders which are so common in this class of patients.

In the case under discussion we had to deal with severe chronic endocervical infection, so that it was only reasonable to expect, if much ovarian structure was left after the first operation, that it would still be subject to cystic disease of the unruptured Graafian follicular type. The writer believes that if the infected cervical endometrium had been removed at the first operation this patient would have remained well.

Let us next consider briefly the question of diagnosis. As stated in the history, the patient had been operated upon about four months previous for the removal of a cystic ovary and a resection of the other ovary. The only point not clear was which ovary had been entirely removed. The pelvic examination disclosed a firm moderately sensitive nodular mass in the right pelvis, which, although adherent, did not seem to blend at all with the surrounding tissue, but could be freely outlined. It caused severe pain only at the time of menstruation. Taking into consideration the fact that the patient also had a badly infected cervix, was it not reasonable in the light of our present knowledge, to suppose that a cystic condition existed in the remaining ovary and that this condition should have been considered a nonmalignant ovarian cyst, since the patient's general condition was good, she had not lost much weight, and had no symptoms of peritoneal or bowel involvement, neither did she appear cachectic. Diagnosis of nonmalignant ovarian cyst was confirmed by microscopical findings of the removed ovary. If this patient had not returned for operation the case would have undoubtedly been looked upon as one of recurrent malignant ovarian cyst cured by radium, since the patient probably would have lived without any treatment for many years and remained in a fair condition of health.

We now come to the most important and interesting consideration in this case, namely: Can the use of radium light up a subacute or chronic pelvic inflammation into an acute one, as Graves suggests? I can offer very little information on this point, but call attention to the fact that I have noted, during operation, a peculiar swollen, boggy and friable condition of the pelvic tissues, different from anything I have encountered in chronic pelvic infections. Graves's article had not then been published and I was at a loss to explain this condition which I now believe to have been due to the action of radium on the old chronic pelvic infection from which this patient had suffered for a long time. Graves, after reporting two very similar cases, says (6): "The injurious influence of radium on chronic inflammatory pelvic conditions is perhaps the most important reason why in the extensive clinical use to which radium is destined very soon to be put, its employment, in gynecological practice at least, should be limited to responsible and well trained operators."

In answer to the question, how long should we wait before operating after radium has been used in pelvic cases, it is difficult at this time to express an opinion of any value. The length of time would, of course, depend somewhat upon the urgency of the case, but the writer would suggest that as long an interval as possible be allowed to elapse. The

pelvic abscess in one of the cases that Graves reports did not develop for six months after the use of radium (Case II in the article referred to above.)

CONCLUSIONS.

It would seem that we were justified in drawing the following conclusions from a study of this case:

1. The chronic cervical infections are the cause of a great proportion of uterine, ovarian and tubal disease, and often cause a return of the trouble, if the infected cervical endometrium is not thoroughly removed.
2. The cases for treatment by radiation should be selected most carefully and the ultimate outcome reported.
3. Operation is better than radiation for early or doubtful malignancies.
4. Operations should not follow radiation except after careful consideration of the case, and then only when absolutely necessary.

TREATMENT OF PUERPERAL INFECTION.

BY CHARLES GREENE CUMSTON, M. D.,
Geneva, Switzerland.

I wish first to speak of a treatment for puerperal sepsis by an old method which is being revived in France and was first carried out by Prof. Fochier, of Lyons, some thirty years ago. I refer to fixation abscess. The success of this procedure, which is undeniable in the case of puerperal infection, depends upon its early employment, when other ordinary therapeutic measures have failed. An important point to remember is that when an abscess does not form its prognostic value is a hundred per cent.; for it means that recovery will not take place. I shall not take up space with statistics, but would say that out of a total of 132 cases collected by Cassedevant an abscess formed in 113, with nine deaths. In the remaining nineteen cases an abscess did not result and only two patients recovered. The total percentage of recoveries was, therefore, seventy-seven.

In spite of these figures, and many other similar ones could be produced, the procedure has been neglected. It is true that it is painful but this is likewise true of the surgical intervention required in puerperal infection. Energetic treatment can alone give results in serious morbid processes. When it is objected that pain and suppuration, being depressing to the vitality, should cause one to reject this procedure it need merely be remarked that when

neither suppuration nor pain occurs and death ensues, recovery will take place when the injection causes a marked local reaction. However, on account of the violence of the reaction in some cases—severe pain, prolonged suppuration and occasionally some undermining—this treatment should not be resorted to without reasonable motive.

The question of contraindications for fixation abscess requires attention. It does not seem that the presence of albumin has any bearing against its employment, for cases of recovery are recorded where it was present and it is unlikely that the treatment caused it to appear. On the other hand, edema should be regarded as a contraindication because an abscess developing in these circumstances will give rise to considerable tissue destruction on account of its low vitality.

The indications are deduced from the form and gravity of the septic process. The procedure is useless when the infection is confined to the organs of generation, as is also the case when there is a generalized peritonitis. Septicemia, and especially pyemia, are the two processes where good results may be looked for. The time at which resort to fixation abscess should be had is somewhat delicate to decide but is of utmost importance, because success depends upon the early application of the treatment. There are no definite rules to go by and each symptom taken by itself will give no indication. The early onset of the infection, a temperature with great oscillations, the rapidity of the pulse, the dyspnea, repeated chills, and the earthy complexion are all sure signs of gravity, but when they are all present the infection is too far advanced for any treatment to be effective. When proper disinfection of the uterus has been accomplished by modern means and the infectious phenomena persist, it is better practice not to wait too long for a hypothetical improvement. There are, however, certain types of subacute pyemia which can be allowed to run and in these cases a fixation abscess will work wonders. In one instance the treatment was given on the fifty-eighth day after the onset of the infection and two weeks later the patient was discharged well. In another instance the injection was given on the thirty-sixth day and nevertheless recovery was rapid. Therefore, the form of the infectious process must be taken seriously into consideration; if the treatment is undertaken too early it may be a useless interference, but, on the other hand, if it is resorted to too late it will not save the patient. Of the two mistakes it is better to err in being too early in applying the treatment.

It was Fochier's practice to make the injection as near as possible to the focus of infection in order to obtain a revulsive action as well. However, the thigh is the best site for giving it and this appears to be the consensus of opinion. It is readily accessible and the dressings can be easily attended to. The same cannot be said of the flanks because the development of a large abscess over the peritoneum is not without danger and although the pus is ordinarily sterile it occasionally contains endogenous bacteria. Then, too, the connective tissue being very loose here extensive undermining may occur. Is a single injection sufficient? Yes, if the abscess de-

velops well and an amelioration is obtained. In some particularly serious cases it will be more prudent, in order to gain time should reaction be delayed, to repeat the injection at the same spot on the next day or a little later. This has been successful in several instances.

The quantity of turpentine to be injected should not be more than two cubic centimetres; larger doses do not appear to be necessary for the formation of the abscess, while there is every reason to believe that in predisposed subjects, larger quantities of turpentine may cause trouble. The injection should be made in the subcutaneous connective tissue with all aseptic precautions. Incision of the abscess should never be made until convalescence is distinctly established. Once incised its action ceases so that until the patient is well on the road to recovery the pus must be allowed to remain. It is also well to employ collargol or a serum at the same time.

TREATMENT OF PERSISTENT VOMITING OF PREGNANCY.

BY MRS. KELLGREN-CYRIAX, L.R.C.P., EDIN.,
London.

Up to the present none of the methods of treatment of persistent vomiting of pregnancy have been so successful as might have been hoped. I therefore venture to think that it may be of interest to give my experience in connection with the mechanotherapeutics for the condition, as I have by their use attained very good and rapid results in several cases.

The pathology of the vomiting of pregnancy has always been obscure. From time to time various theories as to its cause have been suggested, the chief ones being, a, Toxemia; b, stretching of the nerves of the uterus; c, reflex irritation of the gastric nerves from stimulation of the abdominal sympathetic induced either by expansion of the uterus or a tendency for that organ to sink, or both. Personally I have always inclined toward the latter theory and have been led to this conclusion because: a, The drug treatment of the condition is generally unsuccessful; b, the vomiting usually ceases when the uterus rises above the pelvic brim; c, manipulations directed toward removing the pelvic pressure and irritation have proved efficacious in several cases in which I have employed them.

The actual treatment applied is based upon the late Henrik Kellgren's modification of Ling's system of mechanotherapeutics, and consists for the condition under consideration, of the following manipulations:

1. Lifting of the pelvic organs. The patient should be placed in the semirecumbent position with the knees straight (technically known as the half lying position). To have the patient with the knees drawn up, i. e., in the so-called crook half lying position, is not only unnecessary but is an actual disadvantage, as this causes the pelvic organs to slip back somewhat rendering them more difficult of access through the abdominal wall. The operator, sitting to the right of the patient and holding his right forearm horizontal, places his right hand just

above the symphysis so that the fingers lie in the left iliac region just above Poupart's ligament and the thumb on the corresponding spot on the right side. The fingers should be kept flat, i. e. nearly fully extended in all their joints. Employing the palmar surfaces of the distal phalanges the operator gently works down on either side of the uterus until they have gently closed on it, and then executes small lifting movements applied with simultaneous vibrations (1 to 5); in other words, vibroliftings in an upward direction. These should not be applied continuously but intermittently for about ten seconds at a time followed by a pause of a few seconds—this is repeated during a period of about ten minutes. If the pregnancy is not sufficiently advanced to enable the operator to define the uterus the mere fact of the manipulation mentioned above when applied just above the pubis will make itself felt upon the organ. The immediate effect of the manipulation is that the patient experiences a feeling of wellbeing and relief of the existing tension in the pelvis. Incidentally it also relieves incontinence of urine. As regards the possibility of performing lifting of the uterus *per vaginam*, I have never had recourse to it as I have such good results from the external liftings just described.

2. Stationary manual vibrations applied over the stomach itself, paying special attention to any particularly tender area; they should be administered continuously for the space of about ten minutes. They have the effect of further allaying the gastric irritation that is present.

3. Frictions applied to the posterior cervical, dorsal, lumbar and sacral nerves applied for the space of about half a minute (6 to 10.) These act as a general nerve tonic.

4. If excessive salivation is present I apply gentle vibrations to the parotid and submaxillary glands which usually in a very few minutes markedly reduce the amount of secretion.

The following cases serve as illustrations:

CASE I.—Mrs. A., aged thirty-two. One previous pregnancy with normal termination ten years ago. When I first saw the patient she was in the third month of pregnancy; vomiting had commenced four weeks previously and had been getting progressively worse, so that during the last two weeks she had been vomiting twelve times a day or oftener. After the first application of the treatment she only vomited three times during the course of the day and after the fourth application the vomiting entirely ceased. The treatment was administered on three subsequent days in order to prevent a relapse. Normal partus six months later.

CASE II.—Mrs. B., aged twenty-five; neurotic subject, in the sixth week of her first pregnancy. Vomiting had commenced about a fortnight before and had rapidly increased in severity so that when I first saw the patient she could not even look at food and was quite weak from want of nourishment; she was vomiting eight to ten times a day. The treatment was applied on twelve successive days. After its first application there was no vomiting for two days, then once a day on the third and fourth days, after which there was complete cessation with one exception ten days later, in spite of

the fact that the patient had to work very hard moving into a new house. Normal partus ensued later.

CASE III.—Mrs. C., aged thirty-seven. The patient was a healthy subject; she had had two previous children, seven and five years ago, respectively. During both pregnancies she suffered from vomiting (though not salivation) through their entire duration; it was worse during the first three or four months (vomiting eight times a day), after which it became better (vomiting only twice a day). She had tried all the usual remedies, none of which produced even temporary amelioration. During the third pregnancy, vomiting again set in at an early stage and became progressively worse. When I first saw the patient she was in the thirteenth week of her pregnancy. She had sometimes vomited as much as twenty times a day with simultaneous heartburn during the second and third month; this had improved somewhat, but she still vomited about eight times a day and had continual nausea. Coincident, however, with the improvement in the vomiting, excessive salivation had come on and was so severe that her expectoration filled a three pint jar five times during the course of the day and she was unable to speak even a short sentence without having to expectorate. In consequence she was compelled to partake her meals alone and was unable to see either friends or children. Her general condition was one of great weakness; she was only just able to walk across the room. The first day I saw the patient she had already vomited three times; there was hypersensitiveness in the epigastrium and the submaxillary glands felt hard and shotty. Treatment was applied in all on ten successive days. After the first application there was only one vomit during the ensuing twenty-four hours and there ensued some diminution in the amount of salivation. After the next application vomiting entirely ceased for the next day and salivation rapidly diminished, ceasing first for three and then for six hours at a time; finally, on the eighth day after coming on very slightly before breakfast, it became normal. At the close of the eighth and ninth days, both very fatiguing for the patient, she vomited once. By this time there was a great improvement in the general condition and she was enabled to take walks and traveled home, this entailing a railway journey of several hours' duration. Her general condition during the remainder of the pregnancy was better than during any of the previous ones. A slight amount of vomiting occurred about once a week during the ensuing month and the confinement was normal in every respect.

CASE IV.—Mrs. D., strong, healthy subject under ordinary circumstances. She had had three previous children; during her first pregnancy she vomited the whole of the nine months, during the last two pregnancies four and a half months. All the ordinary remedies had proved quite unsuccessful. When I first saw the patient she was in the second month. She suffered from continual severe nausea and had been vomiting about ten times a day. During the vomiting she strained so much that she broke capillaries in the face and neck on several occa-

sions. She was unable to take any food after tea and often could take nothing after breakfast. She was very weak, had not left her room for six weeks, and had become very emaciated. After the first treatment the patient felt better and there was great diminution of the nausea and she only vomited once during the ensuing twenty-four hours. The next day the improvement was fully maintained and she only vomited slightly once. After the fourth treatment the vomiting was in abeyance for thirty-six hours and the patient felt so well that she went for a short walk. On the fifth day, during which no treatment was applied, she vomited once in the evening; there was no recurrence on the following day. During the seventh day she was able to eat some food in the evening and was not sick though slight nausea ensued. The patient received seven more applications of the treatment; the vomiting did not return, and the sensation of nausea was practically never felt. The patient felt stronger every day. Four months later there had been no recurrence of the vomiting and the patient felt very well.

PRENATAL CARE FROM THE VIEWPOINT OF THE HOSPITAL.

BY LIDA STEWART-COGILL, M. D., F.A.C.S.,
Philadelphia.

It is estimated by the Children's Bureau at Washington, D. C., that in the United States, sixteen thousand mothers die needlessly each year from childbirth, and two hundred and fifty thousand infants are lost annually in the first week of life.

According to Snow's statistics, based on one hundred million population, there must be two and a half million births annually and half a million abortions, making a loss to our population of three-fourths of a million a year—largely preventable by better obstetrics and prenatal care.

The newborn babe, the most helpless and most precious of all animals, is the most valuable asset to our nation, and yet the medical profession, with all its knowledge of the value of prenatal care, has been silent on the subject or evidenced an indifference which is quite as deplorable and discouraging. But, like the cause of prohibition and suffrage, in due time prenatal care is bound to become a popular topic and a vital issue of the day. I feel,

however, that the credit should be given the pediatricists for bringing this subject to a focus.

It is said that the index to a city's civic pride is determined by the death rate among its babies. Naturally the pediatricists have been interested in finding the cause of the high infant mortality, and after robbing the second summer of its terrors and solving the difficult problem of infant feeding, the rate still being too high, they went still further back until they found themselves in the obstetrician's domain and it became necessary to insist that the high death rate among infants could be lowered if obstetricians would do more prenatal work. They showed by statistics that the majority of babies dying during the first year of life did so before reaching the first month of life, and that seventy-five per cent. of these deaths could be prevented by prenatal care.

A supervisor of nurses in one of the hospitals with which I am connected, who is of German birth and education, remarked to me that she had never seen anything like the American husband. It seemed, as she expressed it, as if he could not do enough for the comfort of his wife; he fairly carried her around on his hands. "We have nothing like that in our country," she said. We American women proudly acknowledge this to be true, that the American man and husband cannot be excelled by any nation. But do you think we are treating him quite fairly—he who is so anxious to have everything done for the best interest of his wife—in keeping him in ignorance of the great value of prenatal care to his wife and child? Or quite fair to that splendid body of workers, composed of a million women, who in two years turned out one hundred million dollars' worth of surgical articles and garments that the soldiers fighting for democracy might have everything necessary for their welfare? For while seventy thousand of these faithful soldiers died in eighteen months of war, there were two hundred and fifty thousand babies under a month who died in one year, and seventy-five per cent. of these deaths were due to preventable diseases.

Of all the Philadelphia soldiers who were engaged in eighteen months of war, only 1,267 were killed or died of wounds, while according to the Division of Vital Statistics for 1918, in this city, 5,366 babies died who were under a year, 4,172 of whom were less than a month old, which means that over four times as many Philadelphia babies under one year of age died in a year (1918) as Philadelphia soldiers engaged in eighteen months of war, showing it to be true that it is more dangerous to be a baby under one year of life than to be a soldier in the front line trench.

According to the Children's Bureau, the United States stands fourteenth on the list of sixteen civilized nations, in its maternal mortality at childbirth, and eleventh on the list in its infant mortality for the first year of life. These statistics must be kept before the public until every citizen is familiar with them and realizes his duty in the matter, until the banker, the broker, and the business man are asking, What is prenatal care, and why does my wife need it? and until newspapers and magazines have properly written articles on the subject. When

American men and women understand that a large percentage of these maternal and infant deaths are preventable, do you think they will allow such frightful wastage of life to go on? Never! I feel sure when they fully understand the need they will work just as hard to see that the mothers and babies receive proper attention and care as they did for those soldiers.

While searching for words with which to express my deep feeling in regard to the necessity of saving those two hundred and fifty thousand children, and sixteen thousand mothers, it seemed to me nothing could be more beautifully expressed than a paragraph in Mr. Roosevelt's article; you are probably all familiar with the article, but permit me to quote this one part: "Alone of human beings the good and wise mother stands on a plane of equal honor with the truest soldier; for she has gladly gone down to the brink of the chasm of darkness to bring back the children in whose hands rests the future of the years." And the nation should by action mark its attitude alike toward the fighter in war and the childbearer in peace and war.

As it is an acknowledged fact that prenatal care is the greatest factor in the lowering of the death rate of mothers and babies, it is up to the medical profession to depart from its policy of silence on this subject, and present a constructive platform for the furtherance of this work, which will:

1. Arouse the community to the need for more prenatal work.
2. Educate the public for the need of supporting institutions doing this work.
3. Arouse the interest and enthusiasm of managers of institutions and agencies doing this work, to the importance of having a budget of sufficient size for a well developed social service department.
4. And which will see to it that every baby enjoys its inherent birthright of being properly born.

There is no better place in which to demonstrate the effect of prenatal care upon maternal and infant mortality and morbidity than in the clinics and wards of a well equipped maternity hospital, where there is every facility for the proper supervision, care and treatment of the pregnant woman, from the earliest months of pregnancy to the end of the puerperium. With a properly equipped clinic, properly kept records and laboratory facilities, and an enthusiastic corps of workers, composed of physician, nurse, social worker and clerk, wonderful results can be secured, but there must be a co-operative spirit—without this, no matter what the equipment or number of workers, little can be accomplished.

Crane states: "It is the team work that counts, not the individual capacity but the linked capacity that makes a group efficient." In the prenatal clinics every patient must be encouraged to register as early in pregnancy as possible, and attend the clinic at stated intervals, the minimum being every month up to the fifth month, every two weeks until the seventh month, and then be seen either at home or in the clinic every week until delivery. All patients showing toxic symptoms or other serious complications of pregnancy, which are not yielding to treatment, must be admitted to the maternity hospital for observation and treatment. Every patient must

have a thorough physical and internal examination. The pelvic measurements must be taken as well as auscultation and palpation of the abdomen. The blood pressure must be taken at each visit, also uranalysis. The Wassermann test must be done for each patient, and as a matter of routine a microscopical examination made of the cervix, vaginal secretions, and Bartholinian glands.

Instructions should be given as to proper food, clothing of self and infant, exercise, hygiene of home, care of nipples, bowels, and avoidance of miscarriage. A card or leaflet should be given to each patient containing instructions as to care of self and child and the significance of certain dangerous symptoms, such as those of toxemia, bloody discharge, and others. The development of the child in proportion to the pelvis must be watched, also cardiac conditions; tuberculous patients must be looked after, and a gradual or sudden rise in blood pressure must put us on guard as to the possible development of a toxic condition. The patients showing a positive Wassermann test must be placed under proper treatment, also those suffering from gonorrhoea. The social worker often has difficulty in having these patients attend the clinics regularly for treatment. It is needless to state the earlier the treatment is started the better the results will be. Without a social worker to carry out follow-up work, little can be accomplished. Properly kept records and the proper kind of records are essential.

There is great need for the intensive study of the mortality from childbearing. The mother must be under complete supervision before labor, after labor, and between pregnancies in order to accomplish this. A study of the last census shows the death rate for 1900 among women of childbearing age to be 50.3 to the 100,000, and this includes a rate of 21.6 for puerperal sepsis alone, which is a preventable condition. The hospital should carry on a detailed study of the effect of venereal diseases upon mother and child.

There will be little decrease in the mortality from childbirth until the standard of obstetrics is raised to its proper place, where it will rank with major surgery. The public should recognize the necessity for skilled attention for every pregnant woman. Upon discharge from the maternity hospital, the mother and baby should be referred to a health clinic, where they should report at stated intervals for observation and care. Keeping the mother well between pregnancies is a most essential factor in reducing the mortality and morbidity of mother and baby. There should be a prematernity department, distinct from the maternity hospital, for the pregnant woman who needs rest and good food before confinement, and for those who have had complications in former labors and for those whose condition make it necessary for them to be kept under observation and treatment.

The Babies' Welfare Association seems to be the only organization which is endeavoring to put on record the amount and character of the prenatal work being done by institutions and agencies in Philadelphia. There are thirty-two of these organizations, all members of the Babies' Welfare Association, and forming five distinct types, namely:

1, Division of child hygiene; 2, visiting nurse society; 3, dispensary with its own maternity; 4, dispensary without maternity, and 5, health centres. In order to obtain these data a questionnaire is sent each year to these different organizations, the results are compiled, and a copy sent to the Children's Bureau at Washington, D. C., and the American Child Hygiene Association, for their files. The obtaining of these data is attended with considerable difficulty, and we are indebted to the untiring efforts of our assistant secretary that so much has been accomplished.

At the suggestion of one of the social workers, a monthly record sheet has been printed by the Babies' Welfare Association to be used by the different organizations in order to facilitate this work. This sheet contains all the questions asked on the questionnaire and seems to be giving satisfaction. Twenty of the organizations are using them at the present time, so that statistics are more readily obtained. The main handicap in securing data seems to be due to the poorly developed Social Service Department. The governing bodies, either not realizing the great necessity for such a department or being unable to provide funds for the proper carrying out of this work. Only twenty of the thirty-two organizations sent in their questionnaires this year, but each year shows more co-operation. We are unable to give the number of babies living and breast fed, one month after birth, due to lack of followup work. Only five of the twenty organizations are taking routine Wassermann tests and making microscopical examinations of the vaginal secretions, and only fifteen are taking the blood pressure of the patients as a matter of routine, and yet all obstetricians realize the great importance of these tests.

Before these institutions realized what the Babies' Welfare Association was trying to accomplish, the questionnaire was received by them with varying degrees of cordiality. This was due, I feel, to the following reasons: 1. The organizations which were rather indifferent toward prenatal work considered it a bore. 2. The organization which was interested and anxious to do good work, but were prevented either by lack of funds or the proper kind of workers. 3. Those workers who had properly kept records in a well organized social service department were pleased to show the kind of work they were doing.

Do we not owe it to that little atom of humanity, starting on a life more hazardous than that of a soldier in the front line trench, to put into effect these measures which are known to remove seventy-five per cent of its perils?

1831 CHESTNUT STREET.

Röntgen Ray Studies of the Bronchial Function.—Jesse G. M. Bullova and Charles Gottlieb (*American Journal of the Medical Sciences*, July, 1920) have observed a bellows like action in the trachea and bronchi which may be limited by contraction of the bronchial muscles, and a peristaltic action of the bronchial muscles which seems adequate to empty them without invoking ciliary movement.

THE IMPORTANCE OF PRENATAL CARE.

BY MOSES LOBSENZ, M. D.,

New York,

Attending Obstetrician, Berwind Maternity Clinic.

In modern medical progress, particularly in relation to definite diagnosis and treatment, the tendency has been toward group diagnosis. Why, then, should not a gravid woman receive the benefit of this advance? Prenatal care in clinics and among general practitioners is treated with the presumption that pregnancy is a physiological process, able to take care and dispose of itself. At some clinics Wassermann tests are taken. These clinics pride themselves justly with doing a great deal for the woman if the Wassermann happens to be positive and they inaugurate the proper treatment. This is truly a great advance and of great assistance to the woman, the coming fetus, and the community. But the amount of syphilis found by the Wassermann reaction depends entirely upon the locality of the clinic, hospital, or types of patient the physician encounters. We know that in the colored race syphilis is far more prevalent than in the white race and, therefore, when we study statistics we must weigh them by their locality. The blood pressure of the patients is taken; if taken carefully, it is of assistance in corroborating other findings, such as nephritis. Urinalyses are performed, but in most clinics and by most physicians, single specimens are examined. This is erroneous and leads to nothing. A twenty-four hour specimen should be required and a careful examination made, particularly as to specific gravity, amount excreted, albumin, urea, acetone and acetic acid; and a microscopical report of casts, blood, and pus.

Measurements of pelvis are taken. These naturally help us find gross abnormalities. Measurements, even when taken by the most expert, are erroneous, due to the impossibility of measuring accurately the internal strait and the fetus. We have all had the experience of making a diagnosis of a contracted pelvis and preparing the patient for a Cæsarean section only to have labor terminate in a perfectly normal delivery. Similarly a diagnosis of an ample pelvis may be made, only to have to resort to Cæsarean section after an attempt at labor. Therefore a certain number of mishaps to mother and fetus will always occur from this cause. There will always remain a certain number of fatal results from placenta prævia and accidental hemorrhage, eclampsia and nephritic convulsions. Aside from the patients lost from these causes, there are a marked proportion lost from infection of unknown origin. A great many miscarriages and abortions, breast abscesses, pyelitis, and perhaps even cases of placenta prævia and accidental hemorrhage are due to unknown causes. What should be done to give more information in these cases? What are the different channels by which infection may travel?

It is readily seen that, due to engorgement, the uterus would be a favorable seat for almost any focal infection through venous, lymphatic, or arterial channels. It is therefore essential that all possible focal areas of infection should be elim-

inated. First in importance are the teeth. The services of a dentist with the proper x ray facilities are necessary to the obstetrician. He should correct all cases of pyorrhea, and see that all abscess cavities are properly drained. The late Dr. Joseph Bryant always impressed it upon students that wherever pockets of pus were found, immediate drainage should be carried out for fear that these foci would lead to ultimate infection of some other organ. It is known that abscessed teeth and pyorrhea are the cause of rheumatism and joint infections, as well as disorders of the organs of the chest and abdomen. What is to prevent the bacteria from these abscesses finding lodgment in the uterus? Like the spirochete in syphilis, cannot these same bacteria lodge themselves in the placenta and be the cause of some of our cases of miscarriage, abortion, placenta prævia, and accidental hemorrhage? Can they not also be the cause of some of the breast abscess and pyelitis cases of unknown origin? It would be foolish to enumerate cases of this type, for everyone doing obstetrical work has encountered them.

Next in importance is the nose and throat specialist, who should carefully examine the patient. He should treat any infection from the tonsils or sinuses. The lung specialist should note any areas of tuberculosis. If such an area is found, the patient should be kept under close observation and the obstetrician advised. It is known that tuberculosis advances with pregnancy; a patient of this type in the proper environment and under close scrutiny could perhaps continue in her pregnancy and give birth to her child, the obstetrician being advised however if interference is necessary.

The heart specialist should examine and treat all cases of heart murmur. Cardiogram tracings should be taken as well as the blood pressure. In this way instead of the casual taking of blood pressure it would be taken by a man interested in that particular field in conjunction with his other examinations, and would prove of great value to us. Examinations of blood, urine, sputum and feces by a man skilled and interested in this work, would bear great weight in the ultimate treatment of a patient. A social service organization with properly trained nurses, to look after and correct faulty surroundings and hygiene and to see that patients report back as requested, would be excellent. It would be the duty of these nurses to inform the obstetrician of a previous miscarriage, abortion, or dead fetus, and the cause of the accident, if found. In case of syphilis the nurse should follow up patient after discharge (postpartum) and see that another Wassermann is taken subsequently and if positive treatment be continued. The husband of such a patient should have a Wassermann taken and if positive should be properly treated. The obstetrician would then be called upon to pay attention only to his particular field and with all other data on hand would be fit to treat the patient correctly, conscientiously and conservatively.

CONCLUSION.

In order to give the gravid woman proper care, therefore, the following routine ought to be arranged: 1. History taking room for taking careful

and detailed histories; 2, dentist with proper x ray facilities; 3, nose and throat laboratory with proper facilities; 4, lung examination; 5, heart examination; 6, laboratory; 7, social service, and 8, obstetrical care.

This routine, although cumbersome at the start, I am sure could readily be arranged and would do away with much of our maternal and fetal mortality, for the obstetrician who has access to accurate data furnished by physicians interested in their particular fields could pay proper attention to his one duty, namely, the passenger and its passage.

233 WEST 122ND STREET.

THE EARLY DIAGNOSIS OF PREGNANCY.

BY DAVID LAZARUS, M. D.,

New York.

Normally every girl at or about the age of fourteen begins to show signs of a bloody discharge from the vagina, known as menstruation. This process occurs with a regularity of from twenty-four to twenty-eight days, except during pregnancy, lactation, and often in tuberculosis, severe anemia, exposure to sudden cold, weather changes or changes of climate, as is noted in girls emigrating from foreign countries to this land. Should the period not occur, and should there be a clear history of sexual intercourse, with or without the penetration of the penis into the vagina, the absence of menstruation may be regarded as the first sign of pregnancy. Often, however, the sexual act or the coaptation of the penis to or with the vagina is denied, and it is in these cases that other and more reliable signs than amenorrhea must be sought. These signs can be classified as subjective and objective signs and symptoms.

Subjective symptoms.—Sensation in the breasts in that they are feeling heavy, distended and heated; it is also noted that they are beginning to enlarge; feeling ill or nauseated every morning on arising, although not actually vomiting; the abdomen is distending and getting larger and fuller; dark rings are noticed under the eyes; there is a longing for foods never or very seldom desired before; the desire for sexual intercourse is stimulated almost to excess.

Objective signs.—These are best divided into external and internal signs.

The external signs are manifested in a rather selfconsciousness of expression of the patient, in that she imagines all are looking at her and that her condition or state of pregnancy is visible; enlargement of the breasts with an increase of the pigmentation area about the nipple, and the presence of enlarged or radiating veins; colostrum may be squeezed from the nipple, or in the very early days of pregnancy only a few drops of a clear liquid may be expressed from the nipple; enlargement of the abdomen consistent with the period of gestation; a dark line beginning to form in the midline of the body extending from the pubis to the umbilicus; enlarged veins about the vagina, causing the well known classical purplish discoloration.

The internal signs of pregnancy are indeed the

more reliable especially in those cases where sexual relationship has been denied. These signs are ascertainable by a vaginal examination with or without an accompanying abdominal palpation:

A feeling of warmth in the vagina as the hand is introduced therein; an enlarged uterus, assuming a pear shaped outline and uniform softness; softening of a small area in the junction of the cervix with the body of the uterus, known as the Ladinski sign (1), as early as the third week of pregnancy. This in reality is the beginning of the softening of the entire cervix, which in the later weeks of gestation becomes known as the Hegar sign. However, it is a reliable sign and should always be sought for in the examination for pregnancy. Ballotment is perceived in later pregnancy and depends upon the development of the fetus; fetal heart signs are audible at about the fifth month and is the undeniable symptom of pregnancy, as is also the sensation of quickening.

Aside from the symptoms and signs mentioned, one may arrive at a fair diagnosis of pregnancy by the serum test of Abderhalden (2), which manifests the presence of placental tissue as early as the fifth week; this examination of the blood taken in conjunction with some of the signs and symptoms quoted above certainly diagnose pregnancy. The microscopic examination of the urine reveals the presence of endogenous new formations in the cells and is a valuable aid in making a diagnosis.

Recapitulating, the early signs of pregnancy are: amenorrhea, morning sickness, perversion of appetite, enlarged breasts, enlarged abdomen, discoloration of the vagina, enlarged uterus, Ladinski sign, Abderhalden test, urine examination.

THE DIAGNOSIS OF PREGNANCY.

BY MANLY B. ROOT, M. D.,
Syracuse, N. Y.

Pregnancy, usually correctly diagnosed by the woman herself, demands considerable obstetrical skill for its positive recognition. The numerous mistakes that have been made justify a careful consideration of the subject. In a short article we must presuppose a knowledge of the various symptoms and signs and attempt merely to discuss their relative values. We are discussing a positive diagnosis. Presumptive symptoms and signs have therefore no interest for us except that their absence often makes us hesitate to diagnose pregnancy.

An absolutely positive diagnosis can not, it is true, be made before the eighteenth or twentieth week. But to one thoroughly familiar with the size, shape, consistency and relations of normal and pregnant uteri, bimanual examination reveals the presence of signs dependent on uterine changes which make

possible in a normal uncomplicated case a practically certain diagnosis from the second to the fourth month. The lower uterine segment fills out first, changing the shape of the uterus from pyriform to jugshaped, the body becoming spherical. This allows the latter to be felt by vagina more easily than that of a nonpregnant uterus. Moreover it results in an apparently well marked shortening of the cervix so that the examining finger has less room in the anterior and posterior vaginal fornices. Careful palpation gives us von Fernwald's sign: the antero-posterior thickening of the uterus is more marked on the side containing the ovum, if it is located on one side.

The gravid uterus always undergoes a softening which commences about the fifth week as a soft fluctuating area on the anterior wall just above the cervix. The recognition of this is known as Ladinski's sign. This softening soon extends throughout the uterus and by the tenth week we can get Hegar's sign: with fingers of one hand in the posterior fornix and of the other on the abdominal wall, these fingers can be nearly approximated due to the giving away of the softened uterine body. The steady, rapid growth of the uterus at this period is very significant, no tumor increasing as rapidly in size.

When all or nearly all of these signs are present a tentative diagnosis can be made. It is verified, of course, by the early presumptive symptoms: amenorrhea, morning nausea and vomiting, salivation, vesical irritability, and nervous phenomena; and by the presumptive signs: pigmentation, breast changes, purple color of vulvar and vaginal mucosa (Chadwick's sign), and softening of the cervix.

After the eighteenth or twentieth week a diagnosis can be made which cannot be questioned. This is dependent on three signs: 1. Hearing the fetal heart, a sound resembling that made by a watch ticking beneath a pillow, with a rate of 120-160 a minute and not synchronous with the mother's pulse; 2. Feeling the fetal movements, active and passive; the former as transmitted to the hand of the examiner through the abdominal wall. The movements felt by the woman are of little value. The passive movement may be obtained as abdominal ballotment between the fourth and seventh months. With one or two fingers in the anterior vaginal fornix if a tap is imparted upward to the fetus the latter strikes the anterior abdominal wall and returns to the fingers. 3. Ability to map out the parts of the fetus. Any of these three signs make a positive diagnosis, but as a verification the earlier symptoms and signs should still be present.

A word must be said about the differential diagnosis. Pregnancy is most often simulated by subinvolution, chronic metritis, myomata, ovarian cysts, fatty enlargement of the abdomen, and ascites. A careful physical examination resulting in determining the presence or absence of the symptoms and signs described above usually make the diagnosis clear as far as pregnancy is concerned. Here especially the absence of the early presumptive symptoms and signs of pregnancy is of aid in preventing a false diagnosis, although the final decision is dependent on the results of bimanual examination.

121 GREENE STREET.

ILEOCECAL TUBERCULOSIS.*

BY ABRAHAM O. WILENSKY, M. D., F. A. C. S.,
New York.

The cases which I shall describe illustrate exceptionally well some of the manifestations under which tuberculous affections make their appearance in the ileocecal region. The group in which these cases fall is a very large one and is, perhaps, most noted for the frequency with which its acute phenomena mimic other surgical emergencies in the right iliac fossa and for the difficulties in differential diagnosis.

CASE I.—A young man of eighteen years was admitted to the hospital with the clinical picture of an acute perforating lesion of the appendix. His family and previous history had no essential bearing on the present condition and, in fact, this was the first illness the patient had ever had. The illness began on the previous day, was ushered in with severe generalized abdominal cramps and was associated with vomiting and with an inability to move the bowels. Within a few hours after the onset the pain localized to the right iliac fossa and fever appeared. Thereafter the symptoms progressed so that at the time of admission to the hospital they were well marked. The physical examination disclosed generalized abdominal rigidity, most marked on the right side with tenderness limited to the right iliac fossa where a small mass was palpable. The examination of the rest of the patient's body disclosed nothing abnormal.

There seemed to be no doubt about the diagnosis of an acute appendicitis and the patient was immediately subjected to an operation. On opening the abdomen a large inflammatory mass was seen to occupy the right iliac fossa, involving the angle of junction of the ileum and ascending colon. On unravelling the mass it was found that a much thickened, inflamed, gangrenous and perforated appendix passed upward from its usual point of origin in the ileocecal junction to the left and inward toward the median line; partly it, and partly the adjacent coils of ileum and ascending colon formed the dense walls of a small abscess containing about an ounce of grayish white pus. The abscess had burrowed through the mesentery; the abscess cavity lay partly to the right and partly to the left of the corresponding leaf of the mesentery; and the tip of the appendix projected through the resulting communicating opening. As far as one could see there were no other evidences of further disease in the operative field. As a matter of fact, the condition resembled in every particular that seen with the ordinary forms of suppurative appendicitis. The appendix, therefore, was removed, the abscess cavity was cleansed, and, the appropriate drainage having been adequately provided, the abdominal incision was closed with the exception of that part from which the drainage emerged. It was expected that the usual postoperative course would follow and that healing would result in the ordinary manner.

Much to our surprise and chagrin a fecal fistula developed at the end of the first week. The dis-

charge was never profuse and the fecal discharge ceased within a short time. Then the sinus contracted to a narrow deep channel from which an insignificant amount of purulent discharge escaped each day. Every opportunity was afforded for the closure of the wound but at the end of the fourth month practically no progress was made and it became apparent that a secondary operation would be necessary to insure healing.

At the second operation the cause for the persistent sinus became apparent immediately. The sinus led down to a pinpoint perforation in the beginning of the ascending colon; from the latter and extending on both sides but much more in an upward direction, a segment of colon was demarcated by an extraordinary rigidity and thickening of its walls on the peritoneal surface of which a profuse crop of small miliary tubercles testified to the tuberculous nature of the process. No other lesion being found, the terminal portion of the ileum and the caput and ascending colon as far as the hepatic flexure were excised and the continuity of the intestine was reestablished by a side to side suture anastomosis. No drainage was employed and the abdominal wound was closed. An uneventful convalescence followed and at the end of the second week the patient was discharged from the hospital.

In this case an examination of the specimen showed that the entire lesion was in the ascending colon and was of the peritoneal variety. The mucous membrane showed no ulcerations. The thickened wall of the colon encroached somewhat on the lumen of the bowel but no actual stenosis was present and a finger passed easily upward and downward through the compromised area.

CASE II.—The second patient was a young girl aged sixteen years, who, similarly to the previous patient, was admitted to the hospital with what was thought to be an acute appendicitis. The history was quite the orthodox one for such an illness and included an acute onset with generalized abdominal pain associated with vomiting and constipation, followed by a fairly rapid subsidence of the general symptoms concomitantly with the localization and intensification of the symptoms—pain, rigidity and tenderness—in the right iliac fossa. There was nothing in the family or previous history to cause one to suspect an unusual etiology. This patient, too, had never been ill before. The general physical examination disclosed no abnormal findings and locally a small mass was palpable which was interpreted as being a much thickened appendix or an abscess derived therefrom.

Operation was done immediately. On opening the abdomen, however, it was found that the small mass was a group of inflamed glands buried in the mesentery near the ileocecal junction. These were matted together and contained a soft area. The appendix, although it lay close by, was not involved in the process. Nowhere else in the belly could any other lesion be demonstrated and in the immediate neighborhood there was no indication of a spread of the pathological process either from, or to, the intestinal tract. The appendix was removed. An attempt was also made to enucleate

* From the Mount Sinai Hospital.

the glands but, owing to the very nature of the process, this was only partially successful. During the manipulations the abscess ruptured and discharged a small quantity of yellowish pus. Finally, a drain was inserted and the abdominal wound was partially sutured.

A fecal discharge appeared in the second week. This was rather profuse and continued for more than four months unchanged. The sutured part of the abdominal wound, having become infected during the operation, parted later and thereafter the healing proceeded slowly for a number of months until nothing was left but an extremely narrow fistula through which fecal material continued to discharge. The sinus showed no tendency to close. Again exhausted patience prompted the secondary operation. Examination of the lymph nodes, excised during the operation, demonstrated that the process was tuberculous so that, when the sinus developed, became persistent and refused to heal, we were quite cognizant of the underlying cause which prevented the healing. Examination of the rest of the patient's body failed to reveal any other focus of tuberculosis, and, when the secondary operation was determined upon, one felt confident that the success of the procedure, which would prove necessary to ensure closure of the fecal fistula, would not be ultimately jeopardized, or rendered futile, by the flaring up of any pulmonary, or other, focus. To revert to the patient's history:

The abdomen was again opened. Conditions similar to those in the first patient were found. The lesion was partly in the ascending colon and to a slight extent in the terminal ileum. The sinus lead down to a pinpoint opening in the bowel. The wall of the latter was thickened and rigid without, however, having any tubercles visible on its exposed surface; but the general appearances of the gross pathology indicated the tuberculous nature of the infection, even if we had had no previous evidence in the microscopical examination of the lymph nodes. No other lesion being demonstrable in the adjoining coils of gut, the involved ileocecal junction was excised and the continuity of the alimentary canal reestablished by a side-to-side suture anastomosis. Drainage in this patient, too, was omitted and the abdominal wound was closed. The convalescence was again most uneventful and at the end of the fourteenth day the patient left the hospital cured.

The excised specimen differed from the previous one in having the bulk of the lesion on the mucosa side. Here there were a number of large and small ulcerations with overhanging edges and showing a tendency to have their longest diameter in the transverse direction. There was no stenosis of the lumen even at the ileocecal valve. The walls of the bowel showed a marked thickening.

The dominating fact evidenced by these notes is the striking similarity of the initial clinical pictures with that of the ordinary forms of acute nonsuppurative and suppurative appendicitis. This similarity is not peculiar to tuberculous lesions and I have seen similar marked resemblances in the clinical course of other pathological lesions such as carcinoma, lymphosarcoma, or surgical forms of productive colitis of limited extent, all located in

the right lower quadrant of the abdomen. The coincidence may have one of two explanations: In the one case the pathological condition involves the appendix directly and there are a fair number of cases on record in which the tuberculous (or other) lesion is readily demonstrable in the appendix. In the other case, the lesion originally involves an adjacent portion of either the colon or the small intestine; the appendix is subsequently affected either as an entirely new process in which the pathological condition is that of the ordinary forms of appendicitis, or the inflammation is directly due to the extension of the original disease, or is aided by mechanical disabilities produced by the latter leading to stricture and obstruction of the appendix lumen.

The literature of the past few years contains numerous allusions to the difficulties in the differential diagnosis of conditions in the right iliac fossa. All of these enhance the importance of constantly keeping in mind the various forms of disease in the latter region which can be masked under similar subjective and objective symptomatologies. Besides disease of the appendix itself and the neighboring parts of the small and large intestine, these include affections of the omentum, of the mesentery or its contained lymph nodes, of the appropriate part of the genitourinary tract, and of the cellular tissue of the retroperitoneal space, all of these comprising both inflammatory and neoplastic lesions. In a general way the symptomatologies of all of these are not peculiar to any particular one and only indicate the location of the body in which the lesion is to be found. The differentiation must be made upon conclusive local evidence such as is produced by the aid of the cystoscope, upon the conclusive or relative evidence of the röntgen ray, or it is based upon the accumulated experience of the individual observer and is then largely determined by the relative frequency of occurrence of the various forms of disease and is limited by the frailty of the human equation.

In the more chronic forms of disease the difficulties are not nearly so marked and with sufficient care in the taking of histories and in examining the patients the diagnosis should be made and comparatively few errors should occur. In the acute cases the differential diagnosis is sometimes extremely difficult and often accuracy is not possible until the lesion is exposed during the operation. Fortunately, in the majority of such patients the indications are the same and, when it is found that the appendix is involved in a suppurative process, a suspicion that underlying it is a more important lesion, such as a tuberculosis or carcinoma, would not detract from the necessity of reserving for a secondary operation the more extensive resection which would be necessary.

In children the difficulties in the acute cases are multiplied by certain possible, and unavoidable, inaccuracies in the histories, and by the patient's lack of cooperation when the physical examinations are being made. I have in mind a certain group occurring, in my experience, in young children in which the history is always that of a typical attack of acute appendicitis. The physical findings are of

sufficient intensity to demand an emergency exploration; then one is astonished to find that the appendix shows practically no abnormal change, but that the glands of the mesentery show a uniform discrete enlargement. Usually the appendix is removed and one of the glands is excised for microscopical examination. The postoperative course thereafter includes an immediate drop in the temperature and an improvement in the local and general symptoms that is progressive and permanent.

Such adenopathies are rather frequent in the angle of junction of the small and large bowel. Not always is the microscopical picture that of a tuberculous infection and the assumption seems not unreasonable that the adenitis is the reply to some bacterial or other trauma derived from the appropriate part of the alimentary tract. More advanced cases include those in which the glands become matted together, or undergo suppuration and in many of these the infection is demonstrably of a tuberculous nature. There seems to be marked resemblances between these forms of mesenteric adenitis and those occurring in the neck. The second case described belongs in this group.

Very frequently, whether the essential lesion is in the appendix or bowel, or whether it is in the mesenteric nodes, the character of the pathological condition is such as to demand the institution of drainage. This was so in both of the cases described. The occurrence of the fecal fistula in both of the patients seems to be a very common complication of the postoperative period in cases of this kind; in some the wound discharges are profuse, in the others they are not. In all of them the sinus persists for long periods of time and either heals after the lapse of many months, or shows no tendency at all to close. The obstinacy displayed in healing is due to the presence of the communication with the interior of the bowel. In the cases in which the appendix has been ablated the line of closure of the appendix stump, whether it be treated by simple ligation and cauterization as in our cases, or whether the stump is further buried, is rendered rather insecure because of the tuberculous nature of the accompanying lesion and the intestinal fistula is directly attributable to the latter. In extraintestinal lesions the sinus can be due to the extension of the pathological process; or the removal of the gland, or glands, is accompanied by some compromise of the blood supply large enough to result in a local area of necrosis in the bowel wall. I think that all of these mechanisms played a part at some time or other in the pathological findings of the cases described.

In any given case it is not at all simple to decide accurately prior to the second operation as to the nature of the impediment which persists in keeping the sinus open. This is all the more so inasmuch as in certain of the ordinary forms of appendicitis in which drainage is instituted, sinuses persist and are due to mechanical causes, to a reopening of the appendix stump, or to the retention of foreign bodies. In the first of the cases reported the actual nature of the lesion was not suspected and when the sinus refused to heal it was feared that some foreign body had been accidentally retained.

In neither of the two cases did I make use of the röntgen ray as a help towards elucidating the nature of the obstacle which was impeding the healing. In the one case the microscopic examination of one of the excised glands had demonstrated conclusively the tuberculous nature of the affection; in the other it was feared that some foreign body—a piece of rubber tubing or gauze—was present in the wound; in either case it was thought that the x ray would throw no additional light which would be of sufficient value. In uncomplicated cases in which no previous operation had preceded, the x ray is undoubtedly of great help for more than one reason. A röntgenographic picture showing hypermotility and spasm, or filling defects in a patient with pulmonary tuberculosis, should lead to a definite diagnosis of colonic tuberculosis. In moderately early cases certain radiographic shadows cast by the barium meal at the end of six, eighteen or twenty-four hours, determine definitely to the trained radiologist the presence of colonic ulcerations; their absence does not, however, exclude their presence. In the presence of a wound the picture would undoubtedly suffer much distortion owing to the abnormalities which could conceivably result from the operative interference, and the assuredness with which the röntgenographic picture would be interpreted would suffer much deterioration. There would be little need for the x ray to demonstrate the exact point of entry of the sinus into the bowel, inasmuch as such information would be available with sufficient accuracy for practical purposes from the findings of the primary operation.

I am not in favor of any of the temporizing measures or local plastic operations for the closure of these sinuses. With cases of this kind the fistula is very deep and the mucous surface of bowel with which the latter becomes continuous is at quite a distance from the skin. Mechanically, conditions are most favorable for spontaneous closure and, when for one or another reason there is a refusal to heal, a complete exposure of the parts is imperative in order to accurately disclose the offending pathological process.

My usual practice is to close the sinus opening with a running suture after creating by dissection appropriate skin flaps on either side. Then the surface is again sterilized with tincture of iodine and, with clean instruments, the abdomen is entered in the free portion of its peritoneal cavity either above or below the previous operative field and directly in its line. That portion of the intestinal tract to which the sinus leads, as well as the entire surrounding mass of adjacent and adherent coils of intestine and omentum, together with the sinus containing scar in the skin and abdominal wall, can now easily be circumscribed in the dissection until the whole can be freely delivered without the body cavity. The pathological condition is then apparent, the extent of the lesion can be accurately delimited, and, if necessary, any further exploration can be done in complete safety. The risks of infection with this technic are at a minimum and are not any greater, in my experience, than with any other laparotomy; so much is this so, that I do not hesitate at the conclusion of the operation to omit any

form of intraabdominal drainage and to close the abdominal wound in its entirety.

With the parts adequately exposed it is essential to make sure that the lesion is one whose extent is limited within the boundaries of operative removal, and that there are no other similar lesions at some distance away which would nullify the success of the operation. This is absolutely so in any uncomplicated case in which the operative exploration demonstrates a tuberculous lesion; and when the latter is too extensive, or is spread about in multiple fashion, the attempt to do anything of a radical nature must necessarily be abandoned. In the presence of a sinus, however, as in both of the reported cases, an added indication exists, the urgency of which would impel one to resort to some method competent to result in closure of the fistula even when the operation would not remove the entire lesion. There should be no hesitancy in doing so with tuberculous lesions inasmuch as nature frequently helps materially and succeeds in completing the cure when the tissues are primarily aided by the removal of the major focus; this experience is quite common with tuberculous lesions elsewhere.

The procedure of choice in my experience is a clean resection of the ileocecal junction extending well into healthy portions on either side. Especially with tuberculous conditions it seems much the safest way to close completely the stumps of the bowel and to reestablish the continuity of the intestine by side to side suture anastomoses. A great deal of valuable time can be saved by closing the open end of the large bowel and by anastomosing the stump of the small bowel into the side of the colon very near the line of section and closure. With both of these two methods additional time can be saved by making the anastomosis with a Murphy button. I have operated according to all of these methods and have had almost equal satisfaction with all. In one of the button cases a leak developed and the sinus persisted for several months; drainage had been employed and contributed materially towards this complication. In subsequent cases the opportunity for this complication was so minimized by the avoidance of any drainage that it did not occur. I prefer the second of the two methods outlined (with or without the aid of a Murphy button), both because of the time saving factor and because of the close approach of the resulting anatomical relationship to the normal morphology.

With good technic the operative field is not contaminated and the abdominal wound can be closed entirely. It is not necessary and it is a distinct disadvantage to drain in any of these cases; drainage is frequently a broad invitation for trouble. The presence of a tuberculous lesion furnishes an additional and powerful factor for the avoidance of any drainage.

Intestinal tuberculosis is a very common condition, more frequently than not associated with pulmonary foci. When, however, limited to the ileocecal region the tuberculous lesion is quite commonly independent of any other focus in the body and, as a primary condition, forms the portal of entry of the infection. Advanced forms of either

disease can be recognized with the clinical means at our command with a fair degree of certainty. The early and latent cases are not so susceptible of recognition; have few, if any, symptoms; are not accompanied by a perceptible cachexia, and frequently make their initial appearances under the acute and urgent circumstances of an acute appendicitis in the pathological condition of which the true nature of the lesion is successfully camouflaged. This local form of tuberculosis lends itself very readily and efficiently to surgical treatment and gives promise of affording a complete cure when the condition is properly handled.

1200 MADISON AVENUE.

Surgical Aspect of Dysentery.—Z. Cope (*Lancet*, March 13, 1920) gives the results of his experience in Mesopotamia, together with a review of the literature regarding this subject. Dysentery may develop in the course of the surgical treatment of almost any condition as a lighting up of an old process by the preliminary purgation or as a terminal event in a long drawn out surgical condition. It may simulate carcinoma of the gut or almost any of the acute surgical conditions of the abdomen. But of chief interest to the surgeon are the complications of dysentery due to local processes set up by the inflammatory reactions in various parts of the organism. These are:

1. Perforation of the gut, comparatively rare in occurrence, most common in the cecum and sigmoid. When the perforation is into the peritoneal cavity the treatment is rendered difficult by the debilitated state of the patient and by the fact that the intestinal wall of dysentery is extremely friable about the site of the perforation. Suture is rarely successful and patients occasionally recover without interference. Abscesses due to retroperitoneal rupture of the wall respond well to incision and drainage.
2. Acute edematous localized colitis produces symptoms so similar to those of appendicitis that this must be constantly kept in mind. The condition at this point in the intestinal tract does not give rise to the more urgent symptoms of dysentery, so careful stool examinations are necessary.
3. Dysenteric appendicitis occurs occasionally.
4. Extensive sloughing with the formation of large secondarily infected ulcerating areas which fail to respond to emetine requires appendicostomy or valvular cecostomy with systematic irrigations of the large intestine. If this fails to heal the ulceration, open cecostomy or enterostomy with complete division of the small gut to give the colon a complete rest for some weeks should be performed.
5. Cicatrization is exceedingly rare, probably because the cases with ulceration and inflammation enough to produce large cicatrices are so commonly fatal.
6. In eleven cases of perinephritic abscess not due to gross disease of the kidney, the writer found four with a history of previous dysentery or diarrhea and in two of these, amebæ were found in the stool.

The more remote complications, amebic hepatitis, abscess of the liver, brain and spleen, and cystopyelitis, are, aside from the hepatitis and liver abscess, rare in occurrence. They must be treated with emetine as well as surgically

INTRALIGAMENTOUS UTERINE FIBROMYOMATA.

Myomata of the uterus found in the folds of the broad ligament represent a special variety of these neoplasms. They merit a special study by themselves both because of their peculiar clinical character and the somewhat special conduct to be followed in their treatment. These growths are characterized by their implantation on the sides of the uterus, in the body of the organ and more especially the cervix. In order to understand the evolution of intraligamentous myomata the shape, direction and exact site of the broad ligaments, their relationship to all the pelvic viscera—bladder, ureter, intestine, rectum, vessels and nerves—must be clearly understood. The two layers of the broad ligament are separated by a cellular layer—the so-called umbilico-pelvic aponeurosis of Petit—which lines each broad ligament and separates their two folds. These neoplasms are variable in size, sometimes single, at other times multiple, of hard or soft consistency, and always develop in a transversal direction. Like other uterine fibromyomata the intraligamentous variety may undergo malignant changes, and septic processes may occur. Separating the two folds of the broad ligament they may likewise dissect off the mesodermic layer or even decorticate the parietal peritoneum to some extent. The bladder, ureter, rectum, vessels and nerves of the pelvis are often deformed, flattened or changed in their anatomical relationships.

The cause of intraligamentous development of uterine fibromyomata is not clear; their frequency as compared with other similar uterine neoplasms is about one to ten. The symptoms to which they give rise are above all disturbances resulting from compression, while the functional disturbances that constitute the uterine syndrome are usually mild in these cases. The physical signs are otherwise important. The tumor is fibrous in consistency, with a transversal development, slightly movable, connected with the uterus and projecting into one of the vaginal culs-de-sac. The diagnosis is not always an easy matter and can be made by combined abdominal and vaginal palpation. When the growth has a pelvic development the differential diagnosis must be made between hematocele or perhaps inflammation of the adnexa and, when abdomino-pelvic, between tumors of the iliac bones, ovary, or broad ligament and pregnancy.

The prognosis is somewhat serious. When once developed the compression disturbances do not retrogress and more than any other type of fibromyomata those comprised within the broad ligaments disturb pregnancy and interfere with labor. Operation is indicated when the onset of disturbances from compression is detected. Myomectomy should only be employed when the growth is single and connected with the uterus by a thin pedicle, otherwise hysterectomy should be done. If the growth is of medium size and inserted at the upper part of the side of the uterus, supravaginal hysterectomy will suffice, but it should be total when the neoplasm is inserted in the cervix or is large. Should decortication of the tumor prove to be laborious, with rupture of numerous adhesions, not only should careful abdominal drainage be carried out but it is better not to suture the vagina. When the case is complicated by pregnancy and surgical intervention is necessary, myomectomy should be done, if gestation is in the early months, and if toward the end, hysterectomy or Porro's operation. The induction of premature labor should invariably be proscribed.

THE FUTURE OF HOSPITALS.

The trend of the practice of medicine appears to be in many respects changing, that is to say, it seems that the medicine of the future will be more of a preventive character than formerly. If this be so then the hospital system will require a certain amount of revision. Students must be trained as

thoroughly in diagnosing early symptoms of disease and in the best ways of preventing them from becoming serious, as in treating diseases when they have obtained a foothold. This is preventive medicine as expounded by Sir James Mackenzie. In this country as in every civilized country the hospital system must be made to conform with modern views and not continued on the old lines merely because these are hallowed by tradition. In Great Britain, however, the hospital situation is more insistent and acute than in America. The hospitals there are one and all financially embarrassed, as well as being subject to the defects mentioned.

British hospitals, from time immemorial almost, have depended for their support on voluntary contributions, and, up to the time of the war, this system acted in a satisfactory manner on the whole. But the war has changed the entire aspect of affairs and at the present time most of the British hospitals are in a very parlous condition. In fact, if a rational scheme is not evolved soon worse results will ensue. The question is how are these indispensable institutions to be placed on a sound and solvent footing? While the voluntary system of maintaining hospitals has much to be said in its favor, it is nevertheless obvious that if this method does not bring in enough money to conduct the institutions in a proper way, it must either be modified or another plan must be thought out.

The statement, that without ample resources neither a hospital nor a medical school can discharge its functions or even continue to carry on at all, needs no argument. This fact is so thoroughly realized in most European countries that hospitals are maintained by the State or aided by municipalities or wealthy religious communities. It will be superfluous to enter into the many reasons why the voluntary system has proved inadequate. It is plainly evident that hospitals cannot continue to provide gratis medical and surgical attendance to all who ask for it. The most sensible way out of the quandary would seem to be the introduction of the pay ward system or partial pay ward system. At any rate, the hospitals might charge for the board, lodging and drugs supplied. Some institutions have done this.

The class for whom the British voluntary hospitals were in the first instance established, the really poor, are no longer with us, or rather are with us in another guise. Working men and small tradesmen are nowadays comparatively well to do and can easily afford to pay for hospital care and treatment and undoubtedly many in and outpatients are obtaining for nothing the treatment and medicines for which they are able to make a moderate

payment. The poor in Great Britain at the present time are the middle classes who are overburdened with taxation from which the working classes are almost entirely exempt, and the former have never resorted to hospitals, but doubtless would be glad to do so if they could be received as paying guests. State aid is abhorrent to British individualism and the alternative, the pay ward, would appear to be much better suited to the character of the people. In this country the pay ward system, as a rule, works well, it tends to promote self-respect and independence and is fair to all. People will go to hospitals much more than ever before. Home treatment, except for minor ailments, is becoming less and less common.

The future of hospitals is full of promise but at the same time it should be understood that they must move with the times, and that both for preventive and curative and remedial treatment they must be so constituted and equipped that they provide absolutely the best means of treatment. The situation as regards British hospitals has been dealt with in order that the American medical profession may understand the difficulties which confront the medical profession in the British Isles. Some of our readers may like to discuss the point as to how the pay ward system has worked generally in America and to suggest ideas as to the hospital of the future.

PHYSICIAN-AUTHORS: DR. ERASMUS DARWIN.

All educated people today are more or less familiar with the Darwinian theory, evolved by Charles R. Darwin, the greatest English naturalist of the nineteenth century and author of *The Origin of Species* and *The Descent of Man*. Comparatively few, however, know that Darwin succeeded to an intellectual inheritance and carried out a program sketched and left behind by his grandfather, Dr. Erasmus Darwin, an eighteenth century English physician who was possessed of an indefatigable spirit of research and almost the same biological tendency as his illustrious grandson. Both had theories of evolution. The fame of the grandson is based almost wholly upon the theory he so ably expounded, but the grandfather and his theory have been lost sight of almost completely. And yet it was he, and not Lamarck, the French zoologist, who originated the doctrine of organic evolution and of invertebrate paleontology—in other words, that all living beings arose from germs through spontaneous generation. Dr. Samuel Butler—the *Erwhonian* Butler—openly accused Lamarck of having gotten his ideas from Erasmus

Darwin's *Zoonomia*, and in his *Evolution Old and New* Butler takes pains to show the complete coincidence of Dr. Darwin's views with those later expressed by Lamarck. "The chief fault with Dr. Darwin's treatise on evolution," says Butler, "is that there is not enough of it; what there is, so far from being 'erroneous' (as Charles Darwin contended), is admirable. But so great a subject should have had a book by itself, not a mere fraction of a book. . . . That is the only way men can expect to succeed against the vested interests. Dr. Darwin has said enough to show that he had the whole thing clearly before him, and could have elaborated it as finely as or better than Lamarck himself has done, yet the palm must be given to Lamarck on the score of what he actually did, and this, I observe to be the verdict of history, for whereas Lamarck's name is still daily quoted, Dr. Darwin's is seldom mentioned, and never with the applause it deserves."

The essence of Dr. Darwin's theory of evolution is contained in the following passage: "Would it be too bold to imagine that, in the great length of time since the earth began to exist, perhaps millions of ages before the commencement of the history of mankind—would it be too bold to imagine that all warm blooded animals have arisen from one living filament, which the First Cause endued with animality, with the purpose of acquiring new parts, attended with new propensities, directed by irritations, sensations, volitions and associations, and thus possessing the faculty to continue to improve by its own inherent activity, and of delivering down these improvements by generation to its posterity, world without end!"

Zoonomia, in which this theory appeared, was Dr. Darwin's chief prose work. It has been described as "an exhaustless repository of interesting facts, of curious experiments in natural production and in medical effects." The second part of it is devoted to an enumeration of diseases, classified, and suggestions as to their medical treatment, illustrated by brief reports on cases. His theory of evolution was closely connected with his scheme of classifying diseases. The book was read extensively by medical men of Darwin's day, who highly esteemed him as a practitioner. The average man today never so much as heard of Dr. Darwin, but a little more than a century ago he enjoyed a world wide reputation as an author. This was due chiefly to his long didactic poem, *The Botanic Garden*, which was a literary sensation and enjoyed a best seller vogue not only in all English speaking countries but also in France, Germany, Spain, Italy and other countries.

It was in verse that Dr. Darwin usually expressed himself—verse that has been condemned by the critics as being more rhetorical than poetical, and monotonously bloodless and mechanical. Schiller, speaking of *The Botanic Garden*, called it "cold intellectuality disguised in verse"; Coleridge compared it to a Russian ice palace, "glittering, cold and transitory"; and the ruthless Sidney Lanier branded it as "the funniest earnest book in our language." It took Dr. Darwin several years to write *The Botanic Garden*. Every line of it was polished and sharpened elaborately, much of this being done as he rode from one patient to another. The first part appeared in 1781 and it was not until eight years later that the second part, called *The Loves of the Plants*, appeared. But despite the infinite pains Dr. Darwin took with it, its only merit lies in its scientific enthusiasm and the great knowledge of nature which it displays. Dr. Darwin decidedly was no poet. Here and there there are flashes of genuine beauty, but these are very rare. Generally his style is so pompous that it becomes ridiculous and the whole effect is one of artificiality.

The novelty of *The Botanic Garden* had much to do with its wide popularity. It personified the plants (in accordance with the system of Linnaeus, the Swedish naturalist, who demonstrated that all flowers contain families of males or females or both) and described their love affairs. It was an ingenious attempt to unite science and poetry but was almost as short lived as a flower itself. In personifying plant life the Belgian author, Maeterlinck, has done a much better job.

Dr. Darwin's other poetical works were *The Temple of Nature* with philosophical notes, and *The Shrine of Nature*, both of which were published posthumously, and in both of which Darwin embodied an amazing amount of nature research and observation.

Besides *Zoonomia*, Darwin's prose works included *Phytologia, or The Philosophy of Agriculture and Gardening*, in which he announced his belief that plants have sense and volition, and a paper on *Female Education in Boarding Schools*.

In addition to his medical practice and his writing, Darwin was an ardent prohibition worker, one of the pioneer drys, and did much to diminish drunkenness among the poorer classes. Dr. Darwin was born at Elton, Nottinghamshire, England, on December 12, 1731. He studied at St. John's College, Cambridge, then at Edinburgh, and in 1756 began the practice of medicine in Nottingham. Later he practised at Litchfield and at Derby, where he died on April 18, 1802.

SELFCERTIFIED.

Efforts at prevention of disease have gone as far back as endeavoring to influence the shadowy ghost of infant life which feebly raps upon the gate of life as it still lies in the womb. Giving all prenatal care to the mother of the unborn child is a great advance. The great cry now is "Prevent, prevent," and one, almost as loud, is "cooperate," the last phase of cooperation occurring in the British Ministry of Health Bill, Part II, asking the victims of incipient mental disorder, but not yet lunatic, to become voluntary boarders for six months at an institution approved by the Minister of Health, two doctors certifying that by such treatment he is likely to benefit. No stigma of insanity will be attached, and free exit will be allowed. Periodical inspection by health officials will be made. It will also ease families from that most dreaded task of having a member put away for his own protection and that of others.

The special committee of the medicopsychological urge this as an amendment and not a revision of the Lunacy Acts. They urge the need of imposing upon local authorities the duty of providing the requisite treatment directly or through voluntary organization and insist there shall be special staffing and special management, the institution shall be apart from the asylum, as any association would fatally prejudice the place in the eyes of the people.

It is true that there are hundreds who feel they are going mad who dare not confess to being conscious of it because of the stigma on the family (hereditariness) and the horrible fear of being shut up behind bolts and bars, release coming only by consent of relations and doctors. If such institutions were established, a man would have the same relief on giving up the fight against insanity as he has when beaten by any other disease and finally lays his weary head on the pillow and lets that mighty, swift flying, life battering business world go its way without his very important direction. There would be no madness in taking a prolonged rest, rather, the most suspicious would be inclined to regard a man as sane for so doing. A difficulty will be in keeping out those neurotics who keep a mental microscopic, periscopic, telescopic, eye open to all their own symptoms and would rather be treated for insanity than not noticed at all.

A NEW OBSTETRICAL JOURNAL.

The American Journal of Obstetrics and Gynecology, a new monthly periodical devoted to obstetrics and gynecology, made its first appearance in October. Dr. George W. Kosmak, of New York, is editor of the new journal; Dr. Hugo Ehrenfest,

of St. Louis, is associate editor, and many of America's leading obstetricians and gynecologists lend their names to the editorial board. It is stated that a special feature will be the department devoted to current medical literature, which will be under the direction of Dr. Ehrenfest. The first issue of the new journal presents an excellent appearance, and if it fulfills the promise of this first issue it should prove a valuable addition to the medical publications of this country. It is published by the C. V. Mosby Company, St. Louis, Mo.

A PHYSICIAN IN THE HALL OF FAME.

Dr. William Thomas Greene Morton has been elected to a place among the men of achievement in the Hall of Fame. Dr. Morton was first a dental surgeon and later a physician. He received his M. D. from Washington University in 1849. He discovered anesthesia and in this way brought a boon to mankind. Artificial sleep could be induced, enabling surgeons to perform the needful operations, at the same time avoiding pain for the patient. His discovery he called *letheon*; today it is known as ether. The discovery was made public by an operation performed in the Massachusetts General Hospital, October 16, 1846, by Dr. J. C. Warren, to whom Morton had communicated his discovery. To honor the discoverer of this blessing to disordered humanity, the French Academy of Science awarded Morton the Monthyon prize of twenty-five hundred francs.

Obituary.

ISADORE DYER, M. D.,
of New Orleans.

One of the best known and most loved of America's physicians, Dr. Isadore Dyer, died at his home in New Orleans on the morning of October 12, 1920. For thirty years he had given the best of himself in his practice, in his writings and as the coeditor of the *New Orleans Medical and Surgical Journal* and the *American Journal of Tropical Medicine*. He was born in Galveston, Texas, fifty-four years ago and was graduated from the Sheffield Scientific School in 1887 and from Tulane University in 1889. He then began to specialize in skin diseases, serving an internship at the New York Skin and Cancer Hospital. For thirteen years he lectured on diseases of the skin at Tulane University. In 1905 he was made associate professor and finally in 1908 he became professor and dean of the medical school, a position he held until his death. The study of leprosy attracted him and it was with this disease that his name was most frequently associated. He was the founder and the president of the first board of directors of the Louisiana Lepers' Home, and one of the most active physicians connected with this institution. Dr. Dyer was also a member of the Medical Corps of the U. S. Army, achieving the rank of colonel in 1919. His was a useful work in the service of mankind and for this and for his pleasing personality he will be remembered by his patients and colleagues.

News Items.

Harvey Lecture.—The third lecture in the course will be given Saturday evening, November 20th, by Dr. Nellis B. Foster, of Cornell University Medical College, his subject being Uremia.

New Building for National Academy of Sciences.—A site has been obtained for the new building which is to be erected in Washington, D. C., to serve as a home for the National Academy of Sciences and the National Research Council. It comprises the block bounded by B and C and Twenty-first and Twenty-second Streets.

New York State's Birth Rate.—During the four years 1914-1917 the average annual birth rate for the State of New York was 23.8 to the thousand population; in 1918 it fell to 22.7 and in 1919 it declined still further to 20.8. During the first eight months of 1920 the birth rate was 21.7 for the entire state; 22.2 for New York city and 21.0 for the rest of the state.

Mental Hygiene Course at Columbia.—An extension course in mental hygiene for community workers is being given in the sociology department of Columbia University. During the course lectures on special topics will be delivered by Dr. Thomas W. Salmon, Dr. W. A. White, Dr. Pearce Bailey, Dr. Louis Casamajor, Prof. R. S. Woodworth, Dr. William Healy, Dr. Charles B. Davenport, Dr. F. E. Williams, Dr. Walter E. Fernald, Dr. Bernard Glueck, and Miss Maude Miner.

American Public Health Association.—At the annual meeting of this association, held in San Francisco, Cal., on September 15th, the following officers were elected: President, Dr. M. P. Ravenel, of Columbia, Mo.; first vice-president, Dr. Theodore B. Beatty, of Salt Lake City, Utah; second vice-president, Dr. Louis I. Dublin, of New York; third vice-president, Dr. W. C. Hassler, of San Francisco; secretary, Mr. A. W. Hedrich, of Boston; treasurer, Dr. Roger I. Lee, of Cambridge, Mass.

American Association of Military Röntgenologists.—At the recent annual meeting of the American Röntgen Ray Society, the American Association of Military Röntgenologists was organized, with the following officers to serve for the first year: Dr. Arthur C. Christie, of Washington, D. C., president; Dr. Henry K. Pancoast, of Philadelphia, vice-president; Dr. Francis F. Borzell, of Philadelphia, secretary. All officers of the medical and sanitary corps who were actively engaged in x ray work during the war are eligible to membership in the association.

Danger in Horse Hair Shaving Brushes.—The United States Public Health Service issues a warning against the use of horsehair shaving brushes, as a number of cases of anthrax have been traced to their use. Surgeon General Cumming says that every effort possible under existing laws has been made to prevent the occurrence of anthrax due to infected shaving brushes, but in spite of all efforts cases of anthrax will occur as long as the public buys and uses shaving brushes made of horse hair. He says that Congress will be asked to prohibit the use of horsehair for that purpose.

Plague Research in Florida.—The United States Public Health Service has established at Pensacola, Fla., a research station for the study of bubonic plague. Additional trained experts have been detailed to cooperate with those already stationed there, and an increase in research equipment to facilitate investigations will be provided.

Johns Hopkins May Have a Reserve Medical Officers' Training School.—Surgeon General Merritte W. Ireland, United States Army, has offered to establish a Reserve Officers' Medical Training Corps at Johns Hopkins Medical School, provided at least fifty students will agree to enroll in it. The trustees of the school have accepted the offer.

Brooklyn Hospitals Meet Requirements of American College of Surgeons.—Standards of hospital efficiency and administration set by the American College of Surgeons have been met by the following Brooklyn hospitals: Cumberland Street Hospital, Greenpoint Hospital, Coney Island Hospital, and Kings County Hospital. These are all general hospitals conducted under the direction of the Department of Public Welfare.

Philadelphia County Medical Society.—At a business meeting of this society, held on the evening of October 20th, the following officers were nominated for the coming year: President, Dr. John W. West and Dr. G. Morris Piersol; vice-president, Dr. Wilmer Krusen; secretary, Dr. J. Morton Boice; treasurer, Dr. Edward A. Shumway; assistant secretary, Dr. Charles Scott Miller; directors, Dr. F. Hurst Maier, Dr. William E. Parke, and Dr. George A. Knowles; censor, Dr. Levi J. Hammond; district censor to the State society, Dr. E. E. Montgomery.

Kentucky Medical Association.—At the seventieth annual meeting of this association, held in Lexington on September 27th to 30th, Dr. William W. Anderson, of Newport, was elected president, succeeding Dr. John G. South, of Frankfort, and other officers were elected as follows: Dr. Joseph A. Stucky, of Lexington, president-elect; Dr. Robert H. Cowley, of Berea, first vice-president; Dr. Alice N. Pickett, of Louisville, second vice-president; Dr. Elbert W. Jackson, of Paducah, third vice-president; Dr. Arthur T. McCormack, of Bowling Green, secretary. Next year's meeting will be held in Louisville.

University of Buffalo Endowment Fund.—The long felt need for an adequate endowment fund for the University of Buffalo has been recently realized, a campaign made from October 7th to 17th for a five million dollar endowment fund resulting in a total of about \$5,100,000. The scheme of the campus was chosen from competitive plans submitted by landscape architects. The style of the architecture is to be Georgian Colonial. The first building, now in process of construction at an estimated cost of \$400,000, will be devoted to the teaching of chemistry. The liberal arts, library and administration buildings will be the next erected. Other buildings will naturally follow in the development of the University plan. The income from the remaining funds will be available for the use of the several departments.

Relief Work in the Crimea.—To meet the increasing needs of the civilian population and thousands of refugees in the Crimea, the American Red Cross unit there has been authorized to increase its distribution of food and supplies to 500 tons weekly. Supplies now held at the Constantinople base have been made immediately available for this purpose and will be rushed to the Crimean unit as rapidly as distribution warrants. For the purpose of quickly organizing an effective system of distribution throughout the stricken areas, the personnel of the Red Cross unit has been increased to twenty-five men. Native labor is assisting in the work. The work of the American Red Cross in this section is confined entirely to the civilian population.

Civil Service Examinations.—The United States Civil Service Commission announces an examination for the position of physician in the Panama Canal Service, which will be held at various points throughout the United States on December 15, 1920, and January 19 and March 9, 1921. The entrance salary is \$250 a month, and promotion may be made to as high as \$360 and to higher rates for special positions. The salary begins on the date of sailing. Applicants must have graduated from a recognized medical school and have had at least one year's postgraduate hospital experience. They must have reached their twenty-second but not their thirty-first birthday.

Another examination will be held for the position of medical intern in St. Elizabeth's hospital, Washington, D. C., for which applications will be received until March 1, 1921. The salary is \$1200 a year and maintenance. Applicants must not have graduated in medicine previous to the year 1915 unless they have been continuously engaged in hospital, laboratory, or research work along the lines of neurology or psychiatry since graduation.

Personal.—Dr. James F. McKernon has been elected president of the New York Post-Graduate Medical School and Hospital, to succeed Dr. Frederic E. Sondern.

Dr. Blanche Norton, an American physician, has been awarded the Cross of King George I in recognition of her work among the trachoma victims in Greece.

Dr. José S. Salas, of the Chilean Army Medical Corps, is visiting the United States for the purpose of studying methods of venereal disease control.

Dr. Bowman L. Robinson, of the University of Wisconsin, has been appointed professor of hygiene in the University of Mississippi.

Dr. David E. Hoag, has been made associate in neurology, in the department of nervous and mental diseases, at the New York Post-Graduate Medical School and Hospital; also lecturer on nervous and mental diseases, at the University and Bellevue Hospital Medical College.

Dr. James Ewing, professor of pathology at Cornell University Medical College, and former director of cancer research at the General Memorial Hospital, New York, has been appointed a member of the board of trustees of the State Institute for the Study of Malignant Disease, at Buffalo, to fill a vacancy caused by the resignation of Dr. Seymour Oppenheimer.

To Register Disabled Veterans for Vocational Training.—A three months' campaign to register disabled soldiers and sailors for vocational training and education has been inaugurated by the Federal Board for Vocational Training. The board announces that no effort will be spared to locate deserving men who have been injured in military service and to see that every ex-service man entitled to training actually gets it. The \$90,000,000 appropriated by congress for their rehabilitation is now being distributed in the form of compensation ranging from \$80 to \$170 a month.

Meetings of Local Medical Societies.—The following medical societies will meet in New York during the coming week:

MONDAY, *November 15th.*—New York Academy of Medicine (Section in Ophthalmology); Medical Association of the Greater City of New York; Psychiatric Society of Ward's Island.

TUESDAY, *November 16th.*—New York Academy of Medicine (Section in Medicine); Federation of Medical Economic Leagues of New York.

WEDNESDAY, *November 17th.*—New York Academy of Medicine (Section in Genitourinary Diseases); Medico-legal Society; Northwestern Medical and Surgical Society of New York; Woman's Medical Association of New York City; Alumni Association of the City Hospital.

THURSDAY, *November 18th.*—New York Academy of Medicine (stated meeting); New York Celtic Medical Society.

FRIDAY, *November 19th.*—New York Academy of Medicine (Section in Orthopedic Surgery); Clinical Society of the New York Postgraduate Medical School and Hospital; New York Microscopical Society; Alumni Association of Roosevelt Hospital; Brooklyn Medical Society.

Died.

BERNARD.—In Boston, Mass., on Thursday, October 28th, Dr. Barnard L. Bernard, aged fifty-seven years.

BELL.—In Ogdensburg, N. Y., on Thursday, October 28th, Dr. Willard N. Bell, aged sixty-two years.

BOUTWELL.—In Manchester, N. H., on Tuesday, November 4th, Dr. Henry W. Boutwell, aged seventy-two years.

COHOON.—In Los Angeles, Cal., on Friday, October 22nd, Dr. Brock E. Cohoon, of Seattle, Wash., aged thirty-seven years.

COLEMAN.—In Mineral, Va., on Sunday, October 31st, Dr. William J. Coleman, aged sixty-four years.

DENCHFIELD.—In New York, on Thursday, November 4th, Dr. Levi J. Denchfield, aged sixty-five years.

FEATHERSTONHAUGH.—In Duanesburg, N. Y., on Wednesday, October 27th, Dr. Thomas Featherstonhaugh, aged seventy-two years.

GERHARD.—In Philadelphia, Pa., on Tuesday, October 26th, Dr. George Gerhard, aged seventy-one years.

HAWLEY.—In Kalamazoo, Mich., on Monday, October 25th, Dr. Alanson W. Hawley, of Seattle, Wash., aged fifty-four years.

HORNING.—In Norristown, Pa., on Friday, October 26th, Dr. Samuel W. Horning, aged fifty-eight years.

LOTHROP.—In Stanley, Wis., on Tuesday, October 6th, Dr. C. A. Lothrop, aged thirty-eight years.

MELTZER.—In New York, on Sunday, November 7th, Dr. Samuel James Meltzer, aged sixty-nine years.

MORRIS.—In Rockville, Ind., on Thursday, October 28th, Dr. Charles C. Morris, aged seventy-two years.

NEWCOMET.—In Stouchsburg, Pa., on Monday, November 1st, Dr. I. W. Newcomet, aged seventy-seven years.

NOBLE.—In Greencastle, Pa., on Thursday, October 29th, Dr. William P. Noble, aged seventy-five years.

PALMER.—In Johnsonburg, Pa., on Wednesday, November 3rd, Dr. William R. Palmer, aged fifty-seven years.

Book Reviews

STERILITY.

Sterility in Women. By ARTHUR E. GILES, M.D., B.Sc. (London), M.B., Ch.B. (Vict.), F.R.C.S. (Edin.), M.R.C.P. (London), Captain, R.A.M.C. (Temp.); Senior Surgeon to the Chelsea Hospital for Women; Gynecologist to the Prince of Wales's General Hospital, Tottenham. Illustrated. London: Henry Frowde (Oxford University Press) and Hodder & Stoughton, 1919. Pp. xi-227.

Giles, in his preface, considers sterility as an important after the war problem rather than a sociological or biological one. He thinks that with the limitation of marriages those that are consummated should at least be fruitful. Of course it is to be remembered that he is speaking now for England, where conditions are not the same as in this country. On the other hand, when he takes up the issue from his point of view he straightway encounters opposition. First, he will find those who believe in birth control and in this camp recruits have come for two main reasons: The expenditure of energy, men and materials have accentuated the struggle for livelihood, and the lesson of the war, when the sons of Europe's greatest countries were lined up one camp against the other. They do not want their offspring to furnish cannon fodder; to live in vermin filled dugouts; or to become fertilizer for fields made bloody at the will of senile statesmen who have outlived their usefulness. This at least is the argument offered by a faction of the great group who are more interested in controlling the number of their offspring rather than in methods which will ensure their having offspring. This argument is mentioned, not to disprove any of the scientific facts which Giles presents, but merely to check up the motives for which the book was written. Europe was steeped in the turmoil of war for so long a period that many of the inhabitants, victims of quickly formed habits, began to think that war was a normal state of affairs. Many of these people find it hard to adjust themselves to the new conditions; in fact, for a goodly portion of the population peace brought few changes. The tension has been removed, somewhat, but conditions are far from what we were pleased to call normal before the war.

In view of all this we shall disregard what Giles says in his none too spontaneous introduction and consider his researches from a scientific viewpoint alone.

First of all, in considering the etiology of sterility in women, which is the subject discussed, it must be ascertained if the fault lies with the man. This is for the process of elimination. Various authors differ in their estimate of the responsibility of the male, the figures varying from ten to ninety per cent., a wide range, certainly. Most of these references are taken from Hühner. The estimates of the proportion of unproductive marriages also vary from two to over twenty per cent. These figures do not seem high, for most women who are desirous of offspring will sooner or later seek the aid of a gynecologist, and often more than one. So, considering these points, the figures when reduced to the lowest estimate could be lowered considerably

as applied to the population at large. It is somewhat confusing in studying these statistics to find spinsters listed among the case histories studied. From any angle it is difficult to find a reason for this compulsion for completeness on the part of the author. The same note may be made about acrobatic statements such as, "We can say that a woman is sterile and will remain so, whether she be a virgin or a married woman."

First of all the various mechanical defects and obstacles are considered. These are many and varied, some capable of correction and others irremedial. Then sterility—and here the author makes the distinction between sterility and non-productiveness—is divided into functional, primary (acquired and congenital), and secondary. A glance at the list will convince one that many conditions are to be considered. Among the functional causes are grouped: impotence of husband, nonoccurrence of coitus, vaginismus, dyspareunia, sex incompatibility. Then primary sterility is made to embrace the congenital variety, of malformations preventing intercourse, such as absence of vagina, atresia of the vagina, stenosis of the vagina, and where intercourse is allowed, absence or underdevelopment of the ovaries, atresia of the fallopian tubes, atresia of the os uteri, underdevelopment or ante flexion and stenosis of the uterus. Then we have a long list under acquired sterility due to causes such as injuries to the vagina and cervix causing stenosis and atresia, cessation of ovarian activity, pelvic inflammation, uterine displacements, ovarian and uterine tumors and uterine fibrosis.

We have yet to dispose of the secondary sterility due to the effects of labor and the other effects of acquired sterility. Quite a list for so small a proportion of sterile women. However, we might add that this list is not complete, for there are other causes in addition to the long list enumerated. These various causes of sterility have been carefully gone over by Giles and he has assembled a formidable array of literature on the subject. There is little to denote that much recent progress has been made. For example, in considering vaginismus, after allowing that the condition is one of psychic origin, the treatment advised is dilatation. It is stated that the results have been satisfactory for this method of treatment. But it hardly seems consistent to find one cause and then turn about and treat the effect. More recent workers have been successful in their treatment of sterility, when the dysfunction is due to endocrine disorders, by the use of various glands of internal secretion. This seems a field of considerable importance, yet Giles has little to say about it. He confines himself in the main to the grosser, more obvious anatomical and physiological disorders which usually require the surgical or medical hero to correct. So it is with the psychic disorders which he brushes away with a mere mention. The fact that sterility is encountered almost twice as frequently among the well to do should lead us to look into the finer and more important mechanisms which control the workings of the complex human organism.

MATERNITY.

Maternitas. A Book Concerning the Care of the Prospective Mother and Her Child. By CHARLES E. PADDOCK, M. D., Professor of Obstetrics, Chicago Post-graduate Medical School; Assistant Clinical Professor of Obstetrics, Rush Medical College; Attending Obstetrician, St. Luke's Hospital. Illustrated. Chicago: Lloyd J. Head & Co., 1920. Pp. 210.

Half a century ago, the condition of pregnancy and the safe delivery of babies was considered rather an indelicate subject, and it was only whispered that a lady was "in the family way." Books on the subject were few and any possessed were carefully hidden, and so was the young mother to within a month of her delivery, her nerves and her appearance supposedly justifying this, and for a month afterwards she kept to her bed or sofa mainly with the idea of preserving her figure.

Perhaps the young mother of today goes to the other extreme through ignorance or daring. In this book she finds none but reasonable precautions urged and their necessity. Elderly mothers may dissuade the younger ones from reading by quoting those who have had large and healthy families in defiance of all the rules now considered obligatory, but if a record of those who failed were given it would considerably outnumber the totally healthy. The book is not overloaded with details likely to alarm the mother, because the advice generally winds up with "send for the physician." There might be a chapter for mothers in outlying districts and far away places on What to Do When the Doctor Can't Come; but, seriously, the book seems sufficient without sending for him.

The new baby is to have no rubber "comforter," and no kisses except a few sterilized ones from the parents on the forehead or cheek. It is not to suck its thumb or eat pins, buttons and marbles. Part of the daily exercise is "kicking, screaming, and waving the arms," but the screams of illness, hunger and cussedness should be differentiated. Mrs. John Wesley used to spank it for the third, first for crying, then for crying because it disapproved the laying on of hands. The infant is to be on good terms with the doctor, though the next bit of advice that the child should be taught as soon as possible to put out its tongue, is rather suggestive of a baby cave dweller, and not to be followed by polite infants.

The volume concludes with some useful recipes for both mother and child, and the whole tone is so reassuring and cheerful that prospective mothers may face maternity with a light heart.

MEDICAL BIOGRAPHIES.

American Medical Biographies. By HOWARD A. KELLY, M. D., LL. D., F. A. C. S., Hon. F. R. C. S. (Edin.), and WALTER L. BURRAGE, A. M., M. D. Second Edition, Revised and Enlarged. Baltimore: The Norman, Remington Company, 1920. Pp. xix-1320.

In seeking biographical material from books or friends, you get the man from various points of view—as his family, his patients, his confrères, and friends saw him. Often the titles, not the worth of his writings, is given, or his work is intentionally minimized or exaggerated. A man's work was not of much worth, perhaps, but he was, as his biography says "the beloved physician": yet

such qualification standing alone, though not excluding from an ordinary cemetery, would exclude from a hall of fame such as this volume appears intended to be. In the first edition such assertion was sometimes weakly conceded, but the editor says adverse criticism resulted in fifty-one exhumations before the second edition came out.

There will always be men who mistake fault-finding for criticism, but these, having scanned the lists, will agree that an adequate representation has been given to the three cities of New York, Philadelphia and Baltimore. Then there is the question of priority in work. The records of any law court will give surprising cases of similarity in ideas. Also, a man may conceive the idea but neither publish it nor give details except to a friend, so that when the other man proudly claims it as original, he is often quite justified, though the priority as given in a biography gives rise to some bitterness.

One good thing about the book is that it does not include the living. The inclusion would not matter so much if the men could undertake to live until a second edition appeared, otherwise there would be awkward fragments of mortality round the now completed life. Every day the tide of healers, themselves now wounded, is swirling on to death and a second edition. Many are said to create a void which can never be filled, or to have caused an irreparable loss, but such bold assertions as to the Creator's power to duplicate sink silent when the place is once more filled.

The book is not only useful for reference, but interesting in the glimpses it gives of the grim struggles of our earliest doctors against poverty, booklessness, ignorance, and loneliness. Interesting, too, to see how near they came to seeing truths now proved, how strenuously they fought for that which is now proved wrong; how pestilence and epidemic, their true cause now known, ruthlessly swept away both patients and doctors. This second, revised edition of Kelly's book should be welcomed everywhere.

NOCTURNE.

Nocturne. By FRANK SWINNERTON. New York: George H. Doran Company, 1917.

A reputation for perfection is a cross that any writer must bear as best he may. Frank Swinnerton seems to have achieved this dubious distinction by the publication of *Nocturne* and several other novels: as in the case of Leonard Merrick, the acclaim comes mostly from his fellow writers. It is only fair to say that Mr. Swinnerton will be most enjoyed where his reputation has not preceded him. But *Nocturne* is exceedingly interesting from another point of view. It is not perfect, but it is alive. Its spirit and imperfections are of the twentieth century; it is sharply modern even in the selfconsciousness that keeps it from quite achieving beauty. Few studies of women are more searching. There is in this book an unusual combination of effort and artlessness, of psychology and emotion, of classic unity with modern turbulence. It is a book which the reader will not immediately forget.

Emmy and Jenny, the two sisters of the story, are opposites. Emmy is the passive, incurious

woman, finding her complete expression in affection and homekeeping. Jenny is keen, restless, rebellious, impatient of restraints. The entire action of the story takes place on one night when Jenny finds that Emmy is in love with Al, a victim whom Jenny herself is merely dangling. Jenny sends them off to the theatre together and remains at home with Pa, who is paralyzed. But there comes a note from Keith, her sailor, saying that he is in London for just one night and cannot leave his ship, and asking her to come to him. Jenny hesitates between Pa and Keith, between duty and the one mad moment of adventure that may ever come to her, and she chooses Keith. When she returns it is to find Emmy and Al engaged. On the same evening each of the sisters has met her great moment in her own way. Emmy, of course, has no problem; she has found her man and she is satisfied. But there is still Jenny, poignant, unsatisfied Jenny, whose lover has sailed away again and who in addition has to bear her own reproaches because during her absence Pa fell and hurt himself; Jenny who does not want a stew and bread pudding existence; Jenny who is not commonplace but who has nothing ahead of her but commonplaceness. Jenny is not to be so easily dismissed. Her voice is added to the voices of revolt that are crying out everywhere in the world today—revolt against humdrum, empty lives, against the conditions that make men and women machines. She is youth demanding its own.

Mr. Swinnerton has done a rare thing in this book—he has made his characters reveal themselves to a remarkable extent through their own conversation. But, not satisfied with this, he has interpolated lumps of psychology that float around like indigestible dumplings in one of Emmy's own stews. It is drama plus a diagram, and the diagram is superfluous and annoying. One third of *Nocturne* could easily be cut out. But this, too, is characteristic. If Jenny is youth of today, Swinnerton is the writer of today, with a worthy desire to analyze and a fear of being merely limp. But *Nocturne* is an arresting book, and if its faults are those of modernity, who are we to cavil?

MAC OF PLACID.

Mac of Placid. By T. MORRIS LONGSTRETH. New York: The Century Company, 1920. Pp. xi-339.

It will soon be necessary to chart the world for writers and note the places where there is enough room for adventures. Travel by land, water and air, now so easy, quickly makes the unknown familiar and the poor authors have to stage their stories in long ago times when real statisticians and bacteriologists, automobiles, thermos flasks, canned goods and first aid had not arrived. Longstreth chooses the Adirondacks when loggers, hunters and trappers were the chief dwellers, and here he plants Mac at Saranac to win Hallie and circumvent the evil designs of a certain wild Tess and her helper, Ed Touch. Robert Louis Stevenson also spends a winter with Mac and draws plans for Mac's successful wooing of Hallie. But it is not the story itself, though that is sufficiently thrilling; it is the pictures of the country, or, more than pictures, scenes in which you feel the blinding snow and seek some shelter from the pitiless rainstorm. You

stand, forgetting it is only in a book, in reverent silence among the giant trees and see the final advent of spring as a marvelously beautiful coming never seen before. Longstreth loves the Adirondacks and makes his readers see and love them also.

PEARLS ASTRAY.

Pearls Astray. A Romantic Episode of the Last Democracy. By CONSTANCE M. WARREN. Illustrated. Boston: Small, Maynard & Co., 1920. Pp. 158.

This is the dream of a millionaire whose dinner has evidently disagreed with him. It embodies all the delusions caused, and then some. It is a misleading and clever piece of work, with apt characterizations and amusing pictures.

New Publications Received.

[We publish full lists of books received, but we acknowledge no obligation to review them all. Nevertheless, so far as space permits, we review those in which we think our readers are likely to be interested.]

ANNIVERSARY TRIBUTE TO GEORGE MARTIN KOBER IN CELEBRATION OF HIS SEVENTIETH BIRTHDAY. By His Friends and Associates, on March 28, 1920. Edited by Rev. FRANCIS A. TONDORF, S. J., Ph. D. Washington, D. C., 1920. Pp. 381.

THE SCHOOL OF SALERNUM. REGIMEN SANITATIS SALERNITANUM. The English Version by Sir JOHN HARRINGTON. History of the School of Salerno, by FRANCIS R. PACKARD M. D. A Note on the Prehistory of the Regimen Sanitatis, by FIELDING H. GARRISON, M. D. New York: Paul B. Hoeber, 1920. Pp. 213.

ELECTROTHERAPY. ITS RATIONALE AND INDICATIONS. By J. CURTIS WEBB, M. A., M. B., B. C. (Cantab.), Hon. Associate of the Order of St. John of Jerusalem; Order of Merit of the Cruz Vermebla; Hon. Associate, King's College, London, etc. With Six Diagrams. Philadelphia: P. Blakiston's Son & Co., 1920. Pp. 90.

A COURSE OF LECTURES ON MEDICINE TO NURSES. By HERBERT E. CUFF, M. D., F. R. C. S., Principal Medical Officer to the Metropolitan Asylum Board; Late Medical Superintendent, North Eastern Fever Hospital, Tottenham, London. Seventh Edition, with Twenty-Nine Illustrations. Philadelphia: P. Blakiston's Son & Co., 1920. Pp. vii-257.

PUBLIC HEALTH LABORATORY WORK (CHEMISTRY). By HENRY R. KENWOOD, C. M. G., M. B., F. R. S. (Edin.), D. P. H., F. C. S., Chadwick Professor of Hygiene and Public Health, University of London; Medical Officer of Health and Public Analyst for the Metropolitan Borough of Stoke Newington. Seventh Edition, with Illustrations. New York: Paul B. Hoeber, 1920. Pp. xi-420.

PHYSIOLOGY AND BIOCHEMISTRY IN MODERN MEDICINE. By J. J. R. MACLEOD, M. B., Professor of Physiology in the University of Toronto, Toronto, Canada; Formerly Professor of Physiology in the Western Reserve University, Cleveland, Ohio, Assisted by ROY G. PEARCE, A. C. REDFIELD, N. B. TAYLOR, and Others. Third Edition, with Two Hundred and Forty-three Illustrations, Including Nine Plates in Color. St. Louis: C. V. Mosby Company, 1920. Pp. xxxii-992.

MASSAGE. ITS PRINCIPLES AND PRACTICE. By JAMES B. MENNELL, M. D., M. B., B. C. (Cantab.), etc., Medical Officer, Physico-Therapeutic Department, St. Thomas's Hospital; Medical Officer in Charge of the Massage Department, Special Surgical Hospital, Shepherd's Bush; Author of *The Treatment of Fracture by Mobilization and Massage*. With an Introduction by Sir ROBERT JONES, K. B. E., C. B., F. R. C. S., Major General, A. M. S., Inspector of Special Military Surgery. Second Edition. With One Hundred and Sixty-seven Illustrations and Two Appendices. Philadelphia: P. Blakiston's Son & Co., 1920. Pp. xvi-535.

Practical Therapeutics and Preventive Medicine

A Compendium of Treatment and Prophylaxis, Original and Adapted

Venous Thrombosis, Pulmonary Infarction, and Embolism Following Gynecological Operations.—H. H. Hampton and Lawrence R. Wharton (*Bulletin of the Johns Hopkins Hospital*, April, 1920) have analyzed the cases of thrombosis occurring in the Johns Hopkins Hospital from 1890 to 1918 inclusive. During the period 21,000 patients were operated on in the gynecological clinic, with 205 cases of femoral thrombophlébitis following all types of gynecological operations, or an incidence of one per cent. From their extensive study of these cases the following conclusions are drawn: Post-operative venous phlebitis and thrombosis are not peculiar to any particular type of gynecological operation. Of the conditions favoring thrombus formation infection and trauma are the most important. Nearly all the cases of thrombophlebitis are associated with a slight rise in temperature. Phlebitis and thrombosis when associated with pain and swelling are rarely ever followed by fatal embolism. Pulmonary infarction occurs most often in the same class of cases and during the same period of convalescence as femoral thrombophlebitis. Pulmonary infarction may precede pulmonary embolism. Post-operative pulmonary infarction in the majority of cases has heretofore been unrecognized. Its diagnosis must be based on the clinical picture rather than the physical findings alone, and the authors believe that with proper care pulmonary infarction should be diagnosed.

Cicatricial Laryngeal Stenosis in Children.—E. J. Moure (*Journal de médecine de Bordeaux*, February 10, 1920) notes that occasionally this condition is due to ulcerations of the laryngotracheal canal; from diphtheria, measles, scarlet fever, or rarely, typhoid fever. More frequently, however, it results from tracheotomy improperly performed, viz., through the thyroid cartilage, the intercricothyroid space, or simply through the cricoid. The practitioner called in an emergency to a child threatened with asphyxia opens into the laryngotracheal canal at the most convenient point for insertion of the cannula. Some time later he finds that upon tentative removal of the cannula dyspnea reappears, and is prone at once to ascribe the difficulty to a spasmodic closure of the glottis, preventing removal of the cannula. Examination of the child, still wearing the cannula, some months later, reveals a more or less tight stenosis of the larynx, with immobility of the arytenoids in the median line, and below these, bilateral subglottic infiltration. External inspection shows that the opening for the cannula had been made in a faulty position. The proper treatment in such cases is to ignore the larynx and simply make a new opening for the cannula into the trachea itself. Under these conditions patency of the canal will become gradually reestablished and the opportunity given for removal of the tube. During this time the attendant's chief solicitude should be to prevent pericannular accumulation of granula-

tions by excising from time to time or cauterizing with the electrocautery or one in ten chloride of zinc solution the exuberant granulations which invariably develop within a few months. In no case, however, should the cannula be removed without examination as to the permeability of the larynx by laryngoscopy. The children should be trained to breathe through the normal channels by stopping the cannula at first during the daytime only, and later at night. The special cannulas recommended by former writers are unnecessary. In the exceptional cases in which stenosis is actually found to be due to cicatricial tissue within the larynx, the delay will not have been without advantage, for children seven or eight years old are much more favorably situated for supporting the necessary operative procedure than smaller children.

Barium Chloride and Cardiac Inhibition.—Tournade (*Paris médicale*, March 13, 1920) notes that barium chloride antagonizes the slowing of the heart rate caused by stimulation of the vagus nerve. The problem arises, whether this effect on the part of the barium salt is due to paralysis of the vagus, or to a stimulation of the intracardiac nervous structures, thus rendering the heart refractory to the influence of the vagus. The author placed a ligature about the auriculoventricular furrow on the heart of a young dog extracted from the uterus at term. The frequency of the auricular contractions was thus rendered double that of the ventricular beats. When a few drops of barium chloride solution were then injected into the left ventricle, the ventricular beats were accelerated and became much more frequent than the auricular. This was taken to show that barium chloride acts by excitation of the cardiac nervous mechanism.

Intracardiac Pressure as a Standard in Cardiotherapy.—I. Harris (*Lancet*, May 1, 1920) bases his therapy in cardiac failure on the intracardiac pressure as determined by measuring the length of diastole in comparison with the length of systole. The measurement is done with the electrocardiograph. It is assumed that a relatively long diastole compared with systole signifies a high intracardiac pressure, since a long diastole allows a large amount of blood to collect in the ventricle which must be forced out quickly during the short systole. The fact that this measure is only approximate and not necessarily true in all circumstances is recognized, but it is considered true in the majority of cases. Two types of cardiac failure are recognized in this classification, the first with a low intracardiac pressure because of a short diastole and rapid heart rate accompanying a flabby inefficient heart muscle, and the second accompanied by arterial damage, high blood pressure, slow heart rate, long relative diastole, and a very high intracardiac pressure. The treatment of the first type must obviously be directed toward an improvement of the tone, and strength of the muscle wall. Digitalis is the drug

of all others to be chosen here as its tonic effects will be produced before its pressure raising effect can do damage. The amount of drug to be used is regulated by observing the effects of the intracardiac pressure. In the second type of case it is necessary to reduce the intracardiac pressure and caffeine seems to be the most satisfactory drug, though in many cases it cannot be used over long periods because of its property of increasing the nervous excitability of the patient. When it can be no longer used atropine must take its place. As this reduces the intracardiac pressure by increasing the heart rate, digitalis in small doses should be used, for, even in rapid heart action, digitalis benefits the heart muscle. Adrenalin also seems to be beneficial in such cases, particularly in cases with edema, since the author considers it to be a diuretic which does not affect the intracardiac pressure.

Effect of High Temperature upon the Action and Toxicity of Digitalis.—Hirschfelder, Bicek, Kucera, and Hanson (*Journal of Pharmacology and Experimental Therapeutics*, July, 1920) found that the lethal dose of digitalis for cats whose temperature was elevated to 43° C. is much smaller than the lethal dose at normal temperatures. In the febrile animals the drug was found to cause the typical slowing of the pulse rate and increase in the blood pressure, as well as ventricular extrasystoles and inversion of the T wave in the electrocardiogram. Although the heart muscle in these experiments was free from any injury due to prolonged fever or toxemia, the high temperature factor alone was enough to increase greatly its susceptibility to the effects of digitalis. Great care should therefore be exercised in using digitalis in large doses in patients with high fever. For animals at 43° C., the dose recommended by Eggleston in the treatment of clinical cases of myocardial insufficiency would represent about the average lethal dose. The experimental results were in harmony with the recent report of T. Stuart Hart that in four cases of his series of influenzal bronchopneumonia cases heart block resulted from the administration of three drams of tincture of digitalis—about half the dose at which similar effects might be expected in afebrile heart cases. In patients with fever the larger doses of digitalis should be avoided, and the effects of the drug carefully watched throughout the course of the treatment.

Resuscitation of the Heart.—K. Henschen (*Schweizerische medizinische Wochenschrift*, April 1, 1920) reviews the attempts which have been made in the past to effect a resuscitation of the heart after it has ceased to beat through the injection of a stimulant into the pericardium or into one of the cavities of the heart, either with or without the withdrawal of blood or the infusion of a fluid. It appears from his account that a few experiments have succeeded in reviving the heart, at least for a short time, in a number of instances. He reports four cases, which may perhaps be called successful, although in only one did the patient survive. In two patients an injection of one c. c. of adrenalin and 0.5 c. c. of pituitrin into the left ventricle a few minutes after the heart had stopped beating started the heart beat again, but

both died within an hour. In a case of bullet wound of the heart a similar injection revived the heart and the patient seemed to be doing well until a pericarditis proved fatal on the second day. The fourth patient, his second, had suffered a very severe contusion of his chest and upper abdomen. The heart stopped beating during an exploratory laparotomy and could not be revived by massage. One and a half cubic centimetres of a one in one thousand adrenalin solution were injected in the pericardium through the fourth interspace, inside the mammillary line, to a depth of about two cm. The heart then began to beat again, and an intravenous injection was made at once into the arm of 700 c. c. physiological salt solution to which had been added ten drops of adrenalin and 0.5 c. c. of pituitrin. This patient recovered.

Fibromata, with Especial Reference to Radium Treatment.—Everett S. Hicks (*Canadian Medical Association Journal*, July, 1920) states that he has treated ninety-eight cases during the past six years with the following results: Failure, two; all symptoms relieved, tumor largely reduced, twelve; all symptoms relieved, tumor small, seventeen; all symptoms relieved, no appreciable tumor, fifty-three; recent cases, too recent to classify, fourteen. The disadvantages of radium as a treatment are: To the patient, some slight nausea in about five per cent of the cases; to the surgeon, the fear of overlooking a possible carcinoma. The advantages he claims are: Its safety; no loss of patient's time in treatment or convalescence; less expense; patients are in better general health than after operation; radium can be used where operative mortality would be high, as in chronic nephritis, diabetes, severe anemias, heart lesions, or tuberculosis.

Physiological Action of Iodine Fumes.—Luckhardt, Koch, Schroeder, and Weiland (*Journal of Pharmacology and Experimental Therapeutics*, March, 1920) found that iodine deposited on the skin from iodine fumes is absorbed and appears in the urine. The iodine content of the thyroid gland is greatly increased, and there is a pronounced change in the histological features of the gland which clearly indicates absorption of iodine. When iodine fumes are inhaled in the respiratory tract, the excess of iodine appears promptly in the urine and the iodine content of the thyroid gland is invariably increased. Indiscreet use of iodine fumes for inhalation leads to dyspnea, due to an inflammatory reaction in the lungs. When the fumes are inhaled in quantities greater than eighteen milligrams to the kilogram of body weight the animal dies within twenty-four hours from acute pulmonary edema. Intratracheal administration of iodine fumes leads to a temporary moderate rise in blood pressure and an acceleration and increased amplitude of the respiration. Later there occurs a more pronounced fall in the arterial pressure, followed by a partial recovery, and finally, after an interval, a quick drop in arterial pressure, with marked signs and symptoms of pulmonary edema. The respiration ceases while the heart usually shows a decided vagal inhibition. The cause of death is an acute, rapid edema involving chiefly the basal portions of the lungs.

Treatment of Bronchial Fistulæ.—Carl Eggers (*Annals of Surgery*, September, 1920) gives the following conclusions from the results obtained in the treatment of bronchial fistulæ:

1. Bronchopleural fistulæ usually close spontaneously.

2. In the few cases in which a fistula is responsible for the persistence of a chronic empyema, treatment favoring the obliteration of that cavity will result in a closure of the bronchus.

3. Bronchocutaneous fistulæ must be carefully studied and their etiology and the present condition of the lung taken into consideration.

4. As long as the fistula acts as a safety valve for intrapulmonary suppuration, it must not be interfered with.

5. Mobilization of the lung and fistula, allowing it to recede from its fixed position, is the most important factor in bringing about closure.

6. Muscle flaps are valuable to cover the bronchial sinus after the necessary preparation has taken place. They aid in the closure and obviate deformity.

7. Cauterization of the fistula should always be done very slightly, simply to destroy the epithelium, never so deep as to produce a slough.

8. In case the wound is clean, suture of the bronchus should be done.

9. In cases due to lung abscess, in which it is feared that closure of the bronchus may result in damming back of secretions with the danger of pneumonia, the bronchus should not be sutured, but a muscle flap simply laid over it, placing a drainage tube at some distance to act as a safety valve.

10. Whenever possible the operation should be done under local anesthesia.

Specific Treatment of Tuberculosis at High Elevation.—Carl Spengler (*Presse médicale*, April 24, 1920) describes the treatment with the so-called immune bodies as applied in Davos, Switzerland. During one week before the specific treatment is begun hemoglobin is administered to enhance the formation of red blood cells. Iodine with albumen by mouth or inunctions of iothion are also given. For cough and pain codeine or codeine and morphine are given by mouth, and for insomnia due to the tuberculosis poison, hypnotics such as dial, bromural, and adalin until the specific treatment has begun to benefit. The open air cure must be adapted to the individual case. Rest on the steamer chair out of doors is not continued longer than an hour or two morning and afternoon, and in the winter is ordered only on bright, sunny days. By this plan the patients gain much more weight than they do upon the arbitrary open air treatment. Anemic and anorexic patients are not put out of doors at all in the winter season at high altitudes. In cold weather all patients are put in warm beds in their own rooms in the afternoon, with the windows open. Undoubtedly many therapeutic failures at high altitudes are due to excessive open air treatment. The immune bodies or IK are given either hypodermically, by inunction, or by the mouth. One of the chief rules of administration is never to increase the dose where the patient's temperature continues to descend; in contrast to tuberculin therapy, increased

dosage is indicated only when the temperature has become stabilized or has begun to rise again. Tuberculin is dangerous except in the hands of specialists, while the immune bodies may be used by any physician without risk in all cases that are not far advanced. Increased dosage is, furthermore, employed only when local reaction from the previous amount has completely disappeared. Inunctions, when used, are given at weekly intervals, and by mouth the remedy is given two or three times a week; less caution is here required than in the hypodermic method. Excellent analgesic and curative results have been noted upon application of a 0.1 per cent. solution of IK over tuberculous ulcerations; pain and photophobia in ophthalmic involvements are also similarly relieved. Iodine with albumen is particularly indicated in scrofulosis and torpid tuberculosis. In children one or two drops and in adults five or six drops of freshly prepared tincture of iodine, diluted in a cupful of milk, are given at breakfast for two weeks, to be followed by an equal period of rest, and so on. Such medication should be applied *en masse* in schools and among children showing signs of tuberculous heredity or incipient tuberculosis. Iothion inunctions—0.5 to one gram a day—are administered, like mercury, on different surfaces of the body, in fortnightly courses followed by rest for an equal period. By this plan of treatment permanent recoveries are obtained in ninety to 150 days in many cases of tuberculosis not yet too far advanced. Artificial pneumothorax and extrapleural thoracoplasty are indicated only in cases in which specific immunizing therapy has failed, and cannot prove successful unless there is mobilization from the thorax, i. e., collapse of the lung, and also autoimmunization due to the lung collapse. Specific therapy and iodine with albumen should always precede such measures in order to improve the condition of the lung tissues and increase their ability to undergo atelectasis.

Mode of Administration of Antitoxin in Diphtheria.—Weill-Hallé (*Bulletins et mémoires de la Société médicale des hôpitaux de Paris*, January 29, 1920) recommends the intramuscular route as a regular method of antitoxin administration in diphtheria. Injections thus given are better borne than subcutaneous injections, causing none of the sharp and persistent local pain induced by the latter. On the other hand, they are much more easily administered than intravenous injections. The action is more rapid than upon subcutaneous use. Maximum concentration in the blood is obtained in from twenty-four to forty-eight hours, whereas subcutaneous administration yields the maximum concentration only after two or three days. In the majority of cases the dosage used is 250 units to the kilogram of body weight in mild cases and 500 to 600 units in moderately severe and severe cases. A single, massive injection of the entire amount indicated is given. Sometimes the dose is made even slightly larger in order to make good any possible deficiency in the quality of the serum. By this procedure the total amount of antitoxin used is reduced as compared to that employed in the repeated injection method, and the clinical results obtained have been satisfactory.

Miscellany from Home and Foreign Journals

Acute Mania Associated with Plasmodium Vivax Infection.—Haughwout, Lantin, and Fernandez (*Philippine Journal of Science*, December, 1919) report the case of a Filipino, aged nineteen years, who was being experimentally treated with x rays for splenomegaly of malarial origin, and in whom, eight days after the first irradiation, severe mental disturbance occurred and was followed by death after eight more days. Few cases had been previously recorded in which *Plasmodium vivax* infection was associated with cerebral symptoms and death. In this patient the parasites were present in the peripheral circulation in small numbers only and the temperature at no time rose above 39° C.—a point reached a few hours before death. The feces revealed ankylostoma infection. The delirium was preceded for a short time only by restlessness. The eyes then became bloodshot and delirium so noisy and violent that the patient had to be tied in bed. He bit both tongue and lips and spat bloody saliva upon all who came near him. He refused all food and medicine, and his general condition declined very rapidly. Fairly numerous, characteristic trophozoites of *Plasmodium vivax* were found in the peripheral blood. Intramuscular injections of quinine and urea failed to yield any benefit save disappearance of the parasites from the peripheral blood. The patient gave no history of previous attacks of mania and the necropsy failed to disclose any evidence of syphilis. Pais's belief that new generations of the malarial parasite appear to show exalted virulence under the influence of the x rays is offered as a possible explanation of the symptoms in this case. Yet, the parasites never were in the circulation in large numbers and hyperpyrexia never developed.

Acquired Immunity Following Influenza.—Dopter (*Bulletin de l'Académie de médecine*, May 4, 1920) relates that the division to which he was attached in April, 1918, was among the first to be affected by influenza, nearly all the infantry and engineers contracting a mild form of the disease, unaccompanied by pulmonary or other complications. By the close of the month of May the epidemic among these troops had completely ceased. During this time few cases of the disease developed in the field artillery regiment in the same division, but in August it was joined by a group of heavy artillery which brought influenza along with it, and soon the field artillery fell a prey to the infection. At this time the infection was particularly severe in the men who had been spared in the earlier epidemic. Very few of the men previously ill contracted the disease. In the battery most severely involved, the only men remaining healthy were the few who had had the disease in the earlier epidemic. During the severe infection among the artillery, moreover, the infantry and engineers, although necessarily in frequent contact with the artillery regiment, remained unaffected. Finally, about the middle of September, fresh troops joined the division for an attack, all derived from formations

subject at the time to a severe epidemic of influenza. These troops continued to exhibit severe influenzal manifestations in their new assignment, but the original divisional infantry and engineers, who had already gone through the disease in May, remained practically unscathed, only a very few mild cases occurring among them. Recurrences occurred only in the small ratio of 1.6 per cent. These observations constitute important evidence in favor of an acquired immunity following an initial attack of influenza.

Lethal Aspects of Artillery Fire.—R. Mercier (*Bulletin de l'Académie de médecine*, April 20, 1920) presents a statistical study of this question based on five months' continuous observation on three French army fronts during the year 1917. One army, holding a quiet sector, was subjected to the effects of 363,000 German shells—exclusive of gas shells—and suffered casualties of 809 killed and 4,168 wounded, or 0.2 killed and 1.03 wounded per 100 shells. Another army, holding a somewhat more active sector, received 717,000 shells, with 2,753 killed and 10,756 wounded, or 0.38 killed and 1.50 wounded per 100 shells. A third army, in an attacking sector, received 2,529,000 shells, with 9,703 killed and 40,488 wounded, or 0.38 killed and 1.60 wounded per 100 shells. Even during the victorious offensive of this same army, deducting losses due to small arms, the proportion of casualties per 100 German shells was only 0.45 killed and 2.33 wounded. In one of the five test months, account was taken of the different varieties of enemy artillery causing the casualties. During this time four-fifths of the projectiles fired were found to be from the German heavy artillery. The final conclusion reached was that during the summer and fall of 1917 it took 395 German shells to kill and seventy-six shells to wound one French soldier. Knowing the density of the opposed forces and the fact that the French fire was five times as heavy as the German, the French commanders were able to deduce accurately the rate of reduction of the enemy's divisions.

Blood Pressure and the Gallop Rhythm.—A. Amblard (*Presse médicale*, May 1, 1920) discusses in particular the mesosystolic gallop rhythm occurring in infectious diseases, in which the adventitious third sound is mesosystolic in time, and the diastolic or presystolic gallop rhythm noted in patients with combined cardiac and high pressure arterial disease. Concurrent study of the blood pressure and pulse in these cases shows that, however different may be the apparent origin and the classes of cases in which these two forms of gallop rhythm occur, they both set in at a special stage of the disturbance, viz., the moment at which the heart is about to yield. Their appearance is accompanied by a rise in arterial pressure and their disappearance by a reduction in the systolic pressure and the increase of tachycardia necessitated by diminished contractile power of the ventricle. Both types are of considerable prognostic value and afford definite therapeutic indications.

In the mesosystolic gallop rhythm there is no true, continuous arterial hypertension, but instead a weakening of heart action which indicates the use of phosphorus, strychnine, and sparteine. The presystolic gallop rhythm occurs in cases of permanent high tension, and the appropriate therapeutic measures are purgation, diuretics, venesection, and dietetic regulation. In these cases, however, the cardiac insufficiency of which the gallop rhythm is a forerunner must also be combatted through absolute rest in recumbency and digitalis. When intelligently used, digitalis does not raise the blood pressure in hypertension cases. Its administration should be begun as soon as the exercise test brings on an incipient presystolic gallop rhythm perceptible upon auscultation or palpation.

Friedländer Pneuropneumonia with Fetid Rhinitis and Jaundice.—C. Flandin and M. Debray (*Bulletins et mémoires de la Société médicale des hôpitaux de Paris*, January 29, 1920) report the case of a woman, aged forty years, who was suddenly seized with sharp pain in the side and a chill, followed by fever and cough. Pleurisy was suspected, but repeated punctures were negative. On the eleventh day, after defervescence, signs of pneumonia appeared, persisting for over twenty days thereafter. A series of febrile movements gave the case the appearance of subacute illness. There was also ozena from the start, and a varying degree of jaundice. In view of the bloody sputum, infection by the pneumobacillus of Friedländer was suspected, and this was confirmed by microscopic study. The condition is believed to have been a Friedländer septicemia, beginning in the nose, mainly localized in one pulmonary lobe, with extension to the biliary tract, causing infectious jaundice. Recovery took place in one month, in spite of a mitral lesion.

Leptospira Icteroides and Yellow Fever.—Hideyo Noguchi (*Proceedings of the National Academy of Sciences*, March, 1920) notes that in the course of studies conducted in Guayaquil, Ecuador, he was able to detect in certain cases of yellow fever a special spiral organism subsequently termed *Leptospira icteroides*. Guinea pigs and puppies, inoculated with the blood of yellow fever patients or with cultures, present symptoms and lesions closely approximating those of yellow fever in man. The outstanding signs are jaundice, hemorrhage into the lungs and stomach, and albumin and casts in the urine. At autopsy, as in man, the liver, kidneys, and other internal organs are found severely degenerated. The spiral organisms are recoverable from the inoculated guinea pigs, and with them the disease is transmissible through an indefinite series of animals. Furthermore, guinea pigs have been successfully infected with the spiral organisms by means of *Stegomyia* mosquitoes, and *Stegomyias* fed on infected guinea pigs are capable of transmitting the active microbe to still other guinea pigs. Immunological studies indicated the possibility of developing a vaccine and even a curative serum. But until the finding of *Leptospira icteroides* is confirmed by the investigation of cases of yellow fever in still other places, its standing as the inciting agent of yellow fever will have to be regarded as not yet certainly established.

Yellow Fever.—Hideyo Noguchi (*Journal of Experimental Medicine*, February, 1920) used polyvalent immune serum of high potency in treating guinea pigs experimentally infected with *Leptospira icteroides*. When the serum was injected during the time of incubation it prevented further development of the infection. Used in the early stages, it appears to be capable of averting an early termination of the disease, but if it is employed when the guinea pigs are inoculated with a highly virulent culture when the jaundice has existed for some time and the animal is nearing collapse, it is unable to check the course of the infection. Noguchi states that irrespective of the relation which *Leptospira icteroides* may prove to have to the etiology of yellow fever, such patients will probably have little or no chance of deriving benefit from the use of a specific immune serum, when the temperature is subnormal, and the stage of hemorrhages from the gums, nose, stomach, and intestines, with uremia and cholemia, has been reached.

Sulphur Metabolism in the Cancerous Liver.—A. Robin and A. Bournigault (*Bulletin de l'Académie de médecine*, February 24, 1920) found that the least involved portions of the cancerous liver contain about twenty per cent. more of total sulphur than the portions most diseased. These and other estimations tend to show that cancer tissue is built up with much less sulphur than normal liver tissue, and also that the sulphur in the cancerous liver tends to accumulate in the least involved portions of the organ. The ratio of sulphur to dried proteins is much less in cancerous liver tissue than in the uninvolved portions and in normal liver tissue. The accumulation of sulphur in the least involved portions seems to be due to a special mode of disintegration of proteins, this process—preparatory to cancerization—involving the liberation of only certain ones among the aminoacids of the protein molecule in the as yet uninvolved tissues. These special aminoacids are the hexone bases, already found in excessive amounts in cancer tissue by R. A. Kocher, while the sulphur containing cystein remains unaffected. A contrast to this condition is seen in tuberculous tissue in which the sulphur in the least affected portions of the lungs is 16.3 per cent. less than in the most affected portions, and 20.8 per cent. less than in normal lung tissue. Different from the cancer ferment, the tubercle bacillus disintegrates all proteins of the lung tissue, including cystein, and constructs the tuberculous tissue from the débris—another argument against the parasitic theory of cancer. The marked relative increase of sulphuric sulphur, i. e., sulphur oxidized to sulphuric acid, in the most involved portions of the cancerous liver may be considered an indication of a defensive, oxidizing reaction against the noxious aromatic products formed through disintegration of the cancerous tissue. This particular type of defensive reaction does not occur in tuberculous tissue. The study as a whole points to the existence of a dissociating ferment that acts in a special manner upon the proteins of the tissues in which cancer is subsequently to develop. New problems to be solved in the chemotherapy of cancer are thus suggested.

Proceedings of National and Local Societies

AMERICAN ASSOCIATION OF OBSTETRICIANS, GYNECOLOGISTS, AND ABDOMINAL SURGEONS.

Thirty-third Annual Meeting, Held at Atlantic City, N. J., September 20, 21, and 22, 1920.

The President, Dr. GEORGE W. CRILE, in the Chair.

(Continued from page 744.)

Pseudocholecystitis.—Dr. HAROLD D. MEEKER, of New York, drew the following conclusions: 1. The occurrence of adventitious bands in the upper abdomen had been established beyond question. 2. These bands gave rise to definite symptoms. 3. The gallbladder was the viscous most frequently involved; the resulting symptoms simulated a cholecystitis. 4. Plastic surgery had given definite relief. As complete freedom from symptoms had been recorded ten years after operation, it was reasonable to suppose relief might be permanent. 5. It was illogical and unfair to patients to withhold a chance of relief because the origin of these bands might not yet have been definitely established. 6. The frequency with which adventitious bands in other parts of the abdomen coexisted with those of the upper abdomen, emphasized the importance of a thorough search of the entire gastrointestinal tract for abnormal bands and fixed points. 7. It was to be hoped that a comprehensive discussion of these bands would be found in the surgical textbooks of the near future. A knowledge of the condition would be the means of restoring to a life of comfort many individuals otherwise condemned to continued suffering.

Results of Double Flap Low Cæsarean Section.

—Dr. THURSTON SCOTT WELTON, of Brooklyn, N. Y., stated that as a result of the findings in this series of a total of fifty-five cases, he had reached the following conclusions: 1. The double flaps and low incision offered great protection against extension of infection to the peritoneum from an infected uterus. 2. As a result this should be the operation of choice in all potentially infected cases. 3. This fact, also, should extend the field for Cæsarean section to include such patients as had been long in labor with the membranes ruptured and potentially infected from frequent vaginal manipulation in which most men would elect to do a craniotomy on a living child rather than do a classical section. 4. The double flaps, likewise, so completely peritonealized the uterine wound that adhesions and postoperative disturbances were greatly minimized. 5. From the results obtained and the reasons given, the two flap low Cæsarean section should be the operation of choice even in elective cases.

A Preliminary Report of Pyelitis in Pregnancy with Report of Cases.—Dr. GREER BAUGHMAN, of Richmond, Va., reported three cases of pyelitis complicating pregnancy. He showed lantern slides and charts and pyelograms indicating the progress of the cases. All the patients were treated with pelvic lavage. Living babies were born to the two

patients in whom labor was induced at a selected time, while in the patient who entered labor before the time set for the induction of labor, the child died. With the exception of a few treatments, the patients after the first reaction showed marked improvement in symptoms. In all the patients the right pelvis was primarily involved; in two the bladder was involved early, in the other the bladder signs were not prominent. Bacillus coli was the exciting cause of two; staphylococcus albus of the other. In all the cases the curve representing the right and left pelvic sizes were parallel. A marked improvement was noted in all symptoms, pelvic size, and urinary findings following delivery, showing that the obstruction did take place from the uterus and its contents. It was found possible to irrigate all of these patients within two weeks after the time of their delivery; in none was there any rise in temperature during the puerperium.

Borderline Carcinoma of the Cervix and Its Treatment.—Dr. EDWARD A. WEISS, of Pittsburgh, Pa., said that when a diagnosis of cancer of the cervix had been made, appropriate treatment should be given at the earliest possible moment, nevertheless haste in operating was not always advisable. He had found from practical experience that preliminary preoperative rest in bed for several days resulted in a marked diminution in the size of the diseased cervix, but more important still there was often noticed a decided decrease in the thickening and fixation of the broad ligaments, proving that the fixation was inflammatory rather than a malignant invasion of the lymphatics of the broad ligaments. As a result of this observation he had frequently found that the supposedly inoperable case was really operable or borderline. During the period of rest in bed, more careful study of the patient's resistance could be made, and should radical treatment follow, the condition of the patient was greatly improved and offered a better operative risk.

In the borderline cases, the improved Byrne cautery technic, which was practically the first stage of the Werder radical igniextirpation, had given him the best results in many years, and while only a few so-called permanent or five year cures were obtained, yet he had had several instances of complete freedom from symptoms for periods of from three to five years. In thirty-eight borderline cases so treated, there was recurrence with death in one case at six months; two in nine months; five in twelve months; five in eighteen months; eight in two years; five in two and a half years; two in three years; three in three and a half years; two in four years; one in five years, and four were not to be traced after the first year. In this series one death resulted on the fourth day from embolism.

The results obtained by Dr. Weiss with radium in a series of advanced or inoperable cases were so striking, that a series of forty-five borderline or Group IV. cases, radium instead of the cautery was used, and while the results were disappointing

in some instances, he was forced to admit, after taking all factors into consideration, that in a small series radium had proved to be a most valuable adjunct, both as to immediate and remote results. To say that radium used in the cervix was a harmless procedure was not in accordance with facts and its indiscriminate use would bring discredit to a very valuable adjunct in gynecological therapy. In using the cautery in the treatment of borderline cancer, a clear distinction must be made between the so-called Percy cauterization and high amputation by the cautery. In the former the cervix was not removed, but a deep charring resulted which was often followed by fistula formation and severe constitutional reaction. The subsequent use of radium would not only be of little value, but would increase the tendency to fistula. Cancer of the cervix was still to be classed as an operative condition when discovered early and the patient a good risk. When a doubtful borderline condition was presented treatment by radium was advisable and the question of subsequent operation should be decided by the reaction obtained; but if the operation was contraindicated by age, general condition, heart, kidney, or blood vessels, radium alone should be used.

Splenic Leucemia Associated with Pregnancy.

—Dr. GEORGE W. KOSMAK, of New York, stated that a survey of the reported cases of leucemia complicating pregnancy in which a fairly definite diagnosis from the blood picture was made, disclosed a total of twelve, including two of his cases. The ages of the patient varied from twenty-four to forty, the majority being between thirty-two and thirty-six. With the exception of Peterson's case all were multiparæ. A possible hereditary history was mentioned in only one case. The parity varied from three to nine. In most of the cases he got a history of living children that showed no tendency to the disease up to the time of the report, but in a few instances he was told that the babies died at varying periods after labor, from a few days to five months. In four cases mention was made of the birth of macerated or stillborn fetuses. Among these twelve cases the mother survived in but two, but how long these mothers lived was not stated, nor the subsequent course of the disease. In the majority of cases he found that the woman survived, but a short time after labor. One of his patients died before delivery took place. In Peterson's case, death came on an hour after labor, in Hilbert's case, ten hours, and in Laubenburg's, forty hours after labor. There was a record of death in Stillman's case one month after delivery, in his second case death occurred in two weeks, and in Jaggard's case in eleven months after delivery. In every instance but one (his own case), in which the definite diagnosis was presented the splenomedullary type of the disease was observed. It would be noted that in many cases the authors mentioned a prodromal period in which progressive emaciation, anemia and loss of strength were noted soon after a pregnancy, from which no recovery resulted, and during which period the woman again became pregnant. The leucemia itself did not, therefore, appear to be a deterrent factor to conception.

Although the presence of a true leucemia as a complication of pregnancy was from all available records a very rare condition, nevertheless, one ought to be on his guard against it. Probably a considerable number of cases of marked anemia in which no satisfactory blood count had been made might have been true instances of this disease. In any case where an anemic patient failed to recover under proper treatment, a more minute and detailed examination of her blood should be made with reference to the possible diagnosis of leucemia. The occurrence of pregnancy in this disease indicated a most unfavorable outlook for the mother and conception must therefore not be allowed to take place where the condition was suspected. The prognosis was undoubtedly worse in the pregnant than in the nonpregnant and whether the association was accidental or not was immaterial. Where the disease was already present abortion seemed to be the rule, with a rapidly progressing course and a fatal issue. The presence of an enlarged spleen was an almost constant factor in the disease and should lead one to look for this sign in every anemic patient. The value of the x rays in leucemia had been brought forward, but in the event of a pregnancy its application, as a cure for the disease, might work an undoubted harm on the fetus and the induction of labor should be done before radiation was begun.

It was necessary to distinguish between the acute and chronic forms of leucemia. Pregnant women might contract a rapidly fatal leucemia if the evidence of the cases thus far reported, was to be believed, although it seemed possible that the disease was present in a milder form in many of these patients before their last and usually fatal pregnancy occurred. It would be noted that there were apparently, cases of chronic leucemia in this series in which pregnancy and labor occurred, and for this reason conservative treatment had been advised under such circumstances. In view of the rapidly fatal ending during the puerperium it would appear that this advice was not justifiable and that in order to avoid such an outcome labor had better be induced in all cases.

Benign Mammary Tumors and Interstitial Toxemia.—Dr. WILLIAM SEAMAN BAINBRIDGE, of New York, reported a series of twenty-five cases of abnormal mammary changes apparently caused by autointoxication. Each of the patients who suffered from abnormal breast conditions had in addition to the breast changes, coexistent chronic intestinal toxemia, the mammary gland frequently registering the degree of toxic poisoning. He divided the cases roughly into three classes: 1. Patients with a condensation or lobulated induration of the upper, outer quadrant of the breasts, usually along the edge of the large pectoral muscle and where the dependent breast dragged on the upper axillary margin. These were lumpy, toxic, or stasis breasts. 2. Patients with breast changes as in Class I but with the added condition of localized degeneration of the mammary gland, such as adenomata or cysts. 3. Patients with breast changes as in Classes I or II and in conjunction an abnormal discharge from the nipples.

The majority of the cases were in patients with marked intestinal toxemia; a few had complicating pelvic conditions. 1. Patients cured with medical measures, five; patients cured by surgical relief of the chronic intestinal stasis and without operation on the mammae, fifteen; patients cured after operation for adenoma or cystoma and for the intestinal stasis, the remaining indurated, lobulated portion of the breast returning to a normal condition, one; patients cured by the removal of an adenoma or cystoma from a toxic breast, and by preliminary and aftertreatment for the intestinal toxemia, three, and patients from which stasis breasts were removed, the underlying intestinal toxemia not being recognized, one. Dr. Bainbridge presented the following conclusions: 1. There are definite abnormal conditions of the breast tissue due to intestinal toxemia. As the thyroid gland is changed by toxemia, so the mammary gland may be altered completely by chronic intestinal stasis. 2. Under medical treatment an appreciable number of these patients with abnormal breast conditions are cured. A proper uplifting abdominal corset applied for enteroptosis, a careful diet, catharsis, breast supports for dependent organs, digestants, intestinal antiseptics, and certain physiotherapeutic agents are among the corrective measures which often cause even well defined tumors of the breast to disappear. Any element which tends to diminish the gastrointestinal fermentation is of value. A preliminary lessening of the general toxic condition of the patient materially aids the surgeon in determining the true benign neoplasm and saves a considerable amount of recoverable breast tissue too often unnecessarily sacrificed. 3. Surgical procedures frequently are required for the correction of the intestinal stasis and the removal of the cystoma or the adenoma before the indurated, lobulated tissue resumes a healthy gland condition and the breast is brought back to normal. 4. When these toxic cases are seen early the beginning changes in the breast are often overlooked, or, when the condition is well developed, the incorrect diagnosis of malignancy is made. One question naturally forces itself upon the profession in this connection: Would an early recognition of the toxic breast and the timely and efficient treatment of the underlying cause tend to lessen the danger of malignant degeneration of the mammary gland and thereby render unnecessary much of the mutilation of the human breast?

Cases of Thrombophlebitis During the Puerperium Following Influenza.—Dr. LEWIS F. SMEAD, of Toledo, Ohio, said that the present interest in septic, puerperal, pelvic thrombophlebitis dated from a paper by Trendelenburg in 1902. The condition was not infrequent in the puerperium, because of the slowed blood current and the opportunities for infection. The disease consisted usually of a streptococcus infection, entering, as a rule, through the placental site, extending by the ovarian and uterine veins, and resulting in pyemia and death in about fifty per cent. of the cases. The acute cases were rapidly fatal, but in the subacute cases the prognosis was better. The disease was marked by a sudden fluctuating temperature, severe chills, a relatively low pulse rate, and a prolonged course

of the disease. A sharply defined, painless, slightly tender, cordlike induration in the region of the pelvic veins could be made out sooner or later. The results of the blood cultures were uncertain. A striking feature was the surprisingly good condition of the patient between the rigors.

The diagnosis of pelvic thrombophlebitis was fairly accurate. Differentiation must be made from septicemia, pelvic lymphangitis, uterine infection, and thrombophlebitis in other vessels. The operative mortality was undoubtedly somewhat lower than the nonoperative. The indications for operation were hard to define, but in cases with septicemia, metastatic foci, and vena cava involvement, operation was not impossible. Prophylaxis consisted of intelligent obstetrics, careful asepsis, complete evacuation of the uterus, and good drainage, with a minimum amount of traumatism and hemorrhage. The circulation in the puerperium was kept active by good food, fresh air, early rising, and heart stimulation if necessary.

The nonsurgical treatment consisted of general supportive measures with the avoidance of anything which might dislodge a thrombus, such as, douches, enemata, and pelvic examinations. Vaccine and serum treatment had been disappointing. The surgical treatment consisted in the ligation or excision of the involved veins by the transabdominal route and by the drainage of perivascular abscesses. Opinion upon the question of surgical intervention in pelvic thrombophlebitis was still divided, but all agreed that great conservatism must govern the choice of cases and the decision for operation.

Fibroma of the Ovary.—Dr. EDMUND D. CLARK and WILLIAM E. GABE, of Indianapolis, Ind., presented the following conclusions: 1. Ovarian fibromata are sufficiently rare to warrant their report in all carefully studied cases. 2. The diagnosis is dependent solely on microscopic examination. 3. In the presence of a hard, unilateral, movable tumor with ascites, where the more common causes of ascites can be ruled out, ovarian fibroma is highly probable. 4. The treatment is operation; the prognosis good. 5. The gross pathology of the condition is extremely variable; the microscopic pathology, as pointed out by Hellman, must show regularity of the individual fibres or muscular cells and strands, despite varying quantities of cells, fibres, vessels and degenerative changes.

Indications for Hysterectomy.—Dr. JAMES F. BALDWIN, of Columbus, Ohio, states that very many women suffered from chronic uterine hyperplasia, frequently complicated with laceration of the cervix, retroversion, a tendency to procidentia, with leucorrhœa, dyspareunia, sterility, backache, and general ill health. In this type of disease no treatment effected a cure, and little could be accomplished in palliation. Other women suffered from imperfect development of the uterus, with sterility, painful menstruation and other disturbances. The paper was a plea for the radical cure of these two classes of cases by hysterectomy, but with saving of appendages so as to obviate the symptoms of the menopause, except as to the absence of menstruation.

(To be concluded.)

THE UNCONSCIOUS.

By W. H. R. RIVERS, M. D., LL. D., F. R. S.,
Cambridge, England.

The concept of the unconscious in psychology is one which has aroused the liveliest differences of opinion and has been met by bitter opposition. Even those who are ready to accept the vast influence of unconscious factors in psychology may well be appalled by the difficulties of treating the unconscious in a scientific manner and fitting so necessarily hypothetical a factor into the explanation of behavior. One line of opposition has come from advocates of the older introspective school of psychologists who have found it difficult to fit an unconscious region of the mind into their schemes of description and explanation. The aim of the older psychology was to furnish a rational explanation of human behavior and endeavor. As the material for such explanation they used almost exclusively the happenings in their own minds which could be directly, though really only retrospectively, observed, and made this material the basis of constructions whereby they fitted into coherent schemes the infinitely varied experience of the human mind. When their introspective method failed them, and they were driven to assume the existence of factors lying outside those accessible to introspection, they were accustomed to assume subconscious processes or to speak of psychological dispositions and tendencies, or they would even throw psychology wholly aside, bringing into their schemes of explanation factors belonging to the wholly different order of the material world, and used physiological processes as links in the chain whereby they connected one psychological happening with another.

It is noteworthy that the due recognition of the importance of the unconscious and the first comprehensive attempt to formulate a scheme of its organization and of the mechanisms by which it is brought into relation with the conscious, should have come from those whose business it is to deal with the morbid aspect of the human mind. The necessity for the use of unconscious factors continually arises when dealing with the experience of health, but the opportunities afforded by such experience are usually so fleeting, and the experience itself often so apparently trivial, that they failed to force the psychologists of the normal to face the situation. It was only when unconscious experience had contributed to wreck a life or produce a

state with which the physician had to struggle, and then often ineffectually, for months or years, that it became impossible to push such experience aside or take any other line than that involved in the full recognition of its existence. It is only the urgent and inevitable needs of the sick that have driven the physician into the full recognition of the unconscious, while it has needed the vast scale on which nervous and mental disorders have been produced in the war to force this recognition upon more than the few specialists to whom it had been previously confined.

In entering upon an attempt to make clear the sense in which the term unconscious should be used, I will begin by pointing out one sense in which it will not be used. At any given moment we are only clearly conscious of the experience which is in the focus of attention. This forms only an infinitesimal proportion of the experience which is capable, by being brought into the focus of attention, of becoming conscious with an equal degree of clearness. Again, at any one moment a much larger amount of experience is within the region of the conscious though less clearly, but even the largest amount which can thus be brought within the outermost fringe of consciousness at any instant or even within any brief space of time, forms but a very small proportion of that which, with other directions of the attention, could come into the field of consciousness. At any given instant there is a vast body of experience which is not in consciousness only because at that instant it is neither the object of attention nor so connected therewith as to occupy consciousness with more or less clearness at the same time. Experience of this kind will not be included within the unconscious as I shall use the term. In so far as the term the unconscious applies to experience it will be limited to such as is not capable of being brought into the field of consciousness by any of the ordinary processes of memory or association, but can only be recalled under certain special conditions, such as sleep, hypnotism, the method of free association, and certain pathological states.

A good instance of the unconscious is afforded by the conditions underlying the claustrophobia of a sufferer from war neurosis. For as long as he could remember this patient had been subject to a dread of confined spaces so severe and producing states so painful and unendurable that he was debarred from taking part in many of the ordinary

occupations of life, or could do so only at the risk of suffering and discomfort. When I first saw him his earliest memory of the dread went back to the time when at the age of six he slept with his elder brother in what is known in Scotland as a box bed. The bed stood in a recess with doors which could be closed so as to give the appearance of a sitting room. The child slept on the inner side of the bed next to the wall, and he still vividly remembers his fear and the desire to get out of bed, which he did not satisfy for fear of waking his brother. He would lie in a state of terror, wondering if he would be able to get out if the need arose.

The next memory bearing on his phobia is of being taken to see some men descending the shaft of a coal pit. There came to him at once the fear that were he going down something might happen to prevent his getting out. Whenever he was taken in childhood for a journey by train he dreaded the tunnels, and if by chance the train stopped in a tunnel he feared that there might be an accident and that he would not be able to get out. This fear of tunnels became worse as he grew older. When he began to go to the theatre or other crowded building he was always troubled unless he was near the door, and he was never happy unless he could see a clear and speedy mode of exit. He would not travel by the tube railway, and vividly remembers his horror when on one occasion he had to do so. As long as he can recollect he has felt an intense sympathy whenever he has read of prisoners being confined in a narrow cell, and he has always been greatly disturbed by tales of burial alive.

When during the war he went to France as a doctor, he was greatly disturbed by having to live and work in dugouts and would seek excuses to go to the trenches in order to escape from experiences which were to him far more trying than the dangers of the front line. As a result of the strain he broke down and some time later came under my care. In obtaining his history I found that he had been through a course of psychoanalysis of a very crude kind and had for years been seeking some event of childhood which could explain his dreads. We then started on a new attempt in this direction. I asked him to remember as fully as possible his dreams and to record any memories which came into his mind while thinking over the dreams. A few days later he related a dream which I do not purpose to consider here, because it does not directly concern the claustrophobia. Its interest from the present point of view is that in thinking over the dream there had come into his mind an incident going back to the age of six which had, so far as he knew, gone completely out of his mind for many years. Taking the dream and memory as a starting point, he was led on to recall two other incidents of this time, one of which seemed to be definitely related to the dream. All three incidents had been completely forgotten till recalled on this occasion, though they were all associated with a strong emotional tone and had affected him greatly at the time. None of them seemed to have any relation to the claustrophobia, but they were very useful in demonstrating to the patient the value of analyzing dreams, and in showing him that the method, if

persevered in, might lead to something more obviously related to his symptoms.

Three nights later he had another dream. As he lay in bed thinking over the dream, there came into his mind an incident dating back to three or four years of age which had so greatly affected him at the time that it now seemed to the patient almost incredible that it could ever have gone out of his mind, and yet it had so completely gone from his manifest memory that all his attempts at analysis prolonged over years had failed to resuscitate it. The incident was of a kind which convinced him at once that the long sought memory had been found.

The incident which he remembered was a visit to an old rag and bone merchant who lived near the house which his parents then occupied. This old man was in the habit of giving boys a small reward when they took to him anything of value. The child had found something and had taken it alone to the house of the old man. He had been admitted through a dark narrow passage, from which he entered the house by a turning about half way along the passage. At the end of the passage was a brown spaniel. Having received his reward the child came out alone to find the door shut. He was too small to open the door, and the dog at the other end of the passage began to growl. The child was terrified. His state of terror came back to him vividly as the incident returned to his mind after all the years of oblivion in which it had lain.

Ten days later the patient dreamed that he visited Edinburgh for the purpose of taking the diploma in psychological medicine. As he lay in bed thinking over his dream and its possible antecedents, he found that he was saying to himself over and over again the name "McCann." He could not at first remember that he knew anyone so called, but it suddenly flashed on his mind that it was the name of the old rag and bone merchant in whose house he had been terrified.

One thing was needed to make the story complete. It seemed possible that these thoughts, recalled in consequence of thinking over dreams, might be purely fictitious. It might be that in his intense desire to find some experience of childhood which would explain his dread the patient might have dreamed, or thought of, purely imaginary incidents which had been mistaken for real memories. Luckily the patient's parents are still alive, and on inquiry from them it was learned that an old rag and bone merchant had lived in the neighborhood in such a house as the patient remembered and that his name was McCann. Until they were told some twenty-seven years later they had no idea that their child knew anything of the old man or had ever entered his house.

The recovery of his long forgotten fright was followed by a remarkable improvement in his specific dread. A few days after recalling the memory he sat without disturbance in the middle of a crowded moving picture house under conditions which for years before would have given him the most serious discomfort and dread. The patient was so confident that he wished me to lock him in some subterranean chamber of the hospital, but I need hardly say that I declined to put him to

any such heroic test. He has since traveled in the tube railway with no discomfort whatever, so that the ordinary conditions which had brought his phobia into activity for many years no longer have this effect. He has even been down a coal mine, which was especially the object of his former dread, and went more than a mile along narrow passages beneath the ground, the mere thought of which would once have made him shrink in horror. A striking sequel of the recovery of his infantile memory is that terrifying dreams of being unable to escape from enclosed spaces from which he formerly suffered now trouble him no longer, and he had a dream in which he found himself in a narrow cell in the company of a bloodhound, and was amazed in the dream that he should be so happy and comfortable in this situation. We have here a typical example of the kind of experience I have in mind when I speak of the unconscious. We have no direct evidence that the incident has been wholly unconscious during childhood, but owing to his prolonged search for such experience at a later period of life, and its total failure to appear in consciousness, we have the most decisive evidence that an arresting experience, one accompanied by an emotional state of the most poignant kind, can lie dormant and evade the most searching attempts to bring it into the field of consciousness. When it was at last brought to consciousness, this did not happen through any association of waking life but came in the semiwaking state following a dream. Its coming to consciousness occurred in definite connection with an experience of sleep which we know to furnish conditions especially favorable to emergence from the unconscious.

This patient not only affords conclusive evidence for the existence of experience shut off from consciousness under ordinary conditions, but his case shows that this experience, though inaccessible to consciousness directly, may yet be capable of affecting it indirectly. His dread of confined spaces had so definite a relation to the early experience that the two were undoubtedly connected, while the complete disappearance of his claustrophobia after bringing the long dormant experience to the surface affords further, though standing alone not necessarily conclusive, evidence in the same direction.

Psychological literature contains many similar histories. I take this case of claustrophobia as an example, partly because, having come under my own notice, I am able to estimate its trustworthiness. Still more important is the fact that it was possible to obtain conclusive evidence that the infantile experience had really occurred, and was neither the fancy of the patient nor the result of suggestion on the part of the physician, the latter possibility being especially present when a supposed experience of childhood is discovered by means of hypnotism.

The records of others can never, however, carry the conviction which comes from one's own experience, even though such experience can rarely have the dramatic and conclusive character of that I have just cited. One who wishes to satisfy himself whether or no unconscious experience exists should

subject his own life history to the severest scrutiny, either aided by another in a course of psychoanalysis or, though less satisfactory and less likely to convince, by a process of selfanalysis. It will perhaps be instructive if I give a result of my own selfanalysis, which though at present incomplete, has done much to convince me of the reality of the unconscious.

I am one of those persons whose normal waking life is almost wholly free from sensory imagery, either visual, auditory, tactile or of any other kind. Through the experience of dreams, of the half waking, half sleeping state, and of slight delirium in fever, I am quite familiar with imagery, especially of a visual kind, which, so far as I can tell, corresponds with that of the normal experience of others. I am able to recognize also that in the fully waking state I have imagery of the same order, but in general it is so faint and fragmentary that the closest scrutiny is required for its detection. It is clear to me that if it were not for my special knowledge and interest I should be wholly ignorant of its existence. On looking back in my life I am aware that my mental imagery was more definite in youth, and I can remember the presence at that period of fairly vivid visual imagery in connection with certain kinds of experience, especially of an emotional kind.

Some years ago, as part of an examination into my memories of childhood, I discovered that I had a more definite knowledge of the topography of the house I left at the age of five than of any of the many houses I have lived in since. I can make a plan of that house far more detailed, based on memories clearer to myself, than I can make of houses in which I have lived far longer and at times of life when one might expect more permanent and vivid memories. Moreover, I can even now obtain visual images of the early house more clear and definite than any I usually experience, while other memories of my first five years of life bring with them imagery more definite than accompany the memories of later years. I have concluded that before the age of five my visual imagery was far more definite than it became later and was probably as good as that of the average child.

For some time I explained the loss of imagery of which I am the subject as part of a process by which I had become especially interested in the abstract. I supposed that my imagery had faded for lack of the attention and interest which would have kept it active, even if it had not promoted its development into the instrument which imagery has become in the mental life of the majority of human beings. It is only during the last year or two that I have discovered an aspect of my early experience which has led me to revise this earlier opinion. This discovery is that my knowledge of the house I left when five years old is strictly limited to certain parts of it and that the rest is even more inaccessible to memory than any of the houses in which I have lived since. So far as I remember the house had three floors. I can remember, and even now image fairly vividly, every room, passage and doorway of the ground floor. I can in imagination

go down stairs into a kitchen in a basement and I can go upstairs toward the upper floor, but when I reach the top of the stairs I come to the absolutely unknown, an unknown far more complete than is the case with any house occupied more recently, where I have some idea of the topography though this is inexact and vague. For more than a year I have been attempting, by means which have succeeded in evoking other early experience, to penetrate into the mysterious unknown of the upper story. Though I have recalled many incidents of my early life which took place on the ground floor, in the basement, in the regions before and behind the house, no event of any kind which happened in the upper story has ever come to my consciousness. Now and then, when in the half waking, half sleeping state peculiarly favorable in my experience to the recovery of long forgotten events, I have had the sense that something is there, lying very near emergence into consciousness. But I have not yet succeeded in penetrating the veil which separates me from all knowledge of my life in that upper story.

The evidence for the existence of unconscious experience which is provided by these memories of my infancy is, of course, incomplete in that I have not yet discovered the nature of the unconscious experience and have even no certain guarantee that it exists. The feature of the experience which impresses me—I cannot expect it to have an equal influence on others—is the completeness of the blank in my mind in connection with that upper story. I fail to explain that blank by any mechanism provided by differences in affect or interest on memory. A psychologist of the old school would probably say that we tend especially to remember the striking and unusual, and that it is therefore natural that my memories of the upper story, where I probably passed most of my life at that time, should be less vivid than those of the lower parts of the house which I visited less often. This might well explain a different degree of distinctness of memory, but it cannot explain the completeness of the blank left by the memories of the upper story. Another line which might be taken is that at any rate during the year before I left the house, I lived on the ground floor during the day and only visited the upper floor at night when tired. But even if such a reason were valid, it cannot explain the completeness of the blank. Moreover, such explanations seem to be put out of court by the fact that when I recall memories of houses lived in later, I find no such difference between upper and lower stories. Though my memories of later houses are more vague than the early memory, they are quite as definite for the upper as for the lower parts of the buildings.

The two cases I have described as examples of the experience of early life which has become inaccessible to consciousness. This period of life is especially likely to afford occasions for experiences to become unconscious, but the passing of experience into the unconscious may happen at any age, and its occurrence has been brought to notice very widely by the experience of war. One of the most frequent features of the nervous disturbances

of war has been the complete blotting out of the memories of certain events, the obliteration usually extending considerably beyond the event which furnished its special occasion. In some cases, where the loss of memory for a period of the soldier's life has been produced by physical shock accompanied by complete unconsciousness, as in cerebral concussion, the obliteration has been complete and the case does not come within the scope of the present subject, for there is no evidence that any experience exists capable of being again brought to consciousness. In many cases, however, in which the obliteration is due to mental shock or other psychical factors, the experience which is inaccessible to the consciousness of the subject under the usual conditions of memory has been recovered in the hypnotic state or by the method of free association or has expressed itself, usually in a distorted form, in dreams. In such cases soldiers have lost the entire memory of their lives from some moment preceding a shock or severe strain until they have found themselves in hospital, perhaps weeks later, although during at least part of the intervening time they may have been to all appearance fully conscious and may even have distinguished themselves by actions on the field of which they have no recollection. Although these memories may remain for months or years quite inaccessible to memory when approached by the ordinary channels, they may be brought to the surface by means of hypnosis or by the method of free association.

In a case of a somewhat different kind under my care a soldier had lost all memory of his life from a day in July when he was training in England until the following January when he found himself in hospital in Egypt, having no recollection whatever of his service in various parts of England, of the voyage to Egypt, or of his life in Egypt before going to hospital. The memory of this period was not recovered until more than a year later following the disclosure of a painful experience in his life which had a definite connection with his amnesia.

In cases such as these the loss of memory forms part of the complex group of changes which make up the state we call psychoneurosis. There is reason to believe that many of the manifestations or symptoms of this state are due to the activity of the experience which has become unconscious just as the dread of my claustrophobic patient has been ascribed to the unconscious experience of which he was the subject at the age of four. The effects which can be thus ascribed, at any rate in part, to the unconscious experience of war fall into two main groups. There are, on the one hand, general changes in personality, and changes in tastes, in likes and dislikes, in preferences and prejudices, while on the other hand, there are specific dreads or other morbid experiences of waking or sleeping life, such as nightmares, hallucinations or morbid impulses, which can be more or less directly ascribed to the activity of the unconscious experience. In such cases we have definite evidence, not merely for the existence of unconscious experience, but for its activity, or capacity for activity, in this unconscious state.

I have now attempted to make clear the sense in which we should speak of the unconscious. I have illustrated its nature by means of three kinds of example; one taken from a definitely pathological state dependent on an experience of early life; the second derived from my own history, also derived from the unconscious experience of early life, but one which may be regarded as coming within the limits of normal psychology; while the others are taken from cases of psychoneurosis in which the experience which has become unconscious is made up of the events and memories of warfare. I have now to consider how such experience becomes unconscious. I shall speak of this process as suppression. Writers on the unconscious often use repression for the process in question, but I propose to reserve this term for the process by which we wittingly endeavor to banish experience from consciousness. It seems that this process of witting repression may be one means of producing suppression, that experience wittingly repressed may, at any rate under certain conditions succeed in becoming inaccessible to the general body of consciousness. But there is little doubt that this is only one of the ways in which suppression occurs, and that more often it takes place wholly without the intervention of volition, especially when it occurs as the result of some physical or mental shock.

We are still in much uncertainty concerning the exact mechanism by which suppression occurs, but there is reason to believe that in the majority of cases it takes place without conscious effort, or according to the terminology I propose to use, unwittingly. There is even some reason to believe that suppression only follows witting repression, when conditions of some other kind favorable to suppression are present.

I propose now to compare suppression with the ordinary process of forgetting. Suppression is only one form of forgetting—a form in which the forgetting is especially complete—and light should be thrown upon the nature of suppression by a general study of the process by which we forget. Formerly psychologists were especially concerned with the process by which we remember, but they have gradually been coming to recognize that the more important problem is to discover how and why we forget. It is one of the many merits of Freud that he has thrown much light on this problem and with a wealth of examples has illustrated the complex nature of forgetting in the ordinary course of daily life. According to him forgetting is not a passive process, dependent on lack of interest and meaning, or varying with the intensity of an impression, but is an active process in which some part of the mental content is suppressed. The content which is thus suppressed does not disappear because it is uninteresting or unimportant; on the contrary, it is usually of very special interest and has a very definite meaning. It is suppressed because the interest and meaning are of a kind which arouse pain or discomfort and, if present in consciousness, would set up activities which would be painful or uncomfortable. Active forgetting is thus a protective process, one by which conscious-

ness is protected from influences which would interfere with the harmony essential to pleasure or comfort.

The examples of the unconscious which I have given are only pronounced examples of a similar process. Just as we tend to forget an appointment which seems likely to be the occasion of a quarrel or may forget to write a letter which involves the undertaking of an unpleasant responsibility, so we may suppose that the painful experience of my claustrophobic patient was forgotten because the memories of the passage and the dog were so painful as to interfere with his happiness. The completeness of the suppression may have been due to the fact that the interference with the comfort of the child was so great as seriously to disturb his health. In the case of my own experience it is not possible to say why the memory of the upper floor has been forgotten, since I do not yet know the nature of the suppressed experience, but we can be fairly confident that it was of an unpleasant kind and was forgotten because the memory of it interfered with my comfort and happiness.

The memories which disappear in warfare are always of happenings so distressing that the utmost pain is aroused when they reappear in consciousness. The conclusion to which we are led both by the experience of everyday life and by the analysis of pathological and semipathological states is that there is no difference in nature between the forgetting of the unpleasant experience of ordinary life, often quite trivial in character, and such examples of complete and life long suppression as those which I have chosen to illustrate the nature of the unconscious.

If these two kinds of forgetting are essentially alike, if they furnish the two ends of a continuous series, a study of the forgetting of everyday life should provide a means of studying the suppression which occurs in pathological states. If we attempt such a study the first point which may be noticed is that the active forgetting of everyday life is not voluntary and intentional, but is essentially a process which takes place unwittingly. If we try to forget an appointment which we expect to lead to a quarrel or try to forget a letter undertaking an unpleasant responsibility, we should not succeed. We should probably only fix these duties the more firmly in our memories. It is characteristic of the active forgetting of which Freud (1) has provided such a wealth of examples that it occurs spontaneously. In such instances as I have given, we do not know that we have forgotten. It is only when we are reminded of the missed appointment or the overdue letter that we become aware of the lapse. In other cases, as when we forget the name or address of a correspondent to whom we should write, we know that we have forgotten, but the act of forgetting has still been involuntary and unwitting.

The pathological suppression taking place in adult life seems in most cases to be clearly involuntary and unwitting. The most complete cases of suppression do not occur in people who have tried consciously to repress painful experience, but has

come about without any conscious activity on the part of the sufferer, especially as the result of shock or illness. Hypnotism furnishes a striking example of the process by which experience is suppressed. By means of suggestion given in the hypnotic state any experience, pleasant or painful, which occurs during this state may be banished from the memory. When this has been done the hypnotized person is quite unable to recall the experience, and it will remain unconscious until he is again hypnotized or until the experience is recalled under some other condition in which unconscious suppressed experience comes to the surface. In this case the suppression takes place quite independently of the will of the hypnotized person, but there is reason to believe that the suggestion to forget is more likely to be successful, the more the forgetting is in consonance with the conscious wishes of the subject. This probably gives the clue to the fact that conscious repression seems often to lead to suppression. The suppression itself is unwitting, but the wish of the sufferer for suppression assists the process, or at least helps in its maintenance and completeness.

I must now consider briefly a characteristic of active forgetting and suppression which is of great importance in understanding its nature. The experience which tends to be forgotten or repressed is the immediately painful. If we forget an appointment or a letter in connection with which we anticipate unpleasant emotions, the ultimate consequences may be even more unpleasant than the immediate experience from which we escape by the act of forgetting. If we were able to consider rationally the consequences of the lapse, we should find that in most cases the course which would give us least trouble and inconvenience in the long run would be to keep the appointment or write the letter.

The process of active forgetting, however, takes no account of these ultimate consequences, but is directed exclusively towards the avoidance of the more immediate pains and discomforts. The same seems to be true of cases of pathological suppression. If, as I suppose, the claustrophobia of my patient was the result of the suppression of his four year old experience, there can be little doubt that the sum total of unhappiness due to his dreads was far greater than that which would have resulted from the immediate memories of his terror when in the passage with the dog. The memory was suppressed because of its immediately painful character, and in following this course Nature took no account of the effects of the suppression, which were to torment the child and man for thirty years. The suppressions which form so large an element in the neuroses of war are also directed to allow escape from the immediately unpleasant, regardless of the future consequences. Suppression is a process of reaction to pleasures and pains which are immediately present and takes no account of the more extended experience with which it is the function of intelligence to deal.

1. FREUD: *The Psychopathology of Everyday Life*.
ST. JOHN'S COLLEGE.

A NEW PSYCHOANALYTICAL THEORY.

Kempf's Dynamic Mechanism.

BY ANDRÉ TRIDON,
New York.

Valuable as their theories are, one cannot help feeling that Freud's and Jung's mode of thinking is still closely related to that of the academic psychologists. They give the impression that the mental and the physical are two separate entities. The term conversion used by Freud to designate the physical symptoms accompanying certain emotions seems to imply a duality in organic manifestations which, to modern scientists, appears unfounded. When Freud and Jung speak of libido, cravings, and censor, they are almost as vague and unconvincing as Bergson when he speaks of the vital urge. Adler felt the necessity of establishing a more intimate connection between physical and mental manifestations but he did not make the mechanism of compensation clearer to his readers than Freud did the mechanism of conversion.

It will be only when we know what part of the organism produces an emotion and, reciprocally, what part of the organism is affected by a given emotion, that we shall visualize clearly the relations between mind and body. Then we shall understand the meaning of the vital urge and of the libido; then, the so-called nervous disturbances as well as consciousness and its content (thought) shall lose their mystery.

Edward J. Kempf, of Saint Elizabeth's Hospital, Washington, D. C., attacks the problem from a new and original point of view. Kempf states frankly his dislike of the term libido. Although that term attempts to represent graphically the energetic constitution of man and his love of life, it lacks clearness, for the human mind cannot very well conceive of a process as such, unless there is some thing that proceeds. The concept of electricity would be hazy, indeed, were it not that we can visualize dynamos, wires, sparks, bulbs and many other visible means of production or manifestation of the force called electricity.

In order to explain the great physiological changes which influence human thought and behavior and the biological nature of man, Kempf has developed a conception of the personality based on the reflex actions of the autonomic nervous system.

To him the human organism is a biological machine which assimilates, conserves, transforms and expends energy. All those operations are regulated by the autonomic apparatus which keeps in touch with the environment through the projicient sensorimotor nervous system. As the autonomic apparatus becomes conditioned (trained) to have acquisitive and avertive tendencies toward its environment, according to which cravings are active in a given situation, the organism's behavior is the resultant of a compromise between the opposed cravings. The importance of the brain is greatly minimized by this conception. Experiments have proved that the same form of behavior is not always due to the activity of the same brain cells and the theories which localize in certain regions

of the brain the controlling forces of all human conduct must be abandoned.

According to Kempf, brain and personality, so long associated in popular parlance, must no longer be considered as interchangeable terms. In fact, every part of the body contributes something to the personality and to its consciousness of itself. Should some one lose a limb or a group of muscles, he would lose at the same time an important part of his personality. This would manifest itself in the manner in which he would adjust himself to the stresses of daily life, what he would try to do and feel compelled to avoid. Analysis alone would reveal that fact; the natural readjustment of the remaining muscles would prevent any gross change from being observable. For instance, the loss of the eyes and arms would greatly reduce the ability to understand new machinery, new situations and probably reduce to an enormous extent the power of recalling experiences in which the eyes and hands played a predominant part, such as writing.

Because most of our thoughts are dependent upon our muscle sense, it may be said that we actually think with our muscles. If we allow ourselves to become aware of the visual image of an automobile, we are aware that it is moving, because the muscles of the eyeball shift the image by modifying their postural tensions. Sometimes the muscles of the neck may contribute more information by moving the head. If we are pushing the automobile ourselves, the muscles of the body come into play to furnish other images, and if we are pushing it along a cold, wet, muddy road, the sensations of cold, wetness and mud arise from the tactile receptors of our legs.

Such a perfect correlation between our autonomic apparatus and the sensorimotor system is a gradual acquisition of the human being in the course of its development. At birth, we have a welldeveloped, wellbalanced autonomic apparatus and a poorly coordinated sensorimotor system. The autonomic apparatus, however, begins immediately to coordinate and control the sensorimotor system in order to master its environment.

A most important factor begins to exert pressure upon the infant from the moment of its birth and exerts it throughout life. It is the incessant pressure of the social herd, which modifies the autonomic apparatus and compels it to adopt less and less primitive, more and more civilized and indirect methods of satisfying the various human cravings. The tone or tension produced by the autonomic apparatus in the muscles which move our body and limbs determines largely the content of our consciousness or thoughts. This leads us to a complete reversal of the view held by the academic philosophers and psychological laboratory observers.

According to them the emotions are one of the results of the mind's contemplation of phenomena taking place within or without the organism. Bodily reactions and mental reactions take place after the emotion has been experienced. James and Lange advanced the theory that our feeling of bodily changes, following the perception of a stimulus, is the emotion. Kempf goes further and states that if we experience an emotion, it is because some

parts of the autonomic apparatus have assumed a certain tension which produces the motion. As evidence, he cites the fact that we are at times disturbed at night by fearful tensions whose cause is unknown and then awaken to find that there is some one in our room. Nursing mothers experience vigorous disturbances in their sleep long before they become aware that their child is in distress. We become conscious of images of urinating in our dreams and find, upon awakening, that uncomfortable tensions of the bladder have been active for some time owing to the accumulation of urine.

Kempf's theory of the dynamic mechanism is worded as follows: "Whenever any segment of the autonomic-affective apparatus is forced into a state of hypertension through the necessities of metabolism or endogenous or exogenous stimuli, the hypertense segment gives off a stream of emotion or effective craving which compels the propitious apparatus to so adjust the exteroceptors in the environment as to acquire stimuli which have the capacity to produce comfortable postural readjustments in those autonomic segments."

In other words, whenever autonomic nerves, for instance the nerves causing the contractions of the stomach known as hunger are made extremely tense by the sight or smell of food, they produce a strong emotion or desire which compels the sensorimotor nerves to apply the mouth to food, after which the tension of the autonomic nerves is relieved.

Kempf maintains that this biological principle or law is the foundation of all human and animal behavior, to be seen throughout all its workings, whether brief and trivial or prolonged and elaborate. "The seeking and creating follows the corollary 'to obtain a maximum of autonomic gratification with a minimum expenditure of energy,' thus developing increasing skill and power, extension of influence and assurance of comfort and an increasing margin of safety from liability to failure."

Most of the nervous tensions originating in the autonomic apparatus have as their biological aim the acquisition of appropriate pleasant stimulations and the avoidance of destructive unpleasant ones; for instance, they direct us toward food and away from some danger. They are relieved only when their objective stimulus is attained. In certain cases the object is unattainable, being socially tabooed or having passed beyond our reach, as for example when a loved person dies. In such cases, tensions will remain unrelieved and become seriously distressing as well as dangerous for our mental and physical health. Among other things, they disturb the blood supply to certain organs and hence weaken them in their struggle against the bacteria of infectious diseases. In case of tuberculosis, pneumonia, typhoid, excessive fatigue, an exaggerated emotional tension may be fatal. In other words, the individual who represses certain cravings because they are ungratifiable or for fear of the influence their gratification may have on his social standing, tends to have organs which are more susceptible to disease.

The struggle between conflicting cravings was considered by psychologists of the old school as

taking place in our mind. Kempf shows us that it takes place in our autonomic apparatus. The sacral division may be conditioned to need stimuli that are perverse or tabooed and cause irritability and depression until gratified, whereas their unrestrained indulgence may greatly jeopardize the love for social esteem and the feeling of social fitness. The secret sense of social inferiority, due to some one's awareness of tabooed pelvic cravings, makes life in human society a fearful ordeal, which in turn disturbs the respiratory, circulatory and gastronomic functions. Hence the needs or cravings of the different autonomic segments converge upon the projecting apparatus and behavior is the physical or mechanical resultant. This compels the different autonomic segments to wage fierce conflict for control of our conduct and our conduct reveals the conflict.

That struggle grows fiercer as the civilization in which we live grows more complex. At birth, the autonomic apparatus works smoothly, because the infant is dependent upon the mother and hence irresponsible. But when the mother begins to train the infant to nurse, urinate and defecate under certain specific conditions, the autonomic apparatus for the first time clashes with society which insists on selfrestraint, selfcontrol and selfrefinement.

Heedless indulgence by an individual of any age causes uncomfortable tensions in his associates (disgust, fear, anger), and therefore they are compelled to control social tendencies in every individual from his earliest childhood. Acquisitive cravings know no social law, however, and often threaten to jeopardize the personality by impelling it to do something which is illegal or immoral. For, after all, man is simply an ape that has learned to wear clothes, to use words and signs and that can foresee in a general sense the possible biological and social results of certain indulgences.

Autonomic segments of the infant are then trained (conditioned) to react to certain stimuli, for instance, to certain vocal sounds and touches indicating the time for nursing, to signs and touches indicating disapproval of certain acts; the fear of losing certain agreeable stimuli gradually develops in him a certain degree of selfcontrol. Many cravings of an ungratifiable or unjustifiable nature, however, resist all attempts on the part of our environment to curb them. Compensatory strivings are then set in motion to prevent them, either from manifesting themselves or from being recognized in order that the organism may escape the concomitant fear. A state of fear induces malnutrition and impotence and hence would be destructive for the individual and the race.

When a craving is allowed to make the organism aware of its needs, but is not allowed to cause overt acts, it is said to be suppressed. When it is not allowed to cause the organism to become aware of its needs, it may be said to have been repressed. But neither suppression nor repression is synonymous with annihilation. Whether we remain in ignorance of the fact that a boiler is full of steam or simply disregard that fact, the steam is there, seeking an outlet and likely to create an abnormal one, unless a normal outlet is provided.

Repressed autonomic segments, like steam in a boiler, need but the slightest opportunity offered by the environment, or the slightest relaxation of the repressing forces to obtain control of the sensorimotor nervous system. We may suppress our disgust or anger to save appearances, but we will at the same time, by remarks, by our very tone of voice or gestures, betray our real feelings; we will have dreams which picture the attempted or successful gratification of suppressed cravings. The essential difference between most sane and insane people is that insane people cannot control their repressed cravings while sane people can. That is to say, when people become fatigued, toxic, dazed, and can no longer control their repressed cravings, those cravings cause a form of behavior which is termed insane.

As the human individual grows and develops, he gradually becomes able to control the activities of the various cravings with the exception, however, of the sexual cravings. When sexual cravings are normal, they are naturally justified, and, under certain conditions, they are permitted socially to dominate our behavior.

When the personality, on the other hand, considers sexual cravings as shameful inferiorities, either because they are perverse or because the personality has been educated in a prudish way, the individual becomes forced into a form of adjustment which is abnormal on the account of the autonomic conflict it entails. Whenever a violent conflict rages in our autonomic apparatus between acquisitive and avertive cravings, a neurosis ensues, or rather, the neurosis is the conflict. No constitutional predisposition is needed to bring about its onset. Life's experiences and the influence of our environment and associates are sufficient as determining factors.

Kempf does not accept Freud's theory as to the importance of sex (love) in the causation of neurotic disturbances. Any of the primary cravings, love, hate, hunger, shame, sorrow, fear, or disgust, may cause a neurosis under appropriate conditions. The neurotic is suffering from cravings which he cannot allow to dominate his personality. Those cravings are so often located in postural tensions of certain organs that they are probably consistent things, even if they are not always discoverable. A strong craving, like the famishing influence of protracted hunger, which originates in the stomach, or the severe itching of an area of the skin, may finally determine all the adjustments of the entire personality and be felt over the entire body. The result may be a severe struggle to eliminate the craving from the personality. Or the personality may resign itself to the domination of the craving and to a regression in which the individual enjoys tensions and images, fancies, delusions, hallucinations which simulate the craved reality.

On the basis of this conception of the personality, Kempf rejects entirely the usual classification of mental disturbances into neuroses, psychoneuroses and psychoses. That classification is very unscientific and unbiological for it is based upon symptoms which may change under different conditions or under the care of different physicians. In many

institutions, for example, the diagnosis manic depressive tacitly means recoverable, while dementia præcox means incurable, so that if a dementia præcox patient shows a tendency to recovery he is reclassified as manic depressive. Kempf's classification takes into account the nature of the patient's autonomic cravings and his attitude toward them. It is, therefore, essentially mechanistic and truly biological. Every nervous disturbance is designated as a neurosis.

The neurosis, then, is termed acute, chronic, or periodic, according to its duration. The term acute is reserved for cases of less than a year's duration. Chronic is applied to cases having had more than a year's duration, or which have had an insidious course for more than a year before the consultation.

Periodic is applied to cases which have periodic or intermittent episodes or recurrences accompanying natural phenomena, such as menstruation, pregnancy, marriage, death of a child, or other occurrences.

The neurosis is further qualified with regard to its mechanism, that is, the insight the patient has retained. The neurosis is benign when the patient recognizes that his distress or disease is due to the suppression of unjustifiable or ungratifiable cravings which are a part of his personality. The neurosis is pernicious when the patient refuses to attribute his trouble to a personal cause or wish, insists that it is due to an impersonal cause or a malicious influence and tends to hate anyone who would attribute it to a personal source.

According to the mechanism of the autonomic conflict involved, neuroses are differentiated into five types:

The suppression neuroses are characterized by the fact that the patient is more or less conscious of the nature and effect upon himself of his ungratifiable cravings. For instance, a man may be affected by his love for a faithless, indifferent or dead woman; a soldier may be caught between two fears, that of death and that of a court martial, and know that it causes him insomnia, headache, cardiac anxiety, diarrhea, or other disturbance.

In repression neuroses, the individual tries to prevent the autonomic cravings from making themselves known and influencing his personality. A repressed fear may make a man blind or lame and he may feel convinced that an actual fall, bruise or wrench is responsible for his condition, because he has succeeded in making himself forget the cravings that are relieved by being blind or lame.

Compensation neuroses are characterized by a reflex effort to develop functions which will compensate for some organic or functional inferiority or keep an undesirable craving repressed, which is unconsciously causing fear. Often the effort is adapted or designed to destroy or defeat environmental factors which arouse the intolerable craving or oppose the compensation. Egotism, intolerance, and exaggerated claims are typical of compensation neuroses.

Regression neuroses are just the opposite. The individual makes no effort to win or retain social esteem and regresses to a lower, childlike or infantile

level, becoming apathetic, slovenly, irresponsible, often showing suicidal tendencies, and allowing the cravings to do as they please. The regression may be a relatively benign episode of a few months' duration. It may in other cases be followed by a feeling of having died and passed through a rebirth, and also of having eliminated all the sinful cravings in order to begin life anew. This form of adjustment may work as long as the subject lives in a protected, noncompetitive environment. Later, an eccentric overcompensation often takes place which eventually leads to another neurosis or a permanent deterioration of the personality.

In dissociation neuroses, the patient succeeds in keeping his undesirable cravings repressed until they finally become dissociated. The individual is then conscious of weird distorted images, hallucinations of past sensations, and experiences which seem to gratify the dissociated effect although they horrify the individual. The individual is also dominated by unacceptable, mysterious obsessions, fears, compulsions and inspirations. There may be also severe visceral distress, motor disturbances, amnesia, or other manifestations.

The analytical treatment, as mapped out by Kempf, consists in establishing a transference, that is, giving the subject an opportunity to rely upon the altruistic judgment of some authoritative practitioner and enabling him to allow his repressions to make themselves conscious. Kempf disagrees with Jung on the extent to which the transference should be used and he considers it essential in order to help the neurotic to become socially constructive. Only in that way can the analyst fulfill the mission in which the neurotic's parents failed.

After the subject succeeds in giving full expression to his repressed affects, those affects become assimilated with the personality and form an intimate part of it, instead of remaining uncontrollable, unconscious or mysterious factors. In that way the dissociated cravings which cause obsessions, phobias, mannerisms, compulsions, delusions, hallucinations, regressions, eccentric compensations, and prejudices, are once more merged with the organism from which they had been abnormally separated and the functional distortion disappears. The subject having acquired insight and being free from the fear of something within himself, becomes capable of making a sensible, practical adjustment.

When that readjustment is effected an intelligent use of the reconstructive, suggestive method seems to be most effective in giving the neurotic new interests for which to live and work, without seeking abnormal compensations for prudish or fearful repressions or yielding to perverse cravings.

The choice of a method, Kempf thinks, should be left to the patient, but he should not be allowed to avoid the work of reconstruction. Furthermore, the analysis should be accompanied by vigorous indulgence in social play requiring exposure of functional or organic inferiorities to more or less critical evaluation by competitors. Thus the subject will become immune to the fear of failure or inferiority and will avoid eccentric compensation and a seclusive mode of life.

121 MADISON AVENUE.

TRICUSPID STENOSIS AND TRICUSPID
INSUFFICIENCY.*By JOHN J. YOUNG, M. D.,
New York,Instructor in Clinical Medicine, Columbia University, College of
Physicians and Surgeons; Physician to Outpatient Department
and Adjunct Assistant Visiting Physician Bellevue Hospital,

AND

LAWRENCE H. COTTER, M. D.,
New York,

Resident Physician, Bellevue Hospital.

A review of the standard works on diseases of the heart shows that the physical signs of lesions of the tricuspid valve are exceedingly indefinite. Characteristic, if not pathognomonic, auscultatory, palpatory and percussion phenomena are known of most lesions of the heart and great vessels, but the conventional description of the physical signs referable to disease of the tricuspid valve is of little value in distinguishing this lesion from that of mitral stenosis, which, moreover, is an almost constant association. For example, it is stated that in tricuspid stenosis cyanosis is marked, but in our experience cyanosis in these circumstances is no greater in degree, perhaps less so, than that usually encountered in mitral stenosis. Clubbing of the fingers is a non-committal sign and is in no wise characteristic of tricuspid disease. The existence of a presystolic thrill over the tricuspid area, if it occurs at all, is extremely rare. A tapping systolic impulse over the lower sternal region and the adjoining intercostal spaces is of highly doubtful value, since a coexisting mitral tap cannot be excluded.

By percussion it is difficult, if not impossible, to distinguish whether enlargement of the right side of the heart is due to right auricular dilatation or right ventricular hypertrophy. The presence of a sharp valvular sound over the tricuspid region is not necessarily indicative of stenosis of the corresponding orifice, in view of the fact that the sharp contraction of the hypertrophied right ventricle may be invoked to explain the alteration of the first sound in mitral stenosis.

The lack of specificity in the symptomatology of tricuspid disease, as usually described, prompts us to record the anatomical and clinical findings in a series of four cases of tricuspid disease, and to call attention to certain pulsatory phenomena in the liver, which, we think, are characteristic of certain lesions of the right side of the heart.

True intrahepatic pulsation may be venous or arterial in origin. In rare cases of aortic insufficiency expansile enlargement of the liver is clinically appreciable and is arterial in nature. Venous pulsation of the liver is produced by the reflux of blood from the right side of the heart through the inferior vena cava, thence to the hepatic vein and through the liver lobule. It is known that regurgitation through the great veins from the auricles of the heart is favored by dilatation of these chambers and that the venous orifices of communication with the atria participate in the process. In normal circumstances, the circular layer of smooth muscle in the walls of the cavæ at their entrance to the heart acts as a valve and

by its contraction effectually prevents excessive backward flow of blood during auricular systole. Regurgitation is furthermore favored by anatomical alterations in the musculature of the right side of the heart so that dilatation is brought about, producing relative insufficiency of the tricuspid orifice, the valve segments themselves being unchanged but nevertheless inadequate to guard an orifice rendered abnormally large by muscular relaxation.

The presence of the normal jugular pulse with its positive and negative components may be determined, of course, by graphic methods and, indeed, in many individuals several of the waves can be identified by inspection. True intrahepatic pulsation, on the other hand, is never encountered in normal individuals.

Clinically, pulsation of the liver may be transitory or permanent. The former is often observed in association with myocardial insufficiency attended by marked dilatation of the right side of the heart. Physical examination corroborated by graphic methods, shows that this type of pulsation in the jugular vein and in the liver is synchronous with ventricular systole, and that during systole a certain quantity of blood is regurgitated through the incompetent tricuspid orifice into the auricles and thence into the cavæ. Under the influence of rest, with or without digitalis or its allies, the liver ceases to pulsate and venous engorgement and pulsation in the neck become less marked, an effect due, presumably, to decrease in the size of the heart with resumption of the function of the tricuspid valve.

Thus, a patient who, on early examination, presents hepatic pulsation with or without signs of venous engorgement and pulsation in the neck should be investigated from the point of view of possible organic disease of the tricuspid valve, if these signs do not abate under appropriate treatment, and if in other respects improvement occurs, as manifested, for example, by decrease in the amount of edema, lessening of ascites, hydrothorax and other physical signs.

The almost constant association of mitral and tricuspid stenosis and the not infrequent lack of localization of the mitral direct murmur, often render it impossible to accomplish satisfactory examination of the tricuspid area as delimited on the precordium; that is to say, the xiphoid region and the adjoining portions of the sternum and the ribs. Consequently, no satisfactory inference can be drawn from the presence of a rumbling diastolic or presystolic murmur over the tricuspid area that does not differ in quality from the murmur commonly heard over the apex in mitral stenosis, because the possibility of transmission cannot be ignored. If, on the other hand, there is present over the lower sternum a rumbling diastolic or presystolic murmur differing in quality and, perhaps, in intensity and duration from a murmur of similar time heard in the apical region, this finding may serve to aid in the diagnosis of tricuspid stenosis. Nevertheless, corroborative signs are to be sought. For example, if the auricles are acting properly, an excessively large wave in the jugular pulse and in the liver phlebogram is suggestive of tricuspid stenosis. In some cases double liver pulsation is appreciable and is explainable on the basis of a hypertrophied right auricle together with hin-

*From the service of the First Medical Division, Bellevue Hospital.

drance to the entrance of blood into the right ventricle. Combined examination of the apex beat and the jugular pulse may indicate that the exaggerated wave is synchronous with auricular systole, even without the aid of instruments of precision. Tricuspid regurgitation is always a companion lesion of tricuspid stenosis.

When the auricles are fibrillating, the diagnosis is more difficult. In such cases the existence of organic insufficiency of the tricuspid valve must first be ascertained on the strength of continued pulsation of the liver and improvement in other respects, as previously noted. In many instances increased pulsation in the jugular veins may likewise be present. In some cases it is extremely marked, the bulb easily attaining the size of a large adult thumb. In other cases, however, jugular pulsation is a negligible factor. In our experience, on the other hand, hepatic pulsation was present as a constant phenomenon both in those cases in which the condition was correctly diagnosed during life and those in which its clinical recognition was overlooked. Pulsation is, of course, synchronous with ventricular systole. In our experience, too, enlargement of the liver is constantly present and depends on chronic passive congestion. If, in addition, a distinct rumbling diastolic murmur is heard over the tricuspid area, the diagnosis becomes still more probable.

Even though such a murmur cannot be distinguished from an apical murmur similar in time, if tricuspid insufficiency is present, it is reasonable to assume the existence of some degree of stenosis in view of the frequent association of mitral stenosis with mitral insufficiency. In adults with organic mitral disease it is unusual to find pure mitral insufficiency. In such individuals a diastolic rumble can usually be heard in the region of the apex of the heart after having the patient exercise or by placing him in the left lateral recumbent posture, or even without resorting to these expedients. As a rule, stenosis of the tricuspid valve is seldom of the tight variety, although those pathological conditions of the valve segments which make for insufficiency also determine the occurrence of stenosis.

CASE I.—The patient, a male, aged twenty-seven years, was admitted to Bellevue Hospital complaining of dyspnea and edema of the legs. Examination revealed, in brief, the apex beat of the heart in the fifth left interspace at the nipple line. The right border of the heart was made out by percussion midway between the right mammillary line and the sternal line. An inconstant presystolic thrill was palpable at the apex and there was felt a distinct epigastric systolic shock. On auscultation, a rumbling presystolic murmur was heard at the apex, and as the sternum was approached another murmur, systolic in time, was heard, increasing in intensity to the right of the lower part of the sternum, being heard almost to the right nipple line. This murmur was quite harsh. Over the lower part of the sternum a soft diastolic murmur was heard, which at first varied with respiration, disappearing with a full inspiration. On the day before the patient's death it was quite constant. There was no accentuation of either second sound at the base. No pulsation was noted in the veins of the neck. The liver

was large and pulsated distinctly. The radial pulses were small and equal on the two sides. There were signs of congestion at the bases of the lungs. The clinical diagnosis was: Chronic cardiac valvular disease; mitral stenosis and regurgitation; tricuspid stenosis and regurgitation. The diagnosis of old tricuspid valvulitis was made in this case because of the marked extension of cardiac dullness to the right of the sternum, the peculiar murmurs heard at the tricuspid area, entirely different from those heard at the apex and the forcibly pulsating liver. The patient died suddenly.

Autopsy revealed the lungs more or less adherent. There was a hemorrhagic area in one lower lobe. The heart was enormously enlarged and the pericardium adherent throughout. There was marked hypertrophy and dilatation of the right auricle and ventricle and their cavities were filled with blood. The left auricle and ventricle were likewise hypertrophied and dilated. The pulmonic segments were normal. The tricuspid leaflets were adherent and thickened, leaving a ring that admitted two fingers. The mitral orifice was quite contracted, admitting a lead pencil; chordæ tendineæ thickened and retracted; aortic valves thickened and edematous, but not indurated; liver enlarged and congested; spleen and kidneys firm and congested.

CASE II.—The patient, a male, single, aged twenty-eight years, a native of Poland, entered the medical service of Bellevue Hospital with a complaint of shortness of breath of four years' duration. His family history was negative. Except for two attacks of gonorrhœa in youth, a chancre five years ago, and an attack of pains in the legs, not localized to the joints, in childhood, his past history was negative.

Four years previous to admission to the hospital, the patient noticed dyspnea, palpitation and rapid heart action on exertion, and became easily fatigued. For the same length of time he suffered from pain in the right upper quadrant that was not related to the ingestion of food. Two years preceding his entrance into the hospital, he first noticed swelling of the legs that became more marked in the four months just before admission, necessitating confinement to bed at intervals. The patient stated that he was distressed by attacks of vertigo, without syncope or convulsions, and by sharp non-radiating precordial pain.

Physical examination showed a well nourished, well developed adult male patient, acutely ill. There was no orthopnea, and cyanosis was moderate.

Examination of the heart on the day of admission, September 21, 1917, revealed systolic heaving of the entire precordium. The apex beat was felt as a diffuse impulse in the sixth left intercostal space, well outside the nipple line. The percussion outlines of the heart borders were five cm. to the right in the fourth space, and 16 cm. to the left in the sixth space. There was increased dullness over the second left interspace. Over the apex was heard a blowing systolic murmur transmitted to the axilla, and a rumbling diastolic murmur with presystolic intensification. At the ensiform cartilage another blowing systolic murmur was heard. A blowing diastolic murmur was heard along the left margin

of the sternum, with maximum intensity in the fourth left intercostal space; also a soft systolic murmur at the aortic area that was not transmitted. The pulmonic second sound was accentuated and reduplicated and accompanied by a diastolic shock felt in the second left interspace. The heart action was regular, the radial pulses equal, regular, small, and of low tension. On September 22nd, a whistling diastolic murmur was noted over the ensiform that was different in quality from any other murmur heard in the heart. On September 26th, a superficial to and fro scratching murmur was heard to the left of the sternum in the fourth and fifth spaces. The rub was intensified by pressure of the stethoscope. On October 21st, there was heard a systolic murmur over the lower part of the xiphoid, and at times a wavy diastolic murmur was audible in the same location, and was different from the murmur heard at the apex. The spleen was enlarged to percussion, but its edge was not felt. On admission, the liver edge was felt four and one-half fingers' breadth below the costal margin in the mammillary line. The organ was tender and showed distinct pulsation; its surface was smooth. An electrocardiographic tracing taken on September 26th showed auricular flutter and relative preponderance of the right side of the heart. Phlebograms showed a pronounced *a* wave in the jugular pulse and a large *v* wave in the liver pulse. Urinary and ophthalmoscopic examinations were negative.

At autopsy the precordial area was large, measuring seventeen cm. from apex to base, sixteen cm. in the transverse direction. The parietal pericardium was quite thin. The pericardial cavity contained about eight ounces of blood tinged fluid with fibrin flocculi. The visceral pericardium was granular in appearance. There were several small milk patches scattered over the epicardium of the right ventricle. The heart was huge, weighing 570 grams. The apex was blunt but was still formed by the left ventricle. The right auricle was dilated and the musculi pectinati hypertrophied. The tricuspid orifice was constricted, the valve margins being thickened, adherent and rounded. On the edges of the line of closure there were a few small recent verrucous vegetations. The right ventricle was hypertrophied, its wall measuring eight mm. The pulmonary valve was normal. The left ventricle was contracted, its wall measuring twelve mm. The left auricle showed considerable dilatation with slight thickening of its walls. There was marked stenosis of the mitral orifice, the ring being reduced to a narrow slit which did not admit the tip of the little finger. The valve segments were thickened, adherent and calcified. The chordæ tendinæ were short and thick. The aortic cusps were considerably fused, thickened and retracted; coronary arteries and aorta showed no noteworthy changes. The clinical diagnosis was: Chronic valvular disease; mitral stenosis and regurgitation; tricuspid stenosis and regurgitation; aortic regurgitation.

The anatomical diagnosis was: Chronic mitral valvulitis; chronic and acute verrucous tricuspid valvulitis; chronic aortic valvulitis.

CASE III.—A middle aged male patient entered Bellevue Hospital in March, 1920, complaining of

dyspnea and sharp pain in the left side of the chest. His past history was negative except for gonorrhoea followed by multiple arthritis in early life. The patient had no recollection of rheumatic fever. He stated that in early childhood he suffered from dyspnea on exertion, which became progressively worse, and recently had necessitated complete rest in bed.

Examination showed a poorly nourished male, quite dyspneic and cyanotic, propped up in bed. His bodily configuration and the hair distribution conformed to that of status lymphaticus. There was marked arterial pulsation in the neck. There were signs of a small amount of fluid in both pleural cavities. The apex beat of the heart was felt in the sixth left intercostal space in the anterior axillary line. There was dullness to the right in the third space, extending almost to the nipple line. In the region of the apex there was forcible systolic retraction of the ribs and the soft parts; there was a similar phenomenon posteriorly in the tenth and eleventh interspaces on the left. The lung did not move over the precordium on inspiration. It was impossible, in view of the size of the heart, to determine whether its outlines changed with alteration of the patient's position. The sternum rose with inspiration. The pulmonary conus percussed enlarged. At the aortic cartilage there was heard a harsh systolic murmur transmitted to the vessels of the neck. Along the left margin of the sternum a blowing diastolic murmur was audible. At the apex there were heard a blowing systolic murmur and a rumbling diastolic murmur. Over the tip of the xiphoid there was a systolic murmur of higher pitch than that heard at the apex and more musical than the aortic murmur. The diastolic rumble in this area was not as rough as that heard at the apex. The pulmonic second sound was accentuated; the aortic second sound was not heard. The rate of the heart was slow, and its action was absolutely irregular. The radial pulses were small. The liver edge was felt three fingers' breadth below the costal margin, firm and sharp, and the liver pulsated vigorously. There was moderate edema of the lower extremities with slight decubital edema. During the entire stay of the patient in the ward, even though he improved markedly for a time, the liver continued to pulsate.

The clinical diagnosis was: Chronic cardiac valvular disease; aortic stenosis and regurgitation; mitral stenosis and regurgitation; tricuspid stenosis and regurgitation; adherent pericardium (indurative mediastinopericarditis).

At autopsy, the heart was large, the pericardium being everywhere densely adherent, so that it had to be dissected away from the heart muscle. The right auricle was tremendously dilated, the tricuspid valves were thickened and their edges fused. The right ventricle was dilated and somewhat hypertrophied. The pulmonic valves were normal. The left auricle was considerably dilated, the mitral valve presenting a buttonhole stenosis. The left ventricle was much hypertrophied and dilated. The aortic cusps were thickened, retracted and fused for a short distance. The spleen, liver and kidneys showed chronic passive congestion.

CASE IV.—The patient, a man, single, aged twenty-seven years, a native of the Philippine Islands, was admitted to Bellevue Hospital, January 24, 1920. The patient stated that he had had an attack of rheumatic fever two years previously. Three weeks before his entrance to Bellevue Hospital, he was admitted to the New York Hospital with the symptoms of acute heart failure. At that time the Wassermann reaction was strongly positive, and mixed treatment was given in conjunction with injections of salvarsan. At the time of admission to Bellevue Hospital the patient was dyspneic and had to be propped up in bed. Cyanosis was moderate. There was no tracheal tug, no tracheal displacement, no tracheal fixation. Venous pulsation was present in the neck but was not well marked. Examination of the heart showed that the apex beat was to be felt in the seventh left interspace, about seven inches from the midsternal line. It was forcible and localized. The dullness measured two inches to the left and an inch to the right in the second intercostal space, and one and one half inches to the right in the third space. At the apex were to be heard a blowing systolic and a rumbling diastolic murmur. At the base of the heart a long, soft, blowing diastolic murmur was heard with maximum intensity in the third left interspace, adjoining the sternum. A soft systolic murmur was also heard at the base. The pulmonic second sound was accentuated and the heart's action was rapid and irregular. Diagnosis, on admission was: Syphilitic aortitis; dilatation of arch of aorta; aortic insufficiency; cardiac hypertrophy and dilatation with relative mitral insufficiency, relative tricuspid insufficiency; apical murmur, probably Flint.

Two days after admission, a rough systolic murmur was heard over the pulmonic area, sharply circumscribed on the precordium, yet heard in the vessels of the neck. The aortic second sound was not audible over the aortic cartilage nor in the vessels of the neck. The second sound over the pulmonic area was sharply accentuated and accompanied by a diastolic shock. On January 31st, a loud rough systolic murmur was heard with maximum intensity in the third left interspace. It was transmitted upwards and was heard distinctly in the carotid vessels and there was also a marked systolic thrill to be felt in the third left intercostal space. The aortic second sound was faint, if heard at all. On this day it was also noted that the radial pulses were strikingly small for an uncomplicated aortic insufficiency, and the diagnosis was altered to that of aortic stenosis and insufficiency of specific origin, with relative mitral and tricuspid leakage with Flint murmur. On February 3rd, a loud systolic murmur was heard over the tricuspid area that was different from other murmurs noted hitherto, and on the 8th, a questionable diastolic rumble of different quality was also noted at the same situation. There was, however, but little venous pulsation in the neck. The clinical diagnosis was again altered to that of aortic stenosis and insufficiency; mitral stenosis and insufficiency, all lesions of the rheumatic type. An explanatory digression may not be amiss. Organic mitral disease was diagnosed because of the patient's previous

history of rheumatic fever, the enlargement of the pulmonary conus as indicated by extension of percussion dullness to the left in the second interspace, the accentuated pulmonic second sound coupled with a diastolic shock, and, perhaps, the small pulse—features indicative of right heart hypertrophy and characteristic of mitral stenosis. As it is a safe clinical working rule never to invoke two pathological causes to explain a given abnormality if such can be accounted for on a single etiological basis, the diagnosis of syphilitic aortic disease was abandoned for that of old rheumatic endocarditis. The curious tricuspid findings also pointed against the diagnosis of specific aortic valvulitis.

The radial pulses were uniformly small but irregular in force and frequency and Corrigan in type; all palpable pulses were small. The scrotum was markedly edematous and there was marked edema of the lower extremities. The abdomen was distended; there was slight shifting dullness. The liver, on admission, extended two fingers' breadth below the costal margin, was tender, and pulsated. On January 31st, the liver was still pulsating; likewise on February 2nd. On February 8th, the liver was pulsating strongly, in spite of the fact that there was a decrease in the amount of the edema. On February 9th, there was no change. Two murmurs were heard over the tricuspid area, probably different in quality from the others. In view of these findings, coupled with the fact that the hepatic pulsation had become more marked with slowing of the heart, the diagnosis was changed to mitral stenosis and regurgitation; tricuspid stenosis and regurgitation; aortic stenosis and regurgitation. The patient died on February 27th.

Autopsy showed tremendous enlargement of the heart, especially the right side, the inferior vena cava at its junction with the auricle being about twice the normal diameter of the vessel. A small seropurulent encapsulated pericardial effusion lay posteriorly. The diaphragmatic pericardial surfaces were adherent. The aorta lay to the left of the median line, having been displaced by the dilated right heart. The right ventricle was markedly dilated and hypertrophied. The tricuspid valve was thickened; its segments were adherent so that the valves resembled a continuous sheet of tissue. The chordæ tendineæ were shortened and thickened. The orifice admitted about two fingers. The right auricle was huge. The mitral valve was thickened, the segments fused, the chordæ short and thick, and there were many soft, fresh, warty nodules on the line of closure of the valve. The orifice admitted the tips of two fingers. The left auricle was dilated, its walls being somewhat thickened. There was hypertrophy and dilatation of the left ventricle. The aortic cusps were thickened and partly fused. There were many fresh verrucous vegetations along the line of closure of the valve. The pulmonary valve was normal, as was also the aorta in its entire extent. There was no anatomical evidence of lues.

The most valuable clinical sign of organic tricuspid disease is the presence of a pulsating liver which continues to pulsate or even pulsates more markedly under influences calculated to effect disappearance of this phenomenon.

CLINICAL NOTES FROM THE FIRST SUR-
GICAL DIVISION OF FORDHAM
HOSPITAL.

(*Second Series.*)

BY ALEXANDER NICOLL, M. D., F. A. C. S.,
New York,

Director First Surgical Division,

AND HARRY M. RAMMOL, M. D.,
New York,

House Surgeon, First Surgical Division.

The work which forms the basis for this report embodies the efforts of many men associated with the first surgical division of the hospital. Without going too deeply into matters of organization we should like to say that every effort is made to bring our patients into contact with the group idea. By close association of visiting surgeons, associate surgeons, the house staff and the outpatient staffs we attempt to afford the patient the best available skill in diagnosis and treatment while within the hospital walls, together with a properly supervised subsequent treatment after the patient has sufficiently recovered to leave the wards. To this end consultation between the attending surgeon and his associates is frequent, and interchange of opinion is sought, that the best interests of the patient may be served. Co-operation between the strictly professional staff and the social service department is well maintained.

Our first case in this series deals with a condition which is not so frequently met with today as in the past—at least not in the degree observed in our patient. We present this case because of the difficulties of diagnosis arising from the magnitude of the pathological condition—a rather unusual reason for difficulty in diagnosis:

CASE I.—The patient, a girl of twenty, was sent to the hospital with a provisional diagnosis of ascites. For this reason she was admitted to the medical wards and after a short period of observation surgical consultation was asked for. She gave the following history: Occupation, stenographer. Family history: Father and mother both living and well; five brothers and two sisters living and well. Previous history: Up to a year ago the patient had been perfectly well. Present illness: A year ago the patient noticed that her abdomen was increasing in size. She suffered no pain nor discomfort, being able to go about her daily work. Because of the enlargement she consulted a physician who told her that she had fluid in her abdomen and advised her to go to a hospital for treatment. She did not at once accept his advice. Six months ago she found that her menstruation was becoming irregular; previously she had menstruated in a normal manner, beginning when she was twelve years of age, the periods recurring regularly every twenty-eight days, lasting three days, a little scant if anything, and associated with slight premenstrual pain. Six months ago she began to menstruate in a fourteen day cycle, the character of the epoch remaining unchanged. Her chief complaint, therefore, was enlargement of the abdomen with marked menstrual disturbance.

Examination: In general the patient appeared to

be a fairly normal young woman, slight in build, somewhat delicate in appearance, rather markedly anemic, but fairly well nourished. Examination of the heart and lungs showed normal organs. Examination of the liver, kidneys, and spleen was unsatisfactory because of the enlargement of the abdomen. The urine was normal. Leucocyte count showed a total of 8,400 cells, with a percentage count as follows: polymorphonuclear cells sixty-six per cent., lymphocytes twenty-eight per cent., large mononuclear cells six per cent. The contour of the abdomen was smooth and generally rounded, with a slight sagging in the flanks—equally noticeable on right and left sides. The skin was glossy, apparently under some tension, and the superficial veins were dilated in an irregular manner. The percussion note was flat over all the abdomen, and with a change of position of the patient from side to side no tympany could be demonstrated. The position of the intestines could not be made out by percussion. A fluid wave was easily demonstrated. There were no masses, and no points of tenderness. By rectal examination a small markedly retroverted uterus was felt in the posterior cul-de-sac. Diagnostic consultation participated in by members of the staff gave us a choice of three probable diagnoses: a, ascites associated with some form of portal obstruction due to an hepatic sclerosis; b, tuberculous peritonitis; c, a very large ovarian cyst.

Operation: Under ether anesthesia a median hypogastric incision revealed an enormous unilocular ovarian cyst springing from the left side. The left tube, greatly enlarged and thickened, curved over the summit of the cyst, which lay partly between the folds of the extremity of the broad ligament. The cyst contained perfectly clear limpid fluid. There was no distention of the cyst with fluid. It had the appearance of a cyst which had been partially emptied, and this semifilled condition allowed it to accommodate itself to the irregularities of contour of the walls of the abdominal cavity. It was removed together with the incorporated tube. The patient made an uneventful recovery.

It is rare that the large things which we encounter make diagnosis difficult, but in this case it was the hugeness of the cyst, allowing it to fill the abdominal cavity, that caused a doubt to enter our minds as to the correctness of the diagnosis. Afterthought, which is so helpful, permits us to make the diagnosis without difficulty by relying upon the outstanding features of the history and examination: Enlargement of the abdomen without symptoms other than those of ovarian dysfunction, the presence of fluid, and the markedly retroverted uterus.

The next case serves to emphasize the value of close association among members of the staff. In no other type of case is the need for consultation greater than in the head cases of a surgical division. Here the neurologist, the ophthalmologist, the otologist, and in suitable cases the orthopedist, bring help of a very vital nature and it is only by the liberal aid of our associates in these lines that the best results can be obtained by the attending surgeon. It is also in this type of case that the wideawake house surgeon proves his quality by anticipating the need and

arranging for the necessary collaboration. We believe that real team work made possible the favorable outcome in the following case:

CASE II.—Mrs. M. McK., aged fifty-six, was injured in the collision of two automobiles. The car in which she was riding was thrown against a pillar, but it is not known that she struck the pillar. The early notes by the ambulance surgeon show that the patient was found unconscious shortly after the accident, and could not be aroused. Her left clavicle was broken at the midpoint, and there was a severe abrasion over the sacrum. There were no other marks of external injury. There was a slight amount of hemorrhage from the mouth, but none from the ears or nose. There was no local injury about the eyes. There was no laceration of the scalp. No paralysis was evident, and the patient had had no convulsions. Immediate examination of the eyes showed no nystagmus, and no strabismus; the pupils were equal, small, and reacted to light. The pulse was eighty-four with one beat skipped in ten, and the breathing was thirty to the minute, and stertorous.

The patient was brought to the hospital and, after being placed in bed, vomited a large amount of brownish material, with considerable undigested food; there was no blood in the vomitus. She roused from her unconsciousness and was incoherent, and irrational, and inclined to be noisy. Her blood pressure was 160 systolic, 120 diastolic. Otologist's note (Dr. W. M. Dunning): "The ears are normal except for the presence, on the left side, of the evidence of an old inflammatory middle ear condition. There is no evidence here of cranial injury." Neurological examination: Eyes: no conjunctival or subconjunctival ecchymosis; no strabismus; no nystagmus; pupils were equal, smaller than normal, and reacted briskly to light. Reflexes: both knee jerks are lively, the left reflex greater than the right. There was no Babinski reaction and none of the associated and confirmatory signs. Triceps and supinator reflexes were normal. The superficial abdominal reflexes could not be elicited. There was no paralysis, and no anesthesia.

The first day following injury: The patient was kept in bed, and an ice bag was applied to the head. The fractured clavicle was dressed. Her condition changed little; bowels moved and she was able to void urine; there was no incontinence. Her mental condition approached stupor from which she could be aroused for nourishment, and in the periods of consciousness she was irrational but easily controlled. Her temperature was 100.5°, and her breathing changed from stertor to regular and quiet respiration. Her pulse remained about 80 and still showed the tendency to skip. Blood pressure was 140 systolic, 105 diastolic.

The second day following injury: The following ophthalmological observation was made (Dr. Charles Graef): "The pupils are equal and react to light; there is fulness of the veins and a blurring of the disc margins; there is evidence of a low grade neuritis in the left eye, less noticeable in the right eye. There is nothing to base the cerebral condition on at present; patient is rather dull but conscious." The temperature ranged between 99° and 100°, the

respiration was normal in rhythm and rate. The blood pressure was 160 systolic, 120 diastolic.

The third day following injury: The patient's condition was not markedly changed except for lessened irrationality, although any attempt at eliciting information from her caused her soon to relapse into incoherence. She complained of headache. The knee jerks were still very active. The blood pressure was 145 systolic, 110 diastolic. Temperature, pulse, and respiration were normal.

The fourth day following injury: The patient had a little respiratory irregularity which slightly,—but definitely,—upset the rhythm of her breathing. This condition was transitory and was not repeated; the observation was made by the nurse (Miss Kelly). Observation of the mastoid processes at this time did not show any evidence of ecchymosis. Mentally the patient was dull and in her periods of consciousness the same tendency to trail off into irrationality was observed. She still complained of headache. Except as noted, pulse, temperature, and respiration were normal. Blood pressure had fallen to 130 systolic, 90 diastolic.

The fifth day following injury: The signs of increased intracranial pressure were more marked on ophthalmoscopic examination. Dr. Graef confirmed the findings of the director in the following note: "Signs of low grade neuritis most marked in patient's left eye. Very tortuous veins and marked edema of the disc." Neurological examination confirmed the first findings without disclosing any new lesion. The knee jerks were still very lively, and the left more so than the right. The cranial nerves showed no lesion other than that indicated by Dr. Graef's note. The superficial abdominal reflexes were still absent. The blood pressure was 130 systolic, 85 diastolic. The patient still complained of headache but the mental condition showed improvement in that the irrationality was not so marked, although the dulness continued.

In the morning of this day the rhythm of the respiration was again disturbed, the attack this time not being transitory in character but tending distinctly to increase in gravity. The periods of apnea increased from four or five seconds in duration, to an alarming condition in which the respiration was decidedly of the Cheyne Stokes type, and the periods of apnea occasionally exceeded twenty seconds in duration. Before operation the minute count of respirations was frequently less than seven. The pulse began to share in the embarrassment of the medullary centres and decompression was resorted to.

Operation: Subtemporal craniotomy was done on the left side, the opening being by means of the Hudson drill and rongeur. The exposed dura was seen to be whitened, and the vessels not clearly indicated. The feeling transmitted to the finger as it touched the dura was that of boardlike resistance. There was no transmitted pulsation. A small prick was made with the point of a knife in the dura and clear fluid, in a jet six inches' high, spurted from the opening. A test tube was not at hand immediately and while one was being secured from the laboratory adjoining a finger was held over the opening and the fluid allowed to escape slowly.

When the test tube was ready the finger was removed and again the jet of fluid appeared and continued till the tube was filled, as from a fountain, when its escape was again controlled. Decompression was allowed to progress slowly, and it was impossible to estimate the amount of fluid that escaped from the dural opening. When the flow had ceased, the opening was enlarged and the brain was seen, as though at the bottom of a well; it was white, the convolutions were flattened, and only the feeblest pulsation was visible; it had the appearance of an organ which had been held in the hand and squeezed till it had become bloodless. In spite of the efficient decompression which had taken place the brain did not show any tendency to take advantage of the large amount of room that had been created for it by the escape of the fluid. It was quite apparent both from the appearance within the cranial cavity, and from the changed and vastly improved quality of the respiration and pulse, that decompression had been accomplished and was efficient. There was considerable annoying bleeding from the space between the dura and the bone, and this bleeding was checked as far as possible by pressure from within the cranial cavity before the closure of the dura. The dura was sutured with silk. Provision was made for the escape of fluid by means of a gauze wick led down to the wound in the bone and the soft tissue flap was replaced and sutured without any other drainage than this wick, which was led out at the upper angle of the skin wound. During the operation the pulse varied from 70 to 100, and the respiration became normal in rate and rhythm. Immediately after the opening of the dura the blood pressure was 105 systolic, 75 diastolic. The patient was returned to bed in good condition.

The subsequent history of the case is without special interest except for the smoothness of recovery. The temperature never was elevated above 100°, the pulse remained between 70 and 80, and the respirations continued regular in rhythm and normal in rate. Blood pressure varied between 105-75, and 120-75. The wound was dressed on the third day, the gauze wick removed, and primary union secured. The mental condition of the patient was most satisfactory and there was no recurrence of periods of irrationality; the only symptom referable to brain injury was a pronounced euphoria, which was remarked by her family, but which was apparent to us only as that delightful state of mind which we sum up in the phrase, "a very good patient." The clavicle healed in due course, and since discharged from the hospital the patient has remained in good health except for an occasional slight attack of vertigo.

The following cases are presented together because of the similarity of the symptom complex; both patients were admitted to the service at about the same time and the temptation to place them in the same diagnostic niche was strong:

CASE III.—Iris L., aged nine years, was brought to the hospital acutely ill. Past history: The patient had had measles, whooping cough, and bronchitis. Surgical history: Two years ago the little girl had been operated on for intussusception,

the appendix being removed at the operation, after reduction of the invagination.

Present illness: Patient had been well up to the morning of admission when she was awakened by a sharp pain in the right lower quadrant of the abdomen. The pain showed no signs of disappearing and she was given a dose of castor oil; she immediately vomited a large amount of undigested food. The vomiting recurred every five minutes until the patient was brought to the hospital some five hours later. Shortly after the vomiting began the patient had several movements of the bowels, at first diarrheal in character, then becoming decidedly mucous in quality, and finally being bloody. Examination at the time of admission: The patient was markedly in shock, temperature 99° and pulse 100. She complained of pain in her abdomen and examination showed that it was distended, rigid, tender, and contained an irregular ovoid mass in the region of the ascending colon. Operation was clearly indicated both by the findings on examination, and on the history; she was removed to the operating room.

CASE IV.—Mary P., aged three years, was admitted to the hospital and placed in the medical ward. The early history of the little patient was not obtainable, except that she was always considered a perfectly healthy child up to the day before admission.

Present illness: The day before admission the patient ate a large bag of plums—pits and all. Twenty-four hours later she began to vomit, had a little elevation of temperature, and a number of stools filled with mucus. She was brought to the hospital with a diagnosis of gastroenteritis. Examination at the time of admission did not reveal anything unusual except for the noticeable distention of the abdomen. The child was given castor oil and the symptoms abated, but did not completely clear up. The stools continued to have a decided mucus content. For the first four days the temperature ranged between 101° and normal, remaining normal after the fifth day, and until the eighth day. The urine was quite normal. Blood count made on the third day showed a total cell count of 6,800 with a percentage count of polymorphonuclear cells of sixty-five per cent., lymphocytes nineteen per cent., transitional type four per cent., and mononuclear cells twelve per cent. For the first week of its illness the child's diet was carefully supervised and in spite of some loss of weight its condition was considered satisfactory.

On the eighth day of the disease the patient was seized, suddenly, with acute abdominal pain, with distention, rigidity, and tenderness. All these symptoms were more marked on the left side of the abdomen. No movement of the bowels occurred, and no return was obtained from an enema. No mass was felt. The patient began to grow worse very rapidly. On the day following the patient was transferred to the surgical division, and examination revealed an emaciated child in marked shock, with a distended and tender abdomen, in which could be felt an irregular ovoid mass in the region of the descending colon. Blood and mucus had been passed during the night. The temperature was subnormal, the pulse was thready, and the little pa-

tient's face was pinched and white. During the time of her illness the little girl had lost so much weight—most of it in the twenty-four hours immediately after the onset of the acute pain—that the parents were scarcely able to recognize her. The blood count showed a total white cell count of 6,000 with percentage counts as follows: polymorphonuclear cells eighty-three, lymphocytes sixteen, transition type cells one. Operation was determined upon and the patient was removed to the operating room.

There is a decided similarity in the two histories just given: Both patients had sudden onset of pain, with blood and mucus in the stools, both had all the signs of shock, each had a distended, tender, rigid abdomen, and each had an irregular ovoid mass in the abdomen—in the one case over the ascending colon, in the other over the descending colon. Diagnosis was perfectly clear in the first case—the patient was suffering from a recurrence of her intussusception. Diagnosis in the second case was not so clear but the weight of evidence favored the diagnosis of intussusception; in fact it appeared that the signs and symptoms, together with a careful consideration of the history, pointed toward the diagnosis of a chronic intussusception suddenly grown acute. (We should like to say, parenthetically, that we have not yet seen a case in which the diagnosis of chronic intussusception was substantiated.) Brief extracts from the findings at operation are herewith appended, together with the pathologist's report in the second case:

CASE III.—Iris L.: The abdomen was opened in the median line and we immediately encountered and were able to reduce a well marked ileocecal intussusception, the summit of the intussusceptum having reached the middle of the transverse colon. After reduction the abdomen was closed in the usual manner, and there is nothing further to report other than a smooth convalescence. We feel that this case is unusual in that it is a recurrence of intussusception, the first operation having been done only two years previously.

CASE IV.—Mary P.: Laparotomy revealed a mass the size of a cantaloupe lying in the retroperitoneal tissue behind the descending colon, and separating the layers of the descending mesocolon. This tumefaction was found to merge into another irregular mass occupying the region of the pancreas, and spreading laterally into the kidney regions. There was no exudate of any kind within the abdominal cavity; the peritoneal covering of the colon, together with the separated leaves of the mesocolon, showed marked discoloration, and contained petechial hemorrhages. Incision was made into the swelling, through the external leaf of the descending mesocolon, and the larger portion of the mass was entered and found to consist of blood clot. The patient's condition forbade further investigation; a tube was placed in the cavity from which the blood clots had been evacuated and the abdomen was rapidly closed. The little patient did not rally. Pathologist's report (Dr. George Hohmann): "A large mass is palpable in the retroperitoneal space on the left side. At the base of this mass there is a peritoneal perforation one inch in

diameter (the site of the drain). Dissection of the mass reveals the following: It is posterior to the peritoneum; it is round, the size of a small orange, and situated in the region of the left adrenal which it entirely surrounds. The left renal vessels are involved in the new growth. The peritoneal covering gives it an encapsulated appearance. The tumor tissue is soft, mushy, and mottled in appearance, due to hemorrhagic infiltration. It has the gross appearance of hypernephroma; microscopical section of the tumor and enlarged retroperitoneal nodes reveal the growth as a very vascular myxosarcoma, originating in the retroperitoneal tissue."

The following cases of biliary system disease are interesting in view of the wide prevalence of such disease. Our tendency is to get away from the conception of biliary disease as a disease of middle life, and to attempt to bring these patients under treatment as soon after the initial attack of infection as possible. It is our belief that treatment means operation, and that early operation will be infinitely more successful and much less dangerous than the same measure applied once the disease has gained complexity. The following views and rules guide us in our treatment of this type of case, namely, the infectious conditions of the biliary system, gallbladder and ducts, liver, and pancreas:

1. Operation for the relief of biliary system disease is essentially an exploration; therefore it is necessary that the incision should be so situated and of such extent that visual inspection of the gallbladder and ducts is possible.
2. The appendix is more often at fault primarily than not, and should be removed except when acute peritoneal inflammation exists about the gallbladder, when all intra-peritoneal manipulations should be reduced to the minimum.
3. Removal of the gallbladder is indicated in all conditions in which it is diseased.
4. In selected cases the operative treatment is not complete until exposure and exploration of the common bile duct has been done, and conditions found therein properly treated; our rule for this additional procedure of exposure and exploration of the common bile duct is this: The common bile duct is to be exposed and explored in all cases, a, in which there is jaundice or in which there is a history of jaundice; b, in which there is associated pancreatic disease; c, in which the gallbladder is found to contain many little stones; and, d, in which stones can be felt in the common or hepatic ducts. The following cases illustrate the working of these simple rules:

CASE V.—S. L., an ironworker, thirty years of age. He had been a perfectly normal, healthy individual until the beginning of his present illness, without marked constipation, and never having suffered from indigestion. He was able to do his work without undue effort, and ate and slept well,—until a month ago. Present illness: A month ago the patient awoke with no more definite symptom than distaste for food. He went to his work without eating and continued without food for twenty-four hours, simply because of complete loss of appetite. At the end of this twenty-four hours he was seized with a severe pain in the pit of the stomach, had a sour taste in his mouth, heart-burn developed, and he began to belch gas. Six

hours later he vomited. He began to notice that his skin was discolored. He was compelled to take to his bed, and he remained there for three days in about the same condition, namely, with heartburn, pain in the stomach, belching of gas, and an occasional attack of vomiting. At the end of the third day he was able to leave his bed and call on his doctor. At this time he was markedly jaundiced. Under medication he improved somewhat but was never able to resume his work, and eventually—a month after the onset of the disease—he came to the hospital for treatment.

Examination revealed a man profoundly jaundiced, complaining of marked pain in his abdomen. He did not appear to be acutely ill. Abdominal examination showed that there was slight tenderness all over the right side of the abdomen, and over the epigastrium in the median line. The most marked tenderness was over the location of the pylorus. There was slight, but distinct, rigidity in the right upper quadrant. X ray examination gave no direct evidence of gallstones. The Wassermann was negative. Temperature was normal, and pulse varied between 64 and 90. At no time did his temperature rise above 99°, until after operation. Clinical diagnosis: Infectious disease of the biliary system.

Operation: a. Exploration; right transrectus incision over the gallbladder; the gallbladder itself did not appear to be the focus of trouble, there was no change in its color, no adhesions, and no thickening of its coats; there were no stones in the gallbladder. There were many enlarged lymph nodes about the head of the pancreas and at the junction of the cystic and common ducts; the head of the pancreas was large—as big as the clenched fist—soft and bulging forward through the encircling grasp of the duodenum. The neck and body of the pancreas were not enlarged; the foramen of Winslow was patent; the common bile duct was enlarged but did not show any inflammatory change; there was no fat necrosis and no effusion of fluid into the peritoneal cavity. b. Operative diagnosis: acute pancreatitis of the head. c. Treatment: The gallbladder was removed; the common duct was opened, explored for stones or debris, and none found; a No. 10 French catheter was sutured into the common duct and the abdomen was closed.

Postoperative course: The patient made a smooth operative recovery; drainage of bile reached its high point on the fifth day after operation when 600 c. c. were collected. During the next six weeks the flow of bile averaged about 300 c. c. a day, in addition to which amount a certain leakage into the dressings occurred. At the end of the third week the jaundice was imperceptible.

The next case serves to emphasize the early occurrence of infectious disease of the biliary system, and is reported for the purpose of again calling attention to the fact that disease of this system is not confined to middle life:

CASE VI.—Miss S. K., twenty-four years of age, born in Russia. This patient had been sick ever since she was six years of age; she had always had stomach trouble. She complained of fullness and discomfort after eating, especially after a meal in

which there was a large amount of meat. The sense of fullness and discomfort would come on immediately after eating and would last for about two hours. She had never suffered from constipation. From time to time she had suffered attacks of pain on the right side of the abdomen, these attacks having increased in severity and frequency in the past two years. Three months before admission she suffered an especially severe attack of abdominal pain and was advised to come to the hospital for treatment. Examination: The patient was anemic and rather thin. There was no marked abnormality except in the abdominal region; here there was marked pain and tenderness along the entire right side of the abdomen, with a slight amount of muscular defense; distinctly tender spots were discovered over the region of the appendix and the gallbladder. Her urine contained albumin and hyalin and granular casts. Temperature and pulse were normal. White blood count showed a total of 10,800 cells, seventy-six per cent. of which were polymorphonuclear. Diagnosis: Chronic appendicitis and chronic cholecystitis.

Operation: a. Exploration: Through an incision placed midway between gallbladder and appendix regions, and transrectus in type, both gallbladder and appendix were found buried in adhesions. These adhesions by their attachment to the hepatic flexure and to the caput coli, respectively, markedly limited the normal motility of the colon. b. Operative diagnosis: Chronic appendicitis and chronic cholecystitis. c. Treatment: Gallbladder and appendix removed after a clean dissection of the surrounding adhesions. The abdomen was closed about a drainage tube, No. 30 French, leading down to the duodenorenal recess.

Postoperative course: The patient's recovery was decidedly stormy for a few days, and there was some drainage of bile from the wound for about ten days. Following the removal of the tube on the third day her condition improved and she left the hospital well on the road to complete recovery.

We have observed drainage of bile from the wound in a certain small percentage of our cholecystectomy cases in spite of the fact that care is always taken to tie off the cystic duct close to its junction with the common duct, and always separately from the cystic artery. Drainage of bile unquestionably comes from the blowing off of this ligature. We think it likely that this is the result of sphincterospasm at the lower end of the common duct, induced by the trauma of operation. It is of minor importance and except for the necessity for a few more dressings it does no harm. It is possible that the use of a drainage tube favors leakage from the stump of the cystic duct; we feel that the security afforded by the temporary drainage more than compensates for the annoyance of the occasional case which exhibits biliary drainage for a day or two.

CASE VII.—Mrs. I. S., born in Russia, thirty-two years of age. This patient was operated on nine months before admission to the first division of Fordham Hospital. Before this first operation she had complained of stomach trouble which had persisted for a number of years. She had suffered

from the usual type of fullness in the epigastrium after meals, belching of gas, and constipation. In addition to these symptoms she had suffered pain over the region of the gallbladder for the year previous to operation, and before this operation she had noticed a tender spot at the free border of the ribs to the right of the median line. Immediately following her operation she complained of the same pain and when she was eventually discharged from the hospital her condition was not improved. Examination: The patient was thin, anemic, and of sallow complexion. Her chief complaint was constant pain in one spot, over the region of the gallbladder, associated with persistent indigestion. There was a scar in the abdominal wall at about the level of the umbilicus, two inches in length. She said that the pain occasionally radiated to the groin and thigh. She had never been jaundiced, and had never had clay colored stools.

We, therefore, were faced with this proposition: A patient who had all the signs of chronic cholecystitis but who had been subjected to an exploratory operation only nine months previously as a result of which the operating surgeon had caused to be recorded that "gallbladder, duodenum, pancreas, and pelvic organs were all negative." We were moved to stick by our guns in spite of the findings at this operation, and subject this patient to reoperation for chronic cholecystitis. The determining factor lay in the scar of the previous operation; we felt that thorough and definite exploration of the condition of the gallbladder could not be done through a wound only two to two and a half inches long, and placed at the level of the umbilicus or a little above. In fact, we feel that in order definitely to rule out gallbladder disease the surgeon must see the gallbladder as well as feel it; palpation of the gallbladder and the ducts with the tips of the fingers may detect the presence of gross lesions such as stones, but will fail to detect the finer—but very definite and significant—signs of infectious disease, some of the most delicate, and significant, of which lie not in the gallbladder itself but in the contiguous peritoneum.

Operation: a. Exploration; the abdomen was carefully opened beside the old scar. A mass of adhesions firmly bound the small intestines to the parietal peritoneum; at its upper end this mass of adhesions, reinforced with omental grafts, involved the hepatic flexure of the colon and the edge of the liver, the upper right quadrant of the abdominal cavity being completely shut off from exploration by this mass of new formed tissue. In order to complete exploration of the gallbladder region it was necessary to resect these adhesions, and this was done, making use of sharp dissection and ligation where necessary. Coming down upon the edge of the liver in the gallbladder region it was seen that the hepatic flexure of the colon was firmly united to the liver at this point; in freeing these adhesions the edge of the liver was exposed and it was then found that a small process of liver tissue, about two inches in width, hung down over the gallbladder completely hiding it. This little canopylike process was turned upward and the gallbladder, the centre of a mass of adhesions, was seen. b. Op-

erative diagnosis: Chronic cholecystitis. c. Treatment: The gallbladder was freed of all adhesions down to the junction of cystic and common ducts; the cystic artery was ligated and turned aside, and the cystic duct ligated just above its junction with the common duct, and cut away. Tube drainage was introduced to the duodenorenal recess and the abdomen closed.

Postoperative course: Immediate operative recovery was satisfactory; the patient still suffers from some stomach trouble, and a little tenderness along the scar, together with vague abdominal pains. We do not feel that her progress is as rapid as we should like to see it but feel that we should not expect a quick and easy recovery in a patient who has been twice subjected to laparotomy within a period of a year.

It seems to be a more or less generally accepted opinion that it is very difficult to determine positively by palpation plus visual inspection the condition of the gallbladder, when the pathological condition of that organ is in a quiescent stage; is it not likely that a pathological condition of the gallbladder expressed only in perivesical adhesions of the cobweb type may be overlooked when examination is made only by palpation with the tips of the fingers, and through an inadequate incision?

The following case history indicates the value of the history in biliary system disease, and the comparative lack of value of physical examination.

CASE VIII.—Thomas C., thirty-eight years of age, a bookkeeper. His family history had no bearing on his present condition. His past history indicates that he had suffered from pulmonary tuberculosis in an active stage some three years ago. Present illness: For the past nine months the patient had suffered from loss of appetite, constipation, and pains in the abdomen. Nine months ago the first attack of abdominal pain occurred, and it had been repeated at various and irregular times. The duration of the intense pain had frequently been six hours. Vomiting had always relieved him. Two to three hours after meals had been the favorite time for the appearance of a painful attack. He had never been jaundiced, but had noted clay colored stools on several occasions. Physical examination: The patient was a rather slender, anemic male. There was nothing about his objective examination to indicate disease. Specifically there were no tender points, masses, or areas of muscular defense in the abdomen.

Operation: The appendix was chronically inflamed; it was removed. The gallbladder was surrounded by many delicate adhesions, and contained many small stones. The pancreas was normal, and the foramen of Winslow patent. The cystic and hepatic ducts were much dilated, and the common duct was at least a half inch in diameter. The common duct was opened, explored with a scoop and a small stone removed from the ampulla. The common duct was drained with a No. 10 French catheter, and the abdomen closed in the usual manner after the removal of the gallbladder.

Again the close association of the attending surgeon, the neurologist, and the orthopedist, proved of great value to the following patient:

CASE IX.—T., a boy of sixteen, injured his left elbow a month before admission to the hospital. The injury was treated as a dislocation, but function did not tend to return after reduction had been accomplished. He came to the hospital complaining of inability to extend the forearm on the arm, pain over the injured joint, and loss of sensation in the skin of the little finger and half the ring finger. Examination revealed a firmly fixed elbow. The forearm was held at an angle of 90° with the arm, and motion was limited to an arc of about 10° . The elbow was swollen and tender, especially over the inner aspect, and over the internal condyle of the humerus. Passive motion beyond the narrow limits mentioned produced much pain. The finger grip was also limited because of pain. Neurological examination (Dr. Joseph Byrne) indicated a partial division of the ulnar nerve. X ray examination (Dr. I. J. Landsman) disclosed an old fracture of the internal condyle of the humerus, with an absence of the epicondyle at its proper position, and the presence within the joint of a foreign body—probably the missing epicondyle. Dr. Byrne advised open operation with suitable neurorrhaphy. The orthopedist (Dr. S. W. Boorstein) also advised immediate operation for the correction of the ankylosis, the cleaning out of the joint cavity, and the early restoration of motion. In the meantime the Wassermann had proved negative.

Operation: A semicircular incision with convexity toward the radial side of the arm exposed the inner aspect of the joint. The ulnar nerve was recognized above the joint and was carefully dissected from its bed to a point corresponding with the extreme lower level of the joint: here the nerve was seen to be injured, a well marked fibrocystic mass occupying the nerve sheath at this point, the lesion not affecting the entire circumference of the nerve. Dissection of the nerve was carried out to a point about a half inch lower than the point of ganglion formation, and the nerve was gently drawn aside. The capsule of the joint was incised and the internal epicondyle found to be missing from its normal position. Investigation of the joint cavity proper disclosed the missing internal epicondyle lying between the articular surfaces of the humerus and ulna, with its articular surface looking upward and the line of fracture impinged upon the articular surface of the ulna. This little mass of bone was removed and the capsule sutured. The ulnar nerve was freed of all surrounding scar tissue, the little cystlike mass was punctured, and the nerve allowed to drop back into its normal position. The wound was closed without drainage. The elbow was fixed in marked flexion. Postoperative course; the patient made a smooth recovery, and primary union was secured. Active motion was encouraged on the eighth day, and passive motion and massage was added in a day or two. Dr. Byrne's examination showed that there was improvement in sensation on the tenth day. The patient was discharged from the hospital at the end of three weeks, improving in a satisfactory manner, and withdrew himself from observation at the end of about a month, well on the road to complete restoration of function.

The following case well illustrates the wisdom of close association between the attending surgeon and the members of the associated staff, especially the röntgenologist. We are indebted to Dr. I. J. Landsman for the careful and repeated x ray examinations of this case which enabled us to eventually clinch the diagnosis:

CASE X.—S. H., male, thirty-two years of age, married. His family history was not significant. He denied lues and there was no evidence, direct or otherwise, of such infection. He had never been operated on. His history as it bore upon the condition for which he came to the hospital was as follows: He had always been in fair health up to fourteen years ago; at that time he was seized with an attack of abdominal cramps, with obstinate constipation, but no vomiting. Ten years ago he had a similar attack, and again seven years ago. In the intervals between attacks he enjoyed moderately good health, though he was never robust. Since the attack seven years ago he had had occasional attacks of vomiting. About two years ago he showed symptoms of pulmonary tuberculosis and since that time he had never been well. Eight months ago the patient had an attack of abdominal cramps that lasted for three weeks. Seven weeks ago he had a similar seizure, and in this attack the pain radiated to the back on the right side; this pain recurred at irregular intervals throughout the day, each attack lasting about five minutes. He always had the pain if he went any unusual time without food, and he had moderate comfort for about one hour and a half after his meals; the pain had a tendency to localize in the right iliac fossa. During this period of seven weeks he had repeated attacks of vomiting, had persistent sour taste in the mouth, had gaseous eructations, and had been obstinately constipated. He says that he never had a satisfactory movement of the bowels, cathartics and enema being used continually. In this latest attack he had great difficulty in urinating; he found that he was not able to void while standing, nor while lying upon his back or right side—it was necessary for him to lie upon his left side in order to void, and even then urination was difficult and painful. Since the beginning of this latest attack the patient had lost sixteen pounds. Examination: His appearance was that of a chronically ill individual who was suffering from a distinct toxemia; he was emaciated, and the conjunctivæ were blanched; his skin was moist—wet, in fact—with a clammy sweat, and his eyes were unnaturally bright, and the mucous membranes of his nostrils and lips were a brilliant carmine. His mental condition was dull. His lungs showed the evidence of chronic inflammatory disease in a quiescent stage. There was nothing noteworthy about the extremities. The abdomen was markedly distended symmetrically, and there was a general tenderness. Two masses were discovered, one of these about the size of a baby's head and the other a little smaller; these masses were very hard to the touch, slightly tender; the smaller one was rather freely movable, not connected with the larger one, but superimposed upon it; the larger mass was firmly fixed just above the symphysis pubis, a little to the right of the median

line; rectal examination showed that this larger mass almost completely filled the pelvis, and could be moved slightly by pressure from within the rectum, through the rectal wall. Cystoscopic examination was impossible because of the firm impaction of this larger mass in the pelvis. Examination of the urine disclosed perfectly normal urine—quite clear.

Shortly after admission the patient's temperature rose to 104° and the pulse to 108. After catharsis and the use of the enema the temperature returned to normal, although the amount of the bowel movement was slight and no gas was passed.

The x ray examination: The first examination was made at a time when the more movable mass was in the region of the right kidney, and the plates showed what appeared to be a very large calculus in the right kidney. Reexamination disclosed a very large mass in the pelvis, the more movable of the two masses having deserted the kidney region and come to lie in close contact with the larger mass, in such a way as to cause the blending of the two shadows. In view of the urinary difficulty experienced by the patient and because of the density of the mass and its position, it appeared that we might have to deal with a very large vesical calculus; however, the bladder was filled with collargol and the patient reexamined, when the mass was clearly shown to lie outside the urinary tract. By a process of exclusion the diagnosis was arrived at. Operation: Median hypogastric incision; as soon as the peritoneum was opened a tremendously dilated and hypertrophied sigmoid came into view, within which lay the tumor; an attempt was made, by working from within the abdomen and against the fingers of an assistant's hand within the rectum, to break up the mass, but this was found to be impossible both because of the hardness of the lump and because the finger within the rectum could not reach it. The sigmoid was incised in the anti-mesenteric line and a huge enterolith turned out. A second, slightly smaller, enterolith was removed from the afferent loop of the sigmoid, and several smaller rocklike pieces of fecolith were removed from the portion of the sigmoid immediately below the primary mass. Firm lockstitch suture of the sigmoid wound was made and a row of Lembert stitching covered the watertight stitch. The empty sigmoid was seen to be in a state of very active peristalsis. The peritoneal toilet was completed and the abdomen closed with a drainage tube led down to the sigmoid wound. Postoperative course: The patient reacted well from the operation. There ensued suppuration in the abdominal wound. Movement of the bowels was very sluggish and unsatisfactory, and we were convinced that the toxic condition, noted before operation, was entirely unchanged by the operative relief of the mechanical condition from which he had suffered. At the end of ten days the suppurating wound in the abdominal wall was improving, but the patient's general condition did not improve; at no time since operation had there been any vomiting. When the patient's temperature eventually arrived at normal, and the pulse dropped to 60, it was apparent that, while the bowels were moving fairly well, the patient was suffering from

the accumulated toxins of months of obstipation. This patient was removed from the hospital in the fifth week of his convalescence, and two weeks later died in another institution. The cause of death was apparently this peculiar toxic condition from which he suffered, and which persisted unchanged after the condition which had called it into being had been disposed of.

CELLULAR THERAPEUTICS,

By FRANK THOMAS WOODBURY, B.A., M.D.,
Edgewood Arsenal, Md.

Lieutenant Colonel, Medical Corps, U. S. Army.

The disabled cell.—The cell is the unit of altered structure and disordered function. No treatment can be rational which does not consider the cell because the sum total of physiology and pathology is but the aggregate of cellular physiology and pathology. Cellular wellbeing is health; cellular disability is ill health. The relative seriousness of the symptoms, signs, complications, sequelæ and termination of any disability will be directly proportionate to the importance of the functions which the affected cells normally perform.

The physiological needs of cells.—All cells need, 1, a constant supply to the cells of reparative and building material and kinetic energy (furnished as dissolved digested food and oxygen), chemical messengers from the endocrine glands and internal secretions and antitoxins. This is the duty of the arterial blood stream. 2. A constant flow from the cells, draining off excess of blood (thus preventing stasis) whereby wastes and formed products (the result of their life activity and special function) are removed. This is the duty of the lymph channels and the venous system. 3. A coordinating government by vibratory messages from the cerebrospinal sympathetic system.

Rational therapeutics regards the cell and its activities and considers the appropriate treatment to remove disabling causes and restore the relationship outlined above, viz., opening the channels of blood supply to the disabled cells; opening up the channels of drainage from them, and controlling the nervous messages. Rational therapeutics goes even farther. It assists the individual cells to throw off their incubus, spew out their poison, and absorb kinetic energy and reparative and building material, thus renewing their accustomed relation to the rest of the body.

Nature has but one remedy—blood. Blood is the *vis medicatrix naturæ*. Nature's effort is always to afford the disabled cell an increased blood supply. If we employ this agent we follow Nature and the cell, if viable and not crippled, will then build itself up and resume its function, if crippled it may be helped by therapeutic agents acting directly on and in the cell; if dead, the leucocytes will remove the corpse.

If Nature were always successful in her effort, no therapeutic assistance would be required. The body would be its own physician in great as well as in small disabilities, but unfortunately in the desire

to protect the injured cell and to restore continuity and function, deplorable results occur which may be seen in any clinic and most frequently among those races or creeds whose therapeutic knowledge and skill are primitive or nonexistent. Examples of these failures of Nature are: spontaneous amputation, necrotic sphacelus, abscess, intestinal adhesions, bony deformities following fractures, ankylosis following injury or inflammation of joints, cardiac hypertrophy, hob nail liver, pancreatitis, nerve atrophy with loss of motor and sensory function, neuromuscular cripples from neuritis, toxic goitre, uremia from nephritis following toxemia, or diarrhea, etc. Warned by these unhappy results we try to avoid Nature's mistakes in our efforts to aid her.

THE BASIS OF THERAPEUTIC PROCEDURE.

In making our choice of agent or method we should ask ourselves the following questions, the answers to which will be our guide in selection and application of our treatment: What cells are suffering altered function? What is the nature of the alteration? What are the causes of the altered function? How would Nature restore the cells to normal function? What aid does Nature need to bring about the normal function and what agents have we with which to afford that aid? Which of our agents is preferable? What degree of restoration to normal is attainable?

Proceeding in this manner we may find ourselves considering any of a thousand and one pathological conditions, but all resolving themselves into cellular disability, altered blood supply, impaired drainage. It is true that surgery relocates the dislocation, replaces the broken ends of fractures, transplants tissues to restore function and continuity, removes harmful growths, drains toxic abscesses, restores mechanical ability and relieves pressure, but surgery is only a special branch of therapeutics and must in the last analysis consider the cell, which is the agent to complete the restoration of continuity and function, and the blood supply, the *sine qua non*. Surgery is always a violence done to repair a violence or prevent a violence.

NATURAL THERAPEUTIC AGENCIES.

To supply affected cells as well as all cells with the life giving, life maintaining blood, Nature employs the following combination of agencies working in harmonious balance: Cardiac integrity and rhythm; vascular continuity and permeability; lymphatic continuity and permeability; normal blood constituents, which in turn depend upon adequate qualitative and quantitative diet; alimentary adequacy to convert diet into soluble kinetic energy and reparative and building materials; pulmonary respiratory exchange and capacity; renal, dermal and pulmonary excretion; endocrine balance between pituitary, thyroid, adrenals, and gonads; and periodical removal of waste residue from diet; and, finally, automatic (or reflex) cerebrospinal sympathetic control and coordination including special sense organs functions.

When this combination of agencies gets out of proper balance we have first the cells immediately disabled and then in coordinating series other cells which they control or with which they are associated

in bodily functions which may, and usually do, create a vicious circle whose point of creation we must discover.

CLASSES OF DISEASE.

There are only two general classes of diseases: Class I, diseases not transferable (noninfectious), and, Class II, diseases transferable (infectious).

The causes of the first class are: Inherited anomalies; poisons ingested, inhaled or absorbed; traumatisms, mechanical, thermal, electrical; and disregard of the physiological needs of the body as an organism whereby the harmonious relations of the agencies mentioned above are destroyed or hindered. The second class has the first class as a predisposing cause and live parasitic plants and animals as its exciting cause.

THERAPEUTIC AGENTS WHICH REMOVE DISABLING CAUSES OF CLASS I.

1. Exercise: This includes developmental, corrective and remedial exercise.
2. Dietetics: This comprises a chemical and physiological consideration of foods; rations adopted to work, curative and restorative diets.
3. Heat: This includes, a, convection heat obtained by hot water baths, electric hot pads, hot packs, hot water bottles, hot air, hot mud, vapor and shower baths; b, penetration heat obtained by light baths, diathermy, induction, condensation and monopolar high frequency d'Arsonval, Tesla and Oudin currents, brush and spark static current; c, convection cooling or abstraction of heat by cold immersion, ice baths, cold packs, Scotch douche, needle shower, sea baths.
4. Vibration: a, Mass vibration obtained by massage (manual and mechanical); b, tissue vibration obtained by faradic and sinusoidal electricity; c, cellular vibration obtained by actinio (spectral) light; high frequency alternating and oscillating electricity (d'Arsonval, Tesla, Oudin) in the form of induction, condensation, bipolar and monopolar application, static electricity in the form of wave current, induced current, spark, spray, brush and breeze, röntgen ray and radium ray.
5. Antitoxins and vaccines.
6. Opothrapy: The use of glandular substances, glandular extracts and glandular active principles as well as the use of drugs directly affecting the activities of the endocrine glands.
7. Surgery.
8. Galvanism: Dissimilar and characteristic effects of positive and negative poles.
9. Drugs, including ionization by galvanic current.

AGENTS AFFECTING CELLULAR PHYSIOLOGY.

1. Static electricity; the wave, induced, spark, spray, brush and breeze.
2. Bipolar indirect; Tesla or d'Arsonval high frequency current using the effluve, spark or vacuum tube.
3. Direct bipolar application causing thermal penetration at any degree up to incineration according to electrode used.
4. Monopolar high frequency—Oudin current.
5. High frequency condensation and induction.
6. Light rays: Krohmyer or Hanovia lamp or low power Mazda lamps.
7. Röntgen and radium rays.
8. Drugs which can be carried by ionization, with a galvanic current, and
9. Opothrapy.

THERAPEUTIC AGENTS WHICH REMOVE THE DIS-
ABLING CAUSES OF THE SECOND CLASS OF
DISABILITIES BY BEING BACTERICIDAL
WITHIN THE LIVING TISSUES.

Röntgen ray and radium ray; light, especially ultraviolet rays; d'Arsonval and Tesla bipolar (indirect and direct); Oudin current; galvanic positive electrode; antitoxins and vaccines, and antiseptic drugs, especially when ionized by the galvanic current.

USE OF PHYSICAL AGENTS.

The physical agents mentioned are directly indicated in cellular therapy, but to employ them successfully requires an intelligent acquaintance with the physics of each form as well as their physiological effect, and this also implies a thorough knowledge of the technic, that is, the machines and apparatus, their dose and mode of optimum application, to obtain the desired therapeutic effect.

These physical agents have been much neglected because of the failure of medical schools to ground their students in the science of physiology and the art of gymnastics, the science of nutrition and the art of dietetics, the science of electricity and the art of electrotherapeutics, the science of vibration and the art of massage (molar, cellular and molecular), the science of radiant energy and the art of phototherapy, röntgen therapy, and radiotherapy.

This neglect has led our fraternity into the camp of the pharmaceutical nihilist, and expectant treatment which is but one step removed from absent treatment and mental healing. It has led us to look askance at what we did not understand and be satisfied to see the irregular practitioner seize upon these agents as his peculiar field and call himself by a new name. It has permitted medicine to hand over to surgery many conditions which should never require the knife. It has made gynecology almost synonymous with surgery.

Cellular therapeutics demand the use of these agents. It will be impossible to make therapeutic stabs in the pathological dark when we turn our attention to cellular physiology and cellular pathology because we will practice cellular therapeutics.

The cell is the unit of altered structure and disordered function.

CHOLESTEROL THORAX

Report of a Case.

BY JOSEPH H. BARACH, M. D.,
Pittsburgh, Pa.

Since cholesterolin is at most only infrequently found it will not be amiss to review without too much detail what is generally known about its occurrence in the body. It is defined as a monatomic unsaturated secondary alcohol or a complex terpene; its chemical formula is said to be $C_{27}H_{46}O$. It occurs in small amounts in nearly all fluids and juices of the body; in the blood and lymph it exists as a fatty acid ester; in the bile it exists in a free state. Cholesterinemia occurs when there is obstruction to the free flow of bile into the intestines. It is especially abundant in the brain, nerve tissues,

and semen. It appears in the contents of the intestine, in the excreta and in meconium. Ordinarily it is not recognized in the tissues, but under certain pathological conditions necrotic and degenerative crystals are found. They occur in atheromatous areas of the aorta, in arcus senilis, retinitis, atheromatous cysts, in pus, in sputum, in tuberculous masses, old transudates, in tumors undergoing necrosis, in xanthomia (xanthomia tuberosa multiplex occurring about the joints), in gallstones, in old inflammatory processes of the tunica vaginalis and testes with hydrocele, in fluid long retained in a shut off gallbladder, and in old pericardial effusions. From the sites enumerated above, it may readily be seen that in certain locations following the accumulation of fluid, if that fluid remains stagnant for a sufficient length of time, a deposit, or a crystallization of cholesterolin, may occur.

The fluid of cholesterol thorax may be mistaken for chylous or pseudo-chylous fluid if one were to rely upon the macroscopic appearance of the fluid. True chyle will show a fat content of about ten per cent. and small fat globules, while pseudo-chylous fluid will have a fat content of about one half of one per cent., and its fat globules are much larger. Whereas the chylous fluids are milky in appearance, the cholesterol fluids are more of the color of butter.

CASE.—Mr. J. H., aged sixty-seven, a native of Ireland, a laborer, was admitted to my service in the medical ward of the Presbyterian Hospital on December 8, 1919. He had just recovered from a right apical pneumonia. His history revealed the fact that his last illness had occurred thirty years ago, prior to his coming to this country. At that time he suffered from an attack of pleurisy, with which he was ill for two months. Since that time he had worked regularly for thirty years, and did not recall that he had experienced any physical discomfort.

Physical examination revealed a poorly nourished man, with marked arcus senilis; his radials and other superficial vessels contained numerous atheromatous areas and were of pipe stem hardness. His cardiac dullness was increased to the right, left border extended 10.5 cm. from the median line. Epigastric pulsation was prominent. No murmurs could be detected. The first diagnosis was chronic myocarditis, but later events warranted our giving up this diagnosis. When the effusion was removed, the heart settled down to a simple sinus irregularity and showed no evidences of myocardial deficiency.

Examination of the lungs showed that his right apical pneumonia had not completely resolved. On the left were found the usual physical signs of pleural effusion. This diagnosis was verified immediately by aspirating. His temperature for two days had been not over 100° F., his pulse rate 90-100, but his respiratory rate was 32-40. He had leucocytosis and lymphocytosis. The aspirated fluid, which presented the physical appearance of pus and was entirely odorless, was sent to the laboratory for culture. The following report on the examination was wholly unexpected: No pus cells, no bacteria, sediment consists of rhomboid crystals—cholesterin.

The following day, with an aspirator we removed

450 c. c. of this fluid, which gave the patient considerable relief. Two days later physical examination revealed a characteristic metallic tinkling and other evidences of pneumohydrothorax. This was verified by fluoroscopic examination. His condition did not change much and twenty days later, owing to a reaccumulation, we removed 960 c. c. of fluid of the same character. After this he steadily improved, and was walking about two weeks later. At no time did we find evidences of a lung abscess or a tuberculous infection.

The history and course of this case suggests a latent pleural effusion with precipitation of cholesterol, and after the first aspiration, a reaccumulation of serum. The fistula from which metallic tinkling occurred was probably produced by removal of the fluid which had acted as a support to the atelectatic lung. I have previously explained how metallic tinkling is produced (1). That the lower lobe of the left lung was collapsed was seen at the fluoroscopic and radiographic examination.

To the naked eye the fluid in this case appeared to be light yellow in color, of the shade of butter. Upon standing, it separated into two parts, the lower half being fatty, and the upper being a slightly opalescent straw colored fluid. Microscopic examination showed no fat globules, no pus cells, and no bacteria. The only visible constituents were the characteristic rhomboid cholesterol crystals. The reaction to Benedict's solution for sugar was negative. The fluid showed no changes after standing twelve months.

Two cases of cholesterol in pleural effusions were recently reported by Sharpe (2). The first case occurred in an adult, thirty-four years of age, who had an encysted pleural effusion with a straw colored fluid, containing some cells. The cells were polynuclears eight per cent., endothelial fifteen per cent., and lymphocytes seventy-seven per cent. After aspiration the patient recovered and worked for six years. In the seventh year he had a recurrence of symptoms referable to the chest, and aspiration showed a fluid free from cellular elements containing many cholesterol crystals. The sputum showed tubercle bacilli.

The second case occurred in a male child who at the age of two years had an empyema. Seven years later symptoms developed and a left pleural effusion was diagnosed. One and a half pints of spangled fluid were removed. One month later the patient was again tapped and fifty-six ounces of fluid containing cholesterol crystals were removed. At a third tapping two pints of pus were removed.

Alexander has also reported a case of pericardial effusion in which the fluid had the appearance of gold paint, produced by cholesterol crystals. The patient was a male, aged thirty-two, who had been complaining of symptoms for the past five years, which were diagnosed as hypothyroidism. Superimposed upon these were cardiac symptoms of a few months' duration which led to the diagnosis of a pericardial effusion. He was discharged from the hospital after six weeks and resumed his work. Thirteen weeks later he was readmitted, his pericardium was aspirated and three pints of scintillating gold paint were removed. At the end of

two months the patient left the hospital free from symptoms.

Comment.—One thing stands out clearly in the cases here cited, and that is, in not one of them did the cholesterol deposit occur at the time of the primary attack upon the diseased part. The deposit or precipitation of cholesterol crystals occurred in inflammatory exudates within serous sacs, following the subsidence of acute inflammatory processes. The cases cited show that the antecedent history of a deposit of cholesterol may be five or as long as thirty years.

UNDERLYING FACTORS IN GOOD POSTURE.*

BY C. WARD CRAMPTON, M. D.
Battle Creek, Mich.

Gravity is continually pulling down the human body. The erect position of man makes him peculiarly subject to its influence. He is balanced upon a small base and must necessarily keep his balance lest he fall. At various places in his anatomy there are joints which must be kept from bending too far, for the more nearly vertical the body is held, the less force need be exerted to hold it erect. The ankle, knee, hip and the whole spinal column up to the cranium must be kept in balance with the superincumbent weight squarely above. The contents of the trunk are more fluid and tend to flow downward. They also must be held up against gravity.

Bad posture is essentially a ptosis or a group of ptoses. Ptosis is a downward displacement or depression of the various body parts. It is found in the drooping of the head, shoulders, ribs; frequently in the depression of the stomach, intestines, and other abdominal organs; in forward, backward and lateral curvatures of the spine. Any of these gives the body an appearance of sagging downward. There are four kinds of ptosis; skeletal, visceral, circulatory and emotional. They are more often found associated than singly. Each symptom evidences a condition which is the result of low vitality and which in turn tends to cause low vitality, thereby establishing a vicious circle.

TYPES OF PTOSIS

Skeletal ptosis is the downward displacement of bones, and is shown in the drooping of the head, the exaggeration of the normal curves of the spine, the falling in and down of the chest. These cause a decrease in standing height as compared with horizontal length, a comparison which is a definite test of poor skeletal posture. The less the decrease in the standing height, the better the posture. Skeletal ptosis is caused by weak tone, or the relaxation or chronic weariness of the muscles which hold the body erect. It is the natural adjustment of the body to fatigue.

*Address of Temporary President of the Association of Institutions Giving Normal Instruction in Physical Training delivered at Waldorf-Astoria, New York City, April 10, 1920.

Visceral ptosis is the downward displacement of the internal organs and is usually accompanied by skeletal ptosis. It may be local, that is, one organ only may be displaced; or general, in which case the whole body contents sag downward. In the latter case the chest is flattened, its capacity is decreased, and the abdomen becomes protuberant, the lower ribs often bulging. It is the result of constitutional inferiority, low vitality or bad habit. Its presence may be ascertained by percussion of the organs to determine their position, by the use of the x ray and by comparing the girth of the chest and the abdomen.

Circulatory ptosis is the downward displacement of blood and its collection in the abdominal veins and arteries. The splanchnic veins in the abdomen form the most capacious system of blood vessels in the body, and if they are relaxed and distended, a large amount of the blood which should be in other parts of the body drains into them. In the erect position, these vessels continually work against the force of gravity. They are kept from distention by the contraction and tone of the muscles in their walls, which are under sympathetic nervous control, and by the contraction and tone of the walls of the abdomen. If there is an insufficiency of nervous control or if the abdominal wall is weak, permitting relaxation, the resistance to the pressure of gravity is lessened and ptosis results.

An emotional ptosis is a depression of the spirits. The terms dejected, depressed and downcast are all derived from descriptions of physical states. By racially old practice and habit these expressions are applied to emotional states and refer to unpleasant feelings of the asthenic type. Other more or less colloquial terms are downhearted and down-in-the-mouth. These terms, descriptive of emotional ptosis, derived from physical conditions, indicate the correlation between the mental and the physical.

CORRELATION OF PTOSES

All four ptoses as a rule occur together. Any one of them tends to cause the others but the relation of ptoses to each other is not primarily that of cause and effect. They are related to each other mainly as effects of a common cause, to wit, lowered vitality.

Ptoses are likely to occur after illness, a period of loss of sleep, chronic digestive disturbances and the like. Therefore, ptoses are not to be removed permanently without the removal of the common cause, i. e. lowered vitality—the very term in itself expressing a ptosis. There are, however, various other influences which bear upon the case.

Hereditary maladjustment.—The biological causes of bad posture are disharmonies, which correspond to the same forms of ptosis. These are due to the fact that evolution has brought the body from a posture of locomotion on all fours with the trunk horizontal, up through gradual stages to the posture with the trunk erect. The body has not yet sufficiently adapted itself to the change, and the various disharmonies remain.

Skeletal disharmony.—The head, instead of being in the long axis of the body, has rotated ninety degrees to this axis. It is kept erect by muscular force only and tends to go forward and downward if

the muscles are weak. Of the changes in articulation, the hip changes and neck changes are relatively well adjusted. The arch of the foot presents a skeletal disharmony of the worst type; the weight of the body comes on the arch, which was never meant for that purpose. Frequently the arch breaks down, causing flat foot.

Visceral disharmony.—In the old horizontal position of the trunk, the internal organs hung from their attachments to the spinal column with sufficient room and in proper interrelationship. In the erect position they hang from the rear rather than from the top of the abdominal cavity. The intestines are heaped in the bottom of the abdominal chamber and constipation and auto-intoxication result. The contents of the chest rest upon the diaphragm, which in turn presses upon the intestines. The abdominal wall tends to relax, allowing the

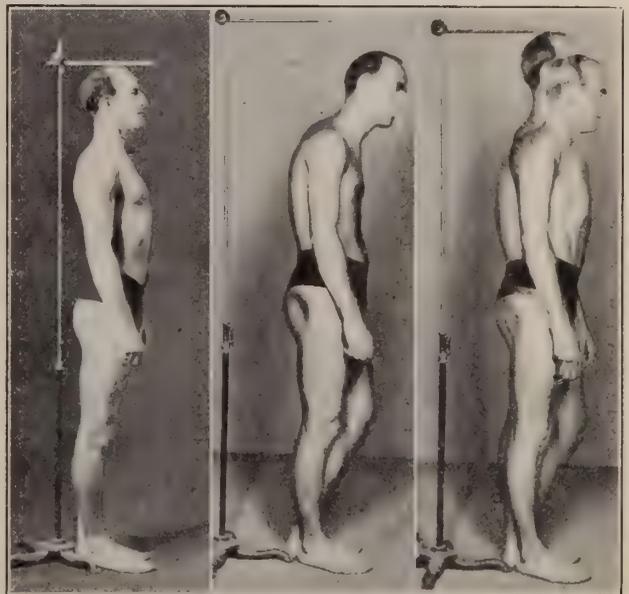

FIG. 1.
Good Posture. Poor Posture Good and Poor Posture

whole body contents to sag down upon the pelvis and causing the abdomen to protrude. The best that can be done to relieve this condition is to keep the chest raised and, by means of strong lower abdominal muscles, to keep the intestines from crowding down.

Circulatory disharmony.—Our physical machinery is relatively weak because of the change of position from the horizontal to the erect. Because it is recent biologically, it is easily wearied, and allows the blood and lymph to go down in response to the influence of gravity. Circulatory disharmony is evidenced in the difficulty that is experienced in getting the blood returned from the feet up to the right side of the heart. This is accomplished by the action of the leg muscles, the contraction and tone of the muscles of the abdomen, which helps to force the blood upward and the suction of the chest (aspiration of the thorax), which lifts the blood out of the abdomen and delivers it to the heart. Circulatory ptosis is relieved by increasing the tone and contraction of the abdominal walls, and by raising the chest, which increases the thoracic aspira-

tion, but most of all by increasing the tone and vitality of the muscles in the blood vessels of the abdomen by hygienic measures.

Lack of vitality or tone.—Anything that causes lower vitality, anything that works against health, and anything that works against happiness, increases the tendency toward bad posture. Bad posture is not so much a cause of low vitality as it is a sign or expression of past or present physical or mental depression. If the person is sick or hurt, the skeletal muscles lose tone and the body droops; if the mind is dejected and low spirited, the physical attitude corresponds to the mental state. Body and mind are depressed together.

Posture and efficiency.—It has been established by statistical tests that physical or mental defect or weakness is related to poor posture. The average record of pupils in the poor posture group has been found to be appreciably lower than the good posture group in attendance, in deportment, in physical activity and endurance, in manual training, and in commercial success after leaving school. It is clear that anything that lowers vitality causes bad posture. To what extent bad posture causes poor vitality is not accurately known. It is certain that by assuming good posture, raising the chest and head, one feels better. This is partly psychological and partly due to an actual improvement in the circulation of the blood.

Limitation of corrective measures.—In the endeavor to correct bad posture by removing causes which result in ptosis, nothing can be done about hereditary disharmonies, and little is possible in resisting the influence of gravity, except the seeking of proper rest and the habitual assumption of corrective positions; but in overcoming the third factor, lack of vitality or tone, physical training finds its great opportunity.

The essentials of tone.—The body is kept erect by bones, muscles, and ligaments. The muscles keep the bones and ligaments in position. Thus, if the muscles are strong and in good tone, they will hold the body parts up properly, the posture will be good, the trunk erect, the chest up and the head held high. These are the signs of vitality. On the contrary, if the vitality is low, the body yields to the influence of gravity and relaxes. Muscular tone continually works against this influence. It is dependent upon muscular training and upon the power of the nervous system which presides over the nutrition of the muscles. This applies to both the skeletal muscles and the muscles of the veins of the abdomen which control blood ptosis.

The muscular element in muscular tone:—1. The nutrition of the muscles which keep the trunk erect, chest high and abdomen flat in a large part determines their tone and their success in doing the work for good posture. Hence, good food, fresh air and the like are fundamental to good posture. 2. The actual strength of the muscles is important, for they must be kept in a state of semicontraction, holding the body straight and its parts adjusted and high. The stronger they are, within reasonable limits, the better. Hence, they must get sufficient special exercise. 3. The muscles which hold body parts in good position against gravity must acquire the structural

habit of being short, for lengthening means giving way, and permits their loads to droop and fall to lower positions. Muscles tend to assume the state in which they are most used; hence, if we desire short muscles, we must exercise them in a shortened state. Thus, we use exercises in which the movement is confined to the proximal (nearest to the trunk), third or half of the arc or movement, and in this we emphasize complete contractions of the muscles we desire to shorten.

The nerve element in muscular tone.—Muscular tone is a continual unnoticed contraction of the muscle which, though practically static, is really due to nerve impulses flowing to the muscle along the motor nerve at the rate of twelve to twenty impulses a second. These impulses come from the motor cells in the interior of the spinal cord and are vigorous or weak according to their nutrition and the amount of fatigue. When they are well nourished and fresh, the muscular tone is good. When they are overcome or exhausted, the muscular tone is correspondingly poor. Hence, nutrition and rest have an increased significance in posture.

When the motor nerve is cut or the motor cells are destroyed by disease, as in infantile paralysis, the muscle loses its tone, becomes weak and anemic and ceases to grow; it becomes atrophic. This proves that the motor cells preside over the nutrition of the muscles, sending them continually what is called the trophic force. This indicates again the rôle the nervous system plays in muscle condition.

The important little muscles surrounding the arteries and veins are supplied with nerves coming from centres in various parts of the body called sympathetic ganglia, and are dependent upon them in much the same way as the voluntary muscles are dependent upon the cells of the spinal cord. Since these muscles control the distribution of the blood, and particularly prevent blood ptosis, the condition of the sympathetic nervous system is of great importance.

The digestive glands—the liver and the pancreas and the muscular walls of the stomach and intestines—are all directed and managed by the sympathetic nervous system. Thus the nerve centres direct processes upon which they themselves depend for nourishment.

The photographs of the excellently built young man should be studied carefully, for they illustrate the important points in the discussion of posture. The photographs were taken within a few minutes of each other. The subject remained standing with his feet in the same place. The only difference is in his slumping from good posture to bad. The cigarette is included because the bad posture produced is a perfect representation of that pose of chronic lassitude, the effect of excessive cigarette smoking.

The decrease in total height amounts, in this case, to four and a half inches. This is not the result of bending the knee, for the right leg is just as straight as it was in good posture. The decrease in height comes from the slumping down of one side of the pelvis, the increase in the curves of the lumbar, dorsal and cervical spine.

The illustration shows clearly the downward dis-

placement of the different parts of the body, which, summed up, make the difference in the total height. The head is downward, tilted forward, hanging heavily upon the posterior neck muscles instead of being evenly poised on the cervical vertebræ. The shoulders go downward. It will be seen, however, that they do not go forward, but the chest rolls downward under the arm, and the back protrudes outward. Notice the whole downward displacement of the chest and the disappearance of the line of the lower ribs.

In good posture the outline of the body from the neck downward over the abdomen is convex, particularly over the thorax. In bad posture this line is concave except for the slight projection of the pectoral muscles. The chest in good posture is deep, the abdomen slim. In bad posture the contents of the abdomen simply drop downward and cause a bulge at the lower waistline. The two photographs clearly show the difference in aspect. The one posture is high, straight, elevated, inspired and strong; the other lax, depressed, downcast and weak.

HOW TO GET GOOD POSTURE

1. *Description.*—In our endeavor to get good posture, children should be informed in a lively interesting way as to what it is. Emphasis should be placed upon the high head, lifted chest, straight back, etc., choosing words which will be of use afterward as elevation cues. Little time, however, need be wasted upon description for the most important thing for the people to know is how it feels to stand in good posture. Before the class, the teacher should demonstrate the various points contrasting the good high erect posture with the lowered poor posture.

2. *Demonstration.*—The teacher of physical training experiences the greatest difficulty in making his pupils understand just why their postures are wrong, and furthermore what kind of effort they should make to correct the bad postures. This was the great fundamental difficulty in the endeavor to get school children to stand up straight. They had been told to stand up straight, but did not know how. Usually they threw the shoulders back and in an endeavor to throw the chest out, stick out the stomach, drawing the hips forward, stiffening the arms straight down to the sides like pokers. This is wrong.

3. *Experience in good posture.*—There are various devices used to put children in good posture. The first one is the use of commands called elevation cues because they are calculated to work against postures. The most important of these are as follows: Stand tall, head up, head high, lift the head, stretch the head upward, chest high, and lift the chest.

Waist flat, lift the waist up, stretch the knees, lift upward from the ankle, and stretch the body upward—all these cues result in increased action of the muscles which keep the body erect. Additional colloquial adjurations may be used by the teacher such as, "try to make the head touch the ceiling," "stand as if you were looking over a fence," "pick up your ears," "make believe you are a soldier," "grow up tall," etc. The commands "chest out," "shoulders back," "hips back," "chin in" and others calling for anterolateral adjustments are discarded.

Words alone will not bring results. A pupil who cannot take correct posture exercises may be stood up with back against the wall and a book placed upon his head. Feeling the wall on his back he will straighten up and try to be as tall as possible. Placing the hand on the abdomen and pressing in and up will help him decrease the lumbar curve. Stretching the arms down at the side, still keeping the shoulders and hips back against the wall will help him straighten up taller.

Once good posture is obtained, a pupil should leave and go about his ordinary business, sitting, standing, working or exercising, but always maintaining the high head and chest position. A full length mirror in which pupils can see their defects and finally their good posture, is valuable to good posture work. Every well equipped gymnasium should have a double or triple mirror permitting the pupil to see himself in profile.

STATIC EXERCISES

The use of the wall and the mirror confine the teacher's attention to the individual. There are certain static exercises which may be used for the whole class. These were the only good posture exercises which I put into official use for all of the eight hundred thousand children in the public schools of New York city, not because there are not other good exercises but because these are the simpler and most effective. It has been found when these exercises are taken there is, by the process of association, a

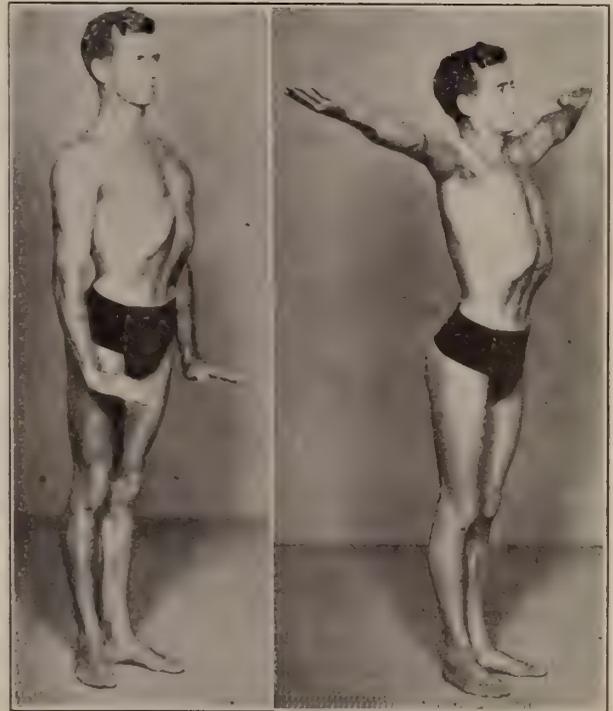

FIG. 2.

Static Exercise No. 1.

Static Exercise No. 2.

straightening up of the body. It is necessary, however, to use them correctly.

Exercise 1.—Stand erect, stretch the arms downward at the side, pointing the fingers forward, bending the hands back on the wrists so the palms are horizontal to the floor. When you have assumed this position, the exercise has only begun. It is

necessary for you to press down as hard as possible toward the floor, still maintaining the hands in exactly the same position, in the meanwhile lifting the chest and head and endeavoring to straighten up as vigorously as possible. This will raise the chest, lift the head and stretch the body most effectively.

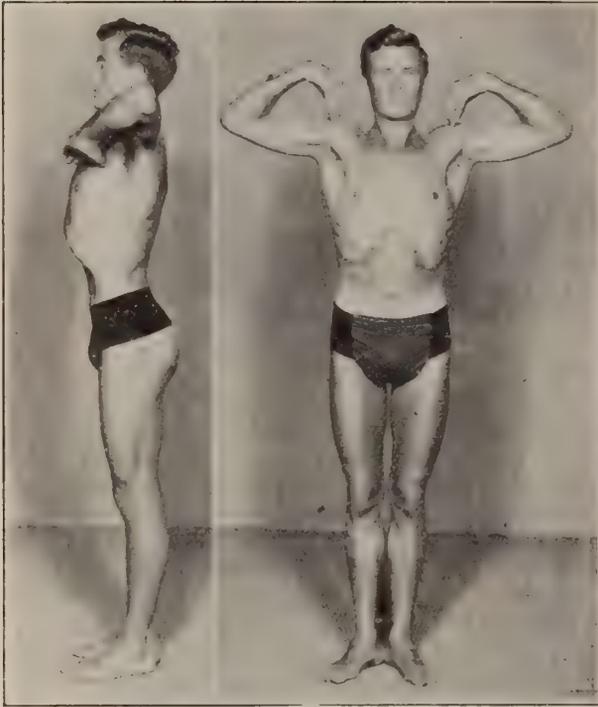

FIG. 3.

Static Exercise No. 3.

Static Exercise No. 4.

This position should be held from five to ten seconds. The hands and wrists are then released, and the body should remain erect and poised high. The body should never be allowed to slump.

When the initial position is taken, there is a tendency to take a full breath and to hold it during the whole of the exercise. At the end of exercise the tendency is to let the breath out and to slump again. The subject should practice breathing in and out in this upwardly held position. In giving this exercise to children it is necessary to give them helpful upward stretching commands when the position is held. These are stand tall, raise the chest, press down on the hands, stretch upward from the ankles, stretch the knees, and the like. These elevation cues are quite as important to the success of the procedure as the actual exercise itself.

Commands.—1, Bending wrists backward, palms toward floor, bend; 2, Press hard! Push down! Lift the chest. Stand tall; 3, Holding the head and chest up! wrists—Relax.

Exercise 2.—Raising the arms sideways, palms turned up at the level of the eyes. In this position the hands are flattened and pressed up, lifting the arms, at the same time trying to stand as tall as possible, lifting the chest and stretching upward from the ankles and knees.

Commands.—1, Stretching arms sideward height of eyes, palms up—Stretch! 2, (Elevation cues.) Lift! Press up! Stretch up! Stand tall! 3, Keeping head and chest up; arms—Down.

Exercise 3.—Bending arms forward at shoulder level. Palms should be perfectly flat and hands free from the chest. The same endeavor should be made to lift the hands as high as possible, and this will lift the chest and straighten the body.

Commands.—1. Bending arms at shoulder level—Bend; 2. Elevation cues; 3. Keeping head and chest up, arms—Down.

Exercise 4.—Finger tips on shoulders, wrist high, elbows to the side. In this position an effort should be made to lift the wrists as high as possible without permitting the finger tips to leave the shoulders. The same results are obtained, lifting the head and chest and straightening the body.

Commands.—1, Finger tips on shoulder, wrist high, elbows up,—Place; 2, (Elevation cues.) Raise the chest. Lift the head. Stretch up. Waist flat. Lift up the waist; 3, Keeping head and chest up, arms—Down.

These static exercises should be used at the beginning of every physical training lesson and in the relief exercises taken between class periods. Emphasis should be placed on the elevation cues while the uplifted position is being held. They not only lift the head and chest but they actually lift the abdominal viscera and relieve blood ptosis as well.

The second class of good posture exercises are those which strengthen the muscles that hold up the head, chest and various body parts against gravity. In order for one to have good posture, these sustentacular muscles should be constantly exercised and strongly developed.

(To be concluded.)

THE CAUSE OF ASTIGMATISM.

BY GEORGE EDWARD BARNES, M. D.,
Herkimer, N. Y.

What is the cause of ordinary astigmatism? Examining eyes for glasses is one thing that I do not do, so I have little opportunity to investigate this problem. However, I have an idea which I believe is correct. Judging from the history of patients, astigmatism often appears at the same time when more or less general ill health appears. When ophthalmologists find astigmatism in patients' eyes it seems to be the prevailing opinion that the patients have always had it and that they have only recently been bothered by it.

Undoubtedly some cases of astigmatism date from the earliest days of life, but I do not believe by any means that all cases do. Intelligent patients observe a sharp transition from many years of perfect and comfortable vision to a time of blurred and uncomfortable (astigmatic) vision. They state on being questioned that their general health became somewhat impaired at the same time. This is most significant. Any sickness which directly or indirectly affects the sympathetic and autonomic nervous systems (1) may directly or indirectly alter the tension of the eyeball and thereby change its curvature. Chronic emotional disturbances (1) through the sympathetic and autonomic nervous systems affect the general blood pressure, which in turn affects the ocular tension and these emotional disturbances also affect the activity of

Mueller's muscle. I have never seen or heard it stated that the general blood pressure had any influence on the ocular tension, but it seems to me that it must have. I believe it is of prime importance as a factor in determining this tension. Furthermore, the condition of the general circulation influences the fullness of the blood vessels in the orbit and thus influences the pressure exerted on the eye by the tissues surrounding it and therefore affects its curvature. The general circulation and general health also influence the amount of fat in the orbit. It is plain that the effect of the action of the extrinsic muscles on the curvature of the eye varies somewhat with the extension of the eyeball.

A CASE OF ERYSIPELAS WITH COMPLETE LOSS OF VISION

Cured and Vision Restored.

By NAVROJI A. COOPER, M. D.,
Bombay, India,

Honorary Physician to the B. D. Petit Parsee General Hospital.

A patient with erysipelas of a severe form complicated with loss of vision was admitted under the care of my predecessor at the B. D. Petit Parsee General Hospital on December 9, 1919. The patient was a female, aged twenty-eight years, very poorly nourished, having had continuous fever for ten days with a large patch of erysipelas on the external surface of the right thigh. The heart sounds were feebly audible; pulse weak and of low volume, with slow and shallow breathing, with normal liver and spleen outline. There was total blindness of both eyes, one eye having been sightless from infancy and the other affected only a few days after her present illness. This patient, who was delirious at times, was treated on ordinary lines with anti-streptococcic (erysipelas) serum injections in large doses. In all about eight injections were given, together with appropriate local treatment.

When the patient came under my care for treatment on October 1, 1919, she was in an extremely bad condition, highly anemic, prostrated, with the heart sounds feebly audible. She had a rapid, weak pulse combined with low muttering delirium. The spleen was normal, but the liver was greatly enlarged and tender. A further dose of twenty-five c.c. of antistreptococcic serum was given and the patient was put on a simple mixture of iron and given brandy in liberal doses as a stimulant. The temperature, which had been 99.6° F., rose after three or four days, and at the same time there was a marked increase in tenderness in the hepatic region. Emetine injections of a quarter grain were given every day for three days. After the third injection of emetine the temperature dropped to

normal. Pain and tenderness in the liver disappeared and the patient was a trifle better. Three more injections were given and the fever remained below normal. During this period the only drug that was administered to the patient by mouth was liquor ferri perchloridi several times a day. The blood picture showed, instead of a leucocytosis, a marked leucopenia, which is very unusual in such diseases, with the red blood cells 2,020,000 to the c.c. and a few microcytes. There were no other changes in the blood. About eight days after the complete fall in temperature, large abscesses suddenly developed on the face of the patient, in both the arm pits and on the buttocks. Autogenous vaccine was prepared and four injections were given. This prevented the development of further abscesses and inhibited the ripening of those already formed. There were no other pyemic complications. About ten days after this the vision of the patient improved. The leucopenia was less marked. On November 2, 1919, the patient told me that she could then see things as well as she used to before her illness. During all the time that she was under my care, she was kept on a mixture of iron which was given in increasing doses. It was due to the iron that her vision was restored and her general health improved so quickly. Though the antistreptococcic serum, the autogenous vaccine and emetine each played their own part against the infection and its pyemic complications, her recovery was due to the iron.

CONCLUSIONS.

1. No case of loss of vision in erysipelas has been recorded as far as I know.
2. The vision was completely restored under a simple treatment of a mixture of iron.
3. Hepatic and pyemic complications yielded rapidly to emetine and autogenous vaccine treatment.
4. Exceptionally quick and complete recovery was due to the iron, which acted as a specific more than the other drugs which were used.

The patient left the hospital in perfect health.

289 HORNBY ROAD, FORT.

Quinine in the Treatment of Hemoptysis.—

Joseph E. Strobel (*Medical Record*, August 21, 1920) reports favorable results from the administration of five grains of quinine every four hours for a week in cases of hemoptysis. Assuming that the theory of mixed infection was the correct explanation of hemoptysis, Strobel injected into fifty-four rabbits subcutaneously one half a cubic centimetre of fresh bloody sputum from as many different patients during different seasons of the year. The result was that in fifty-one of the rabbits lobar pneumonia and pneumococcic septicemia developed, in two a localized tuberculous abscess, and in one an abdominal abscess. Five of the fifty-one rabbits were controlled by a rabbit of similar weight receiving a similar inoculation but to which had been given fifteen minutes previously one grain of quinine bisulphate intravenously. These controls were killed after two to three months, presenting all organs and blood free from tubercles and diplococcic pneumonia.

tation through the mail as second class matter.

NEW YORK, SATURDAY, NOVEMBER 20, 1920.

THE NEW HYGIENE.

The human organism might be defined as a collection of habits (or memories if we use Butler's expression). The production of germ cells is a habit and a strong one; the whole process of development is a habit influenced to some extent by surrounding conditions; the business of feeding and sleeping and getting about and of fighting bacteria are other habits, more modifiable but still habits which become more and more fixed with years. Illness is brought on by mistakes in attempts to establish new habits beyond the capacity of the organism, as in the attempts to overfeed or overwork or under-sleep. It is comparatively easy to see what has gone wrong and usually the sick themselves are aware, but there is a wide range of habit within which the organism can persist for years and it is the course of bad habits of mild degree which slowly kill or slowly injure and which it is the realm of personal hygiene to correct. But habits, being fundamental to existence, are exceedingly difficult to change once they become established. Function makes structure and structure reacts to fix function and make it tyrannous.

The new method of teaching hygiene, fortunately, is based upon an early establishment of healthy habits—not by telling what they are, but by seeing that they are established. It is surprising how few the fundamental habits for health are, and how simple to establish as compared with those developed by other school work. The school, therefore, which fails to make the teaching of hygiene by the new

method an essential part of its course is deserving of strongest condemnation. It must be remembered that the public school child has already spent from four to six years in the formation of habits, in many instances more or less bad from the beginning. The results of medical inspection have made clear the effect of bad habits of the child growing out of bad family habits or customs. The pediatricist, the family physician, and the welfare nurse, are the most important teachers of hygiene because they preside at its source. The welfare of the nation will depend to a large extent on the skill of these workers in properly starting the human machine.

THE PHYSIOPATHOLOGY OF THE TENDON REFLEXES.

According to the recent researches carried out by Lhermitte there are two theories applicable to tendon reflexes; the old one, according to which these have a mesocephalic origin—the cutaneous reflexes being cortical—or more correctly have their centre in the nucleus ruber. Crocq and Van Gehuchten maintain that the preservation of the tendon reflexes is dependent upon the rubrospinal tract, whose origin is the nucleus ruber, the ending point of the superior cerebellar peduncles. Whenever this tract is morbidly disordered the tendon reflexes are also abnormal. This theory is directly related to the opinion upheld by Jackson and Bastian, according to which the cerebellum and cerebrum exercise an antagonistic action on the cord, the cerebrum having an inhibitory action, the cerebellum a tonic one. Now, how is it possible to explain by these hypotheses an increase of the subjacent tendon reflexes which occurs after experimental division of the cord? In point of fact, complete division of the cord, so frequently observed during the recent war, has shown that from this viewpoint only secondary differences exist between man and animals, and that in the former, in cases of medullary division the tendon reflexes are exaggerated, sometimes even accompanied by spinal and patellar trepidation, as observed by Lhermitte, Claude and Roussy.

In reality this phase of exaggeration—immediate in animals—is tardy in man and appears to be preceded by shock; therefore, the reflexes are abolished in the paralyzed segment of the body, so that this absence has as origin the inhibitory action of the medullary wound on the spinal segments separated from their upper connections. Consequently, the centres of tendon reflexes are medullary and not mesocephalic. As to the cutaneous reflexes, it is

known that they consist of reflex contraction of a given muscle following a mild stimulation produced on the cutaneous surface. According to the classic textbooks, they have cortical origin, while Van Gehuchten maintains that they are abolished in many cases and preserved in animals with a complete division of the cord. Here again the war has shown that it is erroneous to compare men with animals in respect to their cutaneous reflexes. All observers who have studied complete revision of the cord in warfare have noted that the cutaneous reflexes remained and this immediately after receipt of the trauma and from the very onset of medullary shock. As to Babinski's reflex it varies, sometimes being absent, at others distinctly present. Generally it is associated with other reflex manifestations of greater interest as pointed out by Marie and Foix, viz., reflexes of medullary automatism.

Marie and Foix had previously demonstrated that in nontraumatic paraplegia the principal phenomena of muscle shortening could be made to reappear. The varied movements that Claude, Lhermitte and Roussy were able to demonstrate in their cases of total transverse division of the cord have a special significance because with one exception they represent the reflexes of the automatism of walking more marked in man than experimentally in animals. Babinski's phenomenon is related to movements of defense, and this would appear to apply as well to the visceral reflexes. The sphincters do not remain indefinitely paralyzed after total division of the cord because quite independently of the will they acquire in time an automatic action. It may, perhaps, be the same with the genital functions. But it would at present seem to be proved that all the reflexes—tendon, cutaneous and visceral—have a medullary origin.

INDUSTRIAL DIRT.

A new offensive is being launched against the twin enemies, disease and dirt. No section of labor brings more dirt home, or is more reluctant to avail itself of cleansing, than the coal miner; yet think what the providing of means for washing the man and his clothes means to the wife. The Board of Health in Great Britain is trying to establish pit-head baths for use at the end of the day. The difficulty is that, given all facilities, how many working men of any dirty occupation would care to take a bath save in a comfortable bathroom at home? To turn out again to get home sounds cheerful. Moreover, the old miner has a confirmed belief that washing the back has a weakening effect, and the elderly wives maintain bathing gives one a cold. The younger miners, fortunately, are becoming interested

in athletics and physical culture; the feeling, too, of self-respect is growing, the dislike of having to face clean people on the cars with dirty clothes and blackened exteriors is inclining them tubwards. It is easy to understand the objections to taking a bath away from home. Forty per cent. of the deaths in Welsh collieries are due to phthisis, pneumonia, and bronchitis, and an enormous number are due to rheumatism, lumbago, and sciatica. Also, some statistics made a few years ago in a Scotch colliery district showed eleven per cent. of the families had one room; sixty-five per cent. two, and twenty-four per cent. three; none had a bathroom. It was even worse in Yorkshire in 1919: 2,793 families lived in one roomed houses and 31,908 in two, and the water supply was deficient.

It all returns to the same issue: bad housing. The doctors, full of zeal, full of righteous anger, realize how they are handicapped and defeated every day by lack of cooperation on the part of employers. The details are rarely published in their actual sordidness, and, if published, would do no good unless some citizens, bold and brave enough, took up and hung on to the matter tenaciously to shame those responsible. Unaided, the doctor is made to feel bitterly his utter impotence, and the futility of urging obviously necessary reforms.

PHYSICIAN-AUTHORS: DR. ABRAHAM COLES.

One of the most famous American hymn writers was Dr. Abraham Coles, a staunch old Covenanter, who was born at Scotch Plains, N. J., on December 26, 1813, and died on May 3, 1891, at Monterey, Cal. (where he had gone for his health), after a distinguished career in the fields of literature and medicine. "Dr. Coles is a born hymn writer," said John Greenleaf Whittier, the Quaker poet. "He has left us a legacy of inestimable worth, some of the sweetest of Christian hymns. His *All the Days* and his *Ever With Thee* are immortal songs. It is better to have written them than the stateliest epics. No man living or dead has so rendered the text and spirit of the old and wonderful Latin hymns." Oliver Wendell Holmes, who, like Dr. Coles, was a physician, compared his hymns to the verses "which John Bunyan sprinkles like drops of heavenly dew along the pages of *Pilgrim's Progress*." Coles's hymns were praised with equal enthusiasm by Henry Wadsworth Longfellow, William Cullen Bryant, James Russell Lowell, William E. Gladstone, England's grand old man, and others.

Dr. Coles was a deeply religious man and through the large number of hymns which he wrote and

translated he promulgated his gospel of faith. He wrote poetry and prose of other sorts, too, but his fame is based primarily on his translation of the supreme product of Latin hymn writing, the *Dies Iræ*. Coles astonished the literary world a few decades ago with no less than eighteen versions of this masterpiece of hymnology, and they are among the finest of the one hundred and fifty or more versions of it in the English language. James Russell Lowell called them the very finest of all the translations. *Dies Iræ* originally was written in Latin by the monk Thomas of Celana, in Italy, in the thirteenth century. It is a chant of eight stanzas of eight lines each, giving a terrible description of the Judgment Day, painting in vivid colors the anguish of the self-condemned sinner and reciting his piteous appeals for mercy. "It is," Coles said, "instinct with music. It sings itself. The grandeur of its rhythm and the assonance and chime of its fit and powerful words are, even in the ears of those unacquainted with the Latin language, suggestive of the richest and mightiest harmonies." His eighteen versions of it show a surprising mastery of language and illustrate the possibilities of variation of language without alteration of the sense.

Coles also translated the *Stabat Mater Dolorosa* and the *Stabat Mater Speciosa*, and these, together with a collection of hymns under the title of *Old Gems in New Settings*, ran through several editions and are still standbys in standard hymnals. One of his most popular original hymns was *In the Sweet By and By*. He also translated from the Hebrew the *Psalms of David*, published with extensive historical and critical notes. His other writings included *The Light of the World*, and *The Evangel*, a life of Christ in verse, which Oliver Wendell Holmes called "charming and impressive" and which Whittier described as "a work of piety and beauty."

The Microcosm, a long poem which was written for the centenary anniversary of the Medical Society of New Jersey, of which Dr. Coles was president at the time, was published in 1881, together with his *National Lyrics* and *Miscellaneous Poems*. It took five editions to supply the demand for this book. George Ripley, one of the pioneer journalists of New York city, writing in the *Tribune*, described *The Microcosm* as "an ingenious attempt to present the principles of the animal economy in a philosophical poem, somewhat after the manner of Lucretius, and combining scientific analysis with religious sentiment." Dr. Coles always linked medicine and religion and regarded his profession as a sacred one. How loyal he was to that profession amid the glow of literary fame is shown in *The Microcosm*, a physician's edition of which was published.

Dr. Coles wrote a large number of medical and scientific papers which were published in various periodicals, and he also translated *The Address to Christ on the Cross*, by Bernard of Clairvaux, and Hildebert's *Address to the Three Persons of the Most Holy Trinity*, together with several selections from the Greek and Latin Classics. These, however, were not published.

When he was fifteen Coles became a clerk in a New York dry goods store and two years later he became a teacher of Latin and mathematics in the Bond Academy at Plainfield, N. J. At eighteen he studied law for a year and then definitely decided to make medicine his life work. He entered the College of Physicians and Surgeons, New York, and after studying there for a while, went to Jefferson Medical College, Philadelphia, where he received his degree in 1835. He practised mostly in Newark, N. J., and was prominent in civic and literary circles there. He served several terms on the Newark Board of Education, was one of the founders of the famous Newark Public Library and also of the New Jersey Historical Society. He made two trips to Europe, in 1848 and 1854, and was in Paris during those stormy revolutionary days of May and June, 1848, which gave him special opportunities for surgical experience and study.

This sturdy old Baptist doctor was one of the most lovable of men personally. "I have always considered it a privilege," said Oliver Wendell Holmes, "to enjoy the friendship of so pure and lofty a spirit; a man who seemed to breathe holiness as his native atmosphere and to carry its influence into his daily life." For his literary work Dr. Coles received the degree of A. M. from Rutgers College; the Ph.D. degree from Lewisburg University, and the LL.D. from Princeton University.

McGILL UNIVERSITY.

Of the twelve pamphlets published by McGill University, Montreal, in connection with the campaign now in progress for a five million dollar fund that entitled *A Greater McGill* is most interesting. In all its history that great university has made only three appeals to the public for assistance. The first was in 1881, when an appeal was made for thirty-three thousand dollars to save the university from a financial crisis. The second was launched in 1911 and brought the university a million dollars. Now the third is on for the amount stated above and the outlook is very promising. Part of the donations to be received will be set apart for memorial purposes as the donors stipulate. The war depleted the ranks of the professorial

staffs as well as the student body, and it is the desire of the governors that their names be perpetuated. During that stressful period no appeals for money were made. On the other hand, the strictest economy was practised in every department. No buildings were enlarged, but the whole policy of the university was one of retrenchment, even to carrying on with the old equipment and apparatus as in the days prior to the Great War.

In 1919 students began to return and more new ones were being admitted than ever before, until it soon began to appear that there was inadequate accommodation all round. Registration in arts sprang from 389 in 1918 to 632 in 1919; in medicine and dentistry, from 526 to 724; and in applied science, from 242 to 643. This large increase in attendance necessitated additional funds to provide competent professors and instructors. Prewar salaries, never great, under the changed conditions of living did not allow professors to live any better than many of the industrial classes. As the average salary of a professor at McGill is about three thousand dollars, the university needs at least a hundred and ninety-five thousand dollars to give living wages to a staff of about five hundred.

If the standard of the work of McGill is to be kept up additional professors must early be appointed and provided. Recently a new department of biochemistry has been established with Professor A. B. Macallum occupying the chair. Professor Macallum is a distinguished scientist, formerly in charge of the similar department in the University of Toronto, but latterly chairman of the Research Commission of the Dominion Government. There will be established shortly another new department in industrial chemistry.

For some time the accommodation for biological work has not been adequate. For that there is now available the sum of seventy-five thousand dollars. The old medical building will be used for this purpose, but the sum of a hundred thousand dollars will be needed for endowment. Then there is in view a new building to house pathology, medical jurisprudence, hygiene and psychiatry, to cost about four hundred and sixty thousand dollars and a further hundred and fifty thousand dollars for endowment. Without the five million dollars McGill would not be able to keep up its high standard, the equal of any other university on the continent of America, and to cover all its requirements no less amount than ten million dollars would begin to meet them. While it is true that McGill has in the past been most fortunate in many generous donations from friends, including Lord Strathcona, Sir

William McDonald, and the late Sir James Douglas, of New York, it was felt by the new president, Sir Arthur Currie, that this appeal should be made to a wide constituency so that the many graduates in Canada and the United States could have an opportunity to come to the assistance of their *alma mater*. The campaign is said to be progressing most favorably and the outlook is, therefore, most promising.

WOMEN WORKERS IN NOVA SCOTIA.

Working conditions of women in Nova Scotia have been under scrutiny by the Nova Scotia Commission on Women in Industry, which has recently issued a report. The general conclusions reached by the commission were that hours were frequently too long, especially where women have to stand or where work is heavy or unhealthy; that working conditions could be improved and should be subject to standard regulations; that the lack of medical inspection, especially in food factories, constitutes a public menace. It was suggested that a board be appointed representative of women workers, employers and the public, with power to secure improvement of conditions. Though the commission found that a large number of women were not earning enough to live on, it did not recommend a flat minimum wage but suggested that the proposed board be empowered to fix suitable standards from time to time.

MENTAL STARVATION.

Those doctors who have a pile of medical journals arriving every month, many of which they have not time to read, can hardly imagine the lassid feeling of the man far away from any library and too poor to afford the latest textbooks. Owing to the war, some of the physiological journals in India are dated 1915. The editor of the *Indian Medical Journal* has therefore resolved to devote a section to physiological science, and invites those who have new ideas and journals to fill it. Dealing food to the starving mind will meet with a rich reward in helping the all too few doctors for India's millions.

News Items.

Bequests to Hospitals.—The will of Henry Culver, of Southampton, L. I., contains a bequest of \$500 to the building fund of the Southampton Hospital.

Medical Society of the County of New York.—The annual meeting of the society will be held Monday evening, November 22d, in Hosack Hall, New York Academy of Medicine.

Whooping Cough in New York.—From January 1 to October 1, 1920, 6,602 cases of whooping cough were reported to the Department of Health of the City of New York. During the same period in 1919 only 827 cases were reported. Thus far this year 550 deaths have been reported, of which ninety-five to ninety-seven per cent. occurred in children under five years of age.

Public Health Affected by High Rents.—According to a report concerning housing conditions in Brooklyn, issued recently by the Brooklyn Bureau of Charities, many of the poorer families are living in such crowded quarters that their health is endangered.

Fifth Avenue Hospital Building Fund.—Recent contributions have brought the amount in hand up to \$1,045,800; the amount desired is \$2,000,000. The Barrymores, John, Lionel, and Mrs. Ethel Barrymore Colt, have given \$30,000 to endow a room in their name for the benefit of members of the theatrical profession.

The Police Hospital.—The first step in the campaign to raise \$5,000,000 to build, equip, and endow the proposed Police Hospital was a luncheon given by Police Commissioner Richard E. Enright to three hundred men of the theatrical and moving picture professions, at which \$75,000 was raised. The campaign for subscriptions will begin on December 9th.

Syracuse Academy of Medicine Meeting Postponed.—Owing to a death in the family of Professor Simon Henry Gage, the regular monthly meeting of the Syracuse Academy of Medicine has been postponed to November 23d. Prof. Gage will present at this meeting a paper on Free Granules of the Blood and Their Dependence on the Kinds of Food Ingested.

Low Death Rate for 1919.—According to the Census Bureau's annual bulletin on mortality statistics, 1,096,436 deaths occurred in the registration area of the United States during the year 1919. This represents a rate of 12.9 in a thousand of population, the lowest on record. The rate for 1918 was 18 in a thousand, due largely to the pandemic of influenza.

Research Information Bureau.—The National Research Council, of Washington, D. C., announces the establishment of a research information service as a general clearing house and information bureau for scientific and industrial research. Wherever possible information is furnished free of charge. All inquiries should be addressed to Research Information Service, National Research Council, 1701 Massachusetts Avenue, Washington, D. C.

Medical Supervision of Football.—The health aspect of football was discussed at a recent meeting of Brooklyn physicians. Dr. Robert E. Coughlin, who has made a study of this sport, considers it a dangerous pastime for boys of immature age and physical development. Others who spoke were Dr. Edward J. Grace and Dr. Earl Wayne, who pointed out that most of the injuries occurred in informal games where the players were not properly trained.

State Civil Service Examinations.—Among the positions for which the New York State Civil Service Commission will hold examinations on December 4th are the following: Assistant x ray operator, State Department of Health, \$1500 to \$1800; laboratory technician, County tuberculosis hospitals, \$900 to \$1500; resident physician, State institutions, \$2000. For full particulars and the proper application forms address the Commission, Albany, N. Y.

Academy Anniversary Address.—Mr. James M. Beck delivered the annual anniversary address at the New York Academy of Medicine, Thursday evening, November 18th, his subject being One Cause of the World Neuroses.

Gross Lecture.—Dr. Raymond Pearl, professor of biometry and vital statistics at the School of Hygiene, Johns Hopkins University, delivered the annual Gross lecture of the Pathological Society of Philadelphia, Thursday evening, November 11th, his subject being Some Biological Aspects of Human Mortality.

Typhoid Epidemic in Salem, Ohio.—An epidemic of typhoid fever has been raging in Salem, Ohio, for the past month, and has got beyond the control of the local authorities. There are approximately one thousand cases in the city, constituting one eleventh of the total population. Seven deaths have been reported. An appeal for help has been sent to the State authorities.

Drug Addicts Transferred from Sing Sing to Dannemora.—Twenty-nine drug addicts recently received at Sing Sing Prison were among seventy-six prisoners transferred to Clinton Prison at Dannemora. Some of these drug addicts, all of whom were suffering when received at Sing Sing, had to be treated in the prison hospital. Unable to get any drugs in Sing Sing, some of them had collapsed.

Patient Receives Fatal Shock from X Ray Machine.—While an x ray photograph was being made of his jaw, Casimir Ilg, thirty-five years of age, received a fatal shock in the office of Dr. Charles F. Baker, Newark, N. J. It is believed that the patient probably came in contact with the steel arm from which the x ray bulb was suspended, sending eighteen milliamperes of electricity through his body.

Personal.—Sir Berkeley Moynihan, professor of clinical surgery, University of Leeds, England, has been recommended for election to honorary fellowship in the New York Academy of Medicine.

Dr. Otto V. Huffman has removed his office to 25 East Sixty-fourth Street, New York.

Dr. William Delaney Thomas, of Baltimore, was elected president of the Homeopathic Medical and Surgical Club, at its recent annual meeting.

Charles Edouard Guillaume Breteuil, head of the International Bureau of Weights and Measures, was awarded the Nobel prize for 1920 for physics by the Swedish Academy of Science, recently. His discoveries relative to the alloys of nickel steel won him this honor.

Druggists Object to Dispensing Whiskey.—The Kings County Pharmaceutical Society, at a recent meeting, went on record as favoring the establishment of government dispensaries at which whiskey could be sold to people needing it for medicinal purposes. Dr. William Anderson, chairman of the legislative committee, reported that under the Volstead act retail druggists alone have the legal authority to deal out alcoholic stimulants. The society is opposed to having druggists deal in whiskey, even on doctors' prescriptions, and it was for this reason that the movement to have the Government undertake the work was started.

Antinoise Campaign in New York.—Health Commissioner Royal S. Copeland will soon begin an active campaign to suppress all unnecessary noises in the city of New York. An investigation of the automobile as a noise maker will be a part of it, and a survey of every motor vehicle in the city will be made, to ascertain how many of them are mechanically perfect. From now on the police will be instructed that on a certain day each week they are to give special attention to noises and their suppression. They will be expected to note the causes of noises, to report flat wheels, barking dogs, hucksters, etc. Noisy industrial plants will also be listed, and will be inspected with a view to stopping all unnecessary noise.

State Hospitals Overcrowded.—New York State's hospitals for the insane are overcrowded to eighteen per cent. above their normal capacity, according to the annual report of the State Charities' Aid Association which has just been issued. Institutions built to accommodate 30,324 persons now contain 35,845, and congestion brought about by the entrance of patients who must be admitted is causing a serious situation, especially in hospitals in and near New York city. These conditions are expected to be remedied through new construction provided for in state appropriations totaling \$5,000,000. Mentally disabled soldiers, now in various State hospitals, will be centred at the new State military hospital at Creedmoor, N. Y., when it is completed about next June.

Fatalities on the Railroads.—Fewer persons were killed on railroads during 1919 than in any year since 1898, and fewer were injured than in any year since 1910, according to a statement issued today by the Interstate Commerce Commission. During 1919 a total of 6,978 persons were killed and 149,053 injured, compared with 6,859 killed in 1898 and 119,507 injured in 1910. Of the killed 273 were passengers and of the injured 7,456 were passengers. Employees killed during the year numbered 2,138 and 131,018 were injured.

Fewer trespassers on railroads were killed in 1919 than during any year of the commission's records, which go back to 1890. Last year 2,553 trespassers were killed and 2,658 injured. Railroad officials pointed out that there were fewer tramps than formerly.

Ohio Public Health Association.—This organization has been formed for the purpose of promoting proper health administration in the State of Ohio. In addition to taking over the duties of the Ohio Society for the Prevention of Tuberculosis, its objects are to promote the organization of local public health leagues; the dissemination of knowledge concerning the prevention of disease, the encouragement and support of organized official work for the prevention of disease, the securing of proper legislation for the prevention of disease, encouraging adequate provision for the prevention of disease by the establishment of hospitals and dispensaries, etc., and the study of conditions regarding the prevalence of preventable disease. The work of the association is educational in character, and does not in any way encroach upon the functions of the state health department.

Yale University Department of Health.—The new department of health at Yale University is in complete operation. Drastic rules have been adopted to stamp out disease and illness of every kind which students, and especially athletes, may contract. Hereafter a general physical examination will be required of every student before he will be permitted to matriculate. Frequent examinations during the year will follow. Rigorous rules for athletes who wish to enter university sports will be adopted, and the health officials will reserve the right to order out of competition any athlete found unsound physically.

The board of health will be headed by Dr. Charles E. A. Winslow, Dr. William G. Anderson, Dr. Nelson Winternitz, new dean of Yale Medical School, and Dr. James C. Greenway. They will be assisted by George P. Day, treasurer for the university; Clarence W. Mendell, head of the Yale Athletic Council, and Professor L. E. Rettger, professor of bacteriology.

Meetings of Local Medical Societies.—The following medical societies will meet in New York during the coming week:

TUESDAY, November 23rd.—New York Academy of Medicine (Section in Obstetrics and Gynecology); New York Dermatological Society; New York Medical Union; Metropolitan Medical Society of New York; New York Otolological Society (annual meeting); New York Psychoanalytical Society; Therapeutic Club; Valentine Mott Society; Washington Heights Medical Society (annual); Clinical Society of the Hospital and Dispensary for Deformities and Joint Diseases.

WEDNESDAY, November 24th.—New York Academy of Medicine (Section in Laryngology and Rhinology); New York Society of Internal Medicine; New York Surgical Society; Brooklyn Pediatric Society.

THURSDAY, November 25th.—Hospital Graduates' Club of New York; New York Physicians' Association; Ex-Intern Society of the Methodist Episcopal Hospital, Brooklyn.

FRIDAY, November 26th.—Academy of Pathological Science; Audubon Medical Society; New York Clinical Society; Brooklyn Society of Internal Medicine.

SATURDAY, November 27th.—Harvard Medical Society; Lenox Medical and Surgical Society; New York Medical and Surgical Society; West End Medical Society.

Died.

BRONK.—In Amsterdam, N. Y., on Tuesday, October 2nd, Dr. E. F. Bronk, aged sixty-two years.

JAMES.—In Lexington, Ky., on Sunday, November 14th, Dr. Robert C. James, aged fifty-five years.

JOERG.—In Brooklyn, N. Y., on Thursday, November 4th, Dr. Oswald Joerg, aged seventy-six years.

PERKINS.—In South Otselic, N. Y., on Tuesday, November 2nd, Dr. Archibald T. Perkins, aged fifty-three years.

PRATT.—In Binghamton, N. Y., on Wednesday, November 3rd, Dr. John F. Pratt, aged sixty-four years.

WRIGHT.—In New York, on Monday, November 1st, Dr. T. S. Wright, aged eighty-six years.

WHITTEN.—In Peoria, Ill., on Sunday, October 31st, Dr. Thomas J. Whitten, aged seventy-six years.

WILLIAMSON.—In Santa Monica, Cal., on Thursday, October 21st, Dr. Alonzo P. Williamson, aged sixty-six years.

YOUNG.—In Amesbury, Mass., on Saturday, October 23rd, Dr. Benjamin Young, aged sixty-six years.

Book Reviews

LOOSE LEAF MEDICINE.

The Oxford Medicine. By Various Authors. Edited by HENRY A. CHRISTIAN, A. M., M. D., Hersey Professor of the Theory and Practice of Physic, Harvard University; Physician in Chief to the Peter Bent Brigham Hospital, Boston, Mass., and Sir JAMES MACKENZIE, M. D., F. R. C. P., LL. D., F. R. S., Consulting Physician to the London Hospital, and Director of the Clinical Institute, St. Andrews, Scotland. In Six Volumes. Illustrated. Volume I: Medicine; Volume II: Diseases of Bronchi, Lungs, Mediastinum, Heart, Arteries, and Blood. London, Toronto, Melbourne, Bombay, and New York: Oxford University Press, 1920. Pp. xv-817.

Two volumes of the Oxford loose leaf system of medicine have been published. The loose leaf system as applied to a publication of this kind is splendid, as it will allow for great flexibility. Changes that occur in one branch of medicine will not necessitate a complete new edition. In other fields where progress does not take place with the same rapidity the new pages will not be required so frequently. In a work of this kind two principal requirements stand out: first, the quality of the initial material presented, and, second, keeping the new sections abreast of the times. The first requirement has been met fully. In the first volume the subject of medicine is covered in a broad and understanding way. Two more progressive and able men could not have been selected as editors, Henry A. Christian, of Boston, and Sir James Mackenzie, of Scotland. A list of contributors, as a rule, makes dull reading, but in this case medical men who follow the work of achievement in modern medicine will recognize among the following list names of men who have prevented medicine from falling into the quagmire of mediocrity. So without apology we may name the following contributors: Lewellys F. Barker, Frank Billings, William T. Bovie, Richard Cabot, Joseph A. Capps, Henry A. Christian, Charles B. Davenport, Eugene F. Du Bois, Frederick P. Gay, Lawrence J. Henderson, Walter A. Hewlett, Guy Hinsdale, Walter B. James, William B. Johnston, Lucas P. Williams, Elmer V. McCollum, Sir James Mackenzie, Sir William Osler, John J. Mackenzie, Francis W. Peabody, Leonard G. Rowntree, Henry Sewall, Donald D. Van Slyke, William H. Wilmer.

The entire work is to consist of six volumes. The publishers feel that the change brought about by the war, in regard to the manner in which patients were handled and the new point of view gained by the medical men who were engaged in active work, should be emphasized in the medical works of today. This influence is noted in the first two volumes that have appeared. Sir James Mackenzie has been saying many very essential things in regard to medicine recently. His views are sane and have a tendency to induce the too theoretical practitioner who has his head in the clouds, or the practitioner who places too much reliance on laboratory findings, to come back to earth, stand on his own feet, and develop the faculty of relying upon himself. Too much cannot be said upon this subject. We have been too prone to remember the test tube and forget the patient. In his chapter on *The Future of Medicine* Sir James brings these points

home with great vigor. The first volume is replete with chapters as essential as those of Mackenzie's. They deal with problems ranging from those of focal infection to others of a forensic nature. These fields are well covered.

The second volume takes up the diseases of the bronchi, lungs, mediastinum, heart, arteries, and blood. Many new names are among the contributors of this volume; names that have appeared frequently in the current medical literature associated with the disorders of respiration and circulation. A great effort has been made to incorporate the latest findings and it is gratifying to see under the various headings the most modern views as they have appeared in the current literature. The project of the loose leaf system is not a fad. It should supersede the older forms of binding for works of this character. Fortunately, this effort is being made by men of repute and should meet with success.

EXPERIMENTS IN VITAL ENERGY.

Life. A Study of the Means of Restoring Vital Energy and Prolonging Life. By Dr. SERGE VORONOFF, Director of Experimental Surgery at the Laboratory of Physiology of the Collège de France. Translated by EVELYN BOSTWICK VERNOFF. New York: E. P. Dutton & Co., 1920. Pp. xx-160.

Frequently an attempt is made to present scientific works in an entertaining manner. At times success is attained. Fabre, in his descriptions of animal life, and the elder Darwin in his writings on plants and insects, and others, have been successful in combining literature, art and science, and at times have awakened an interest in topics which are usually presented in a dry and uninteresting fashion. Voronoff has attempted something similar in his near dramatic book, *Life*. He appears to be appealing to the gallery, crying aloud his wares and findings over the heads of the medical profession. Can it be that this is necessary?

He presents a few interesting findings and if they prove to be corroborated by further experiments in the hands of other observers no doubt will prove a boon to many who have neglected to make the most of life as they have found it; for others it will mean an opportunity of completing unfinished tasks. Truly the span of life of man seems short. The time he actually lives after he is equipped for life's struggle and after he has attained maturity of physical and mental development is brief. It seems but a fleeting moment that the race is run after the years of training and growth that man passes through in order to attain his adult status. Many other fields of application will also present themselves when the technic of glandular transplantation is perfected. A case is shown where the thyroid of an ape was successfully transplanted to a boy with beneficial results. The point made that the transplants should be made from man to man or from the animals more closely related to man is important. Too frequently in animal experimentation the error is made of using the lower animals and attempting to apply the results to the human family.

A definite result cannot be asserted at the present

time. More work must be done. Steinach, of Vienna, has many contributions to offer in this field which seem to be more far reaching than those of Voronoff. Lydston, of Chicago, has also done much work along similar lines. His papers have appeared in the *NEW YORK MEDICAL JOURNAL*. All of these men are undoubtedly the heralds of what will be an important therapeutic branch of medicine in the future.

PROGRESS OF SCIENCE.

The New World of Science. Its Development During the War. Edited by ROBERT M. YERKES, Chairman, Research Information Service, National Research Council. Illustrated. New York: The Century Company, 1920. Pp. vi-443.

Prowling around the second hand bookshops on Third Avenue, the reviewer came across many old volumes detailing the wonderful progress science had made, and it seemed that the title *New World* was a trifle arrogant, that the enlarging world would be more correct, for nothing has been sudden in discovery. The origin has lain far away back some hundreds of years. Glimpses they had, those old scientists, of possibilities, faith they had that knowledge has no boundaries. Nevertheless, the great tide of progress today astonishes us, awes us, sweeps us off our feet, destroys our conservative clinging to the old, lands us on eminences from whence we see all nations deserving recognition as the marvelous facts are garnered and used for man's help and delight.

Now that the war is said to be over, those in authority are showing us what a haggard, overworked, weary eyed servant science was. How she was referred to even in small matters, such as the amount of wool in military breeches, and the total of calories in a soldier's stew, how metallurgists and explosivists, bacteriologists, geologists, geographers, psychologists, radiotherapists, and physicists brought her their problems to solve and, war being ended, they gave her the biggest of all, how to avert another carnage, how to economize in and rightly use the new powers she had bestowed.

The first question should have been a just reward to the poorly paid scientist, whose incidental expenses often consume nearly all his income. There are scientists today who cheerfully gave their whole time during the war who find themselves worse off, financially, than the artisan.

Each section of the volume is a book in itself, increasing our feeling of indebtedness to those who have studied man and natural forces. A long list of familiar names tell us of deeds done: Ellery Hale, Robert Nillikan, Augustus Trowbridge, Herbert Ives, Harrison Howe, deal with the physical sciences. The rôle of chemistry has papers from Arthur Noyes, Charles Munro and Clarence West. Douglas Johnson records the wonderful, hitherto unknown, work done in geography, and equally good is the account of geology, though few associate its vital connection with wartime. Engineering is told by A. E. Kenelly; metallurgy by Henry Howe. Biology and medicine are safe with Vernon Kellogg, Frederick Russell, John Hanner, and Robert Yerkes.

To appreciate the medical and surgical side, it

would be well to read some of the books on those subjects during the Civil and the Crimean wars. It might be well also to read some of that date when the foolhardiness of risking one's life in a railway train was denounced in the pulpit, and the suggestion of gas illumined streets was greeted with derisive laughter in the House of Commons. At an annual picnic of the Philosophical Society, Benjamin Franklin jestingly said the society might some day cross the Schuylkill in an electric boat and dine off a turkey cooked by electricity. Rather a mad president, the guests deemed him, but the river is crossed, the turkey cooked, and incredulous old ghosts are convinced.

The people should be glad of this book. It gives in one volume that which has only appeared at intervals in scientific journals inaccessible to most. Even while the volume was in printing science has gone on still farther, lighting up obscurities, exciting her followers, and, fifty years hence, when the undreamed of has become the commonplace, the account of the *New World* will provoke even a smile for the scientists who only guessed at the marvels to be revealed before 1970. Even then, though disease may have its strongholds shaken, the Power which lets loose the fury of a tornado, an earthquake, a tumultuous flood, may see us still impotent before these forces.

THE HISTORY OF MEDICINE

An Introduction to the History of Medicine. By FIELDING H. GARRISON, A. B., M. D., Principal Assistant Librarian, Surgeon General's Office, Washington, D. C. Second Edition, Revised and Enlarged. Illustrated. Philadelphia: W. B. Saunders Company, 1917. Pp. vii-905.

Only those who have tried to write the history of any science can appreciate the immense amount of research in the first edition of this book; only those who know Fielding Garrison and his intense desire for accuracy, could be sure that in a second edition all which had provoked criticism as to correctness or omission would be rectified. One great attraction is the grouping, so arranged that any man wanting to know the stars in any particular science will find them under that heading, the difficulties of a man being eminent in two sciences, say, anatomy and biology, being obviated by his name being given under both. The fact that it is not a biographical volume permits the allusion to the work of many men still living, though the rapidity of time is somewhat sadly shown by men who, in the first edition had just a birth date, now appearing with two.

The most exigent should be satisfied with a medical chronology which extends from B. C. 7000 to 1914 A. D. It has also references for those wanting to study medical history, and an index of personal names and one of subjects. There are many pictures added in the new edition which give pleasure to those who have never seen some of the modern men. One of its best tributes is the fact that the reviewer mistook it for the first edition on the New York Academy of Medicine shelves when it had only been there three weeks: it already bore the traces of much consultation. And the men who had used it were perfectly safe in quoting it

as a reference. There is a report at Johns Hopkins Hospital that if you were to ask William Welch something on medical history while he was asleep, a correct answer would be given. Assuredly Fielding Garrison would stand the same test.

ANALOGIES

Our Great War and the War of the Ancient Greeks. By GILBERT MURRAY, LL. D., D. Litt., F. B. A., Regius Professor of Greek in the University of Oxford. New York: Thomas Seltzer, 1920. Pp. v-85.

Gilbert Murray, that most imaginative of scholars, who has recreated an interest in so much of Greek thought in his writings and his incomparable translations, has written a little book about two wars. He is ostensibly writing about the Peloponnesian War—the book purports to be “a study of the criticisms passed on the War Party at Athens by their contemporaries.” But one feels that for Professor Murray this study has been used to symbolize, to some slight extent, the hate and ferocity engendered by the world catastrophe just passed. His interpretation of affairs at Athens is too clear, too warmed by the *lacrimae rerum* to which he refers, for a hundred per cent. imperialist. He is a poet as well as a scholar, and he knows that history repeats itself.

The war between Athens and Sparta, as he shows, was “in many respects curiously similar to the present war.” It was a war primarily due to commercial rivalries, a fight to the last ditch, involving the attrition of both of the combatants. In the Athens of that day there were refugees and informers, militarists and rational persons; it was a war in which glory was mixed with sordidness, and in which the people who were responsible for the whole business suffered the least. And it left both Athens and Sparta ruined. Professor Murray sees the analogy clearly, but when it comes to the future outlook he is sympathetic, and disquieted, and hopeless. He hopes civilization will recover, but he is not entirely sure about it. He has a pathetic faith that by “some spirit of cooperation instead of strife, by sobriety instead of madness, by resolute sincerity in public and private things, and surely by some self-consecration to the great hope for which those who loved us gave their lives” things may be made better. But his faith is not the faith that moves mountains, and his last words are tinged with disillusionment: “That was the old dream that failed. Is it to fail always and forever?”

New Publications Received.

[We publish full lists of books received, but we acknowledge no obligation to review them all. Nevertheless, so far as space permits, we review those in which we think our readers are likely to be interested.]

THE ADVENTUROUS LADY. By J. C. SNAITH. New York: D. Appleton & Co., 1920. Pp. 321.

THE NERVOUS HOUSEWIFE. By ABRAHAM MYERSON. Boston: Little, Brown & Co., 1920. Pp. 273.

CHARLES E. CHAPIN'S STORY. Written in Sing Sing Prison. With an Introduction by BASIL KING. New York: G. P. Putnam's Sons; London: The Knickerbocker Press, 1920. Pp. xv-334.

THE AGE OF INNOCENCE. By EDITH WHARTON. New York: D. Appleton & Co., 1920. Pp. 365.

OFFICIAL BULLETIN OF THE ROYAL SOCIETY OF MEDICINE. London: John Bale, Sons & Danielsson, 1920. Pp. 19.

LIFE. By JOHAN BOJER. Translated from the Norwegian by JESSIE MUIR. New York: Moffat, Yard & Co., 1920. Pp. 339.

THE STORY OF THE AMERICAN RED CROSS IN ITALY. By CHARLES M. BAKEWELL. New York: The Macmillan Company, 1920. Pp. viii-253.

A TEXTBOOK OF HISTOLOGY. By FREDERICK R. BAILEY, A. M., M. D. Sixth Revised Edition. Profusely Illustrated. New York: William Wood & Co., 1920. Pp. xviii-733.

PROCEEDINGS OF THE ROYAL SOCIETY OF MEDICINE. Edited by Sir JOHN Y. W. MACALISTER, Under the Direction of The Editorial Committee. New York, Bombay, Calcutta, Madras, and London: Longmans, Green & Co., 1920.

THE NEW WORLD OF SCIENCE, ITS DEVELOPMENT DURING THE WAR. Edited by ROBERT M. YERKES, Chairman of the Research Information Service, National Research Council. Illustrated. New York: The Century Company, 1920. Pp. vi-443.

MORALE. THE SUPREME STANDARD OF LIFE AND CONDUCT. By G. STANLEY HALL, Ph. D., LL. D., President of Clark University; Author of *Adolescence*, *Founders of Modern Psychology*, etc. New York: D. Appleton & Co., 1920. Pp. ix-378.

PHYSIOLOGICAL CHEMISTRY. A Textbook and Manual for Students. By ALBERT P. MATHEWS, Ph. D., Professor of Biochemistry, University of Cincinnati. Third Edition, Illustrated. New York: William Wood & Co., 1920. Pp. xiv-1154.

PATIENT'S HANDBOOK ON THE TREATMENT OF DIABETES MELLITUS. By THOMAS W. EDGAR, M. D., Author of *Psychology of Prognosis*, *Edgar Serum Treatment of Diabetes*, *Limitation of Starvation in Diabetes*. Boston: Richard G. Badger, 1920. Pp. 100.

A PRACTICAL MEDICAL DICTIONARY. By THOMAS LATHROP STEDMAN, A. M., M. D., Editor of the *Twentieth Century Practice of Medicine*, of the *Reference Handbook of the Medical Sciences*, and of the *Medical Record*. Sixth Revised Edition. Illustrated. New York: William Wood & Co., 1920. Pp. viii-1144.

LEHRBUCH DER MIKROPHOTOGRAPHIE. Von Dr. med. KURT LAUBENHEIMER a. o. Professor für Hygiene und Bakteriologie an der Universität Heidelberg. Mit 116 zum Teil farbigen Abbildungen im Text und 13 mikrophotographischer Aufnahmen auf 6 Tafeln. Berlin-Wien: Urban & Schwarzenberg, 1920. Pp. viii-220.

RELIGION AND HEALTH. By JAMES J. WALSH, M. D., Ph. D., Sc. D., Medical Director of Fordham University School of Sociology; Professor of Physiological Psychology, Cathedral College Lecturer on Psychology and Sociology, Marywood College, Scranton, Pa., Mt. St. Mary's, Plainfield, N. J. Boston: Little, Brown & Co., 1920. Pp. 341.

DIATHERMY IN MEDICAL AND SURGICAL PRACTICE. By CLAUDE SABERTON, M. D., Hon. Radiologist to the Harrogate Infirmary and to the Royal Bath Hospital, Harrogate; Late Hon. Medical Officer to the X Ray and Electrical Department, Royal Victoria and West Hants Hospital. With Thirty-three Illustrations. New York: Paul B. Hoeber, 1920. Pp. xii-138.

THE OXFORD MEDICINE. By Various Authors. Edited by HENRY A. CHRISTIAN, A. M., M. D., Hersey Professor of the Theory and Practice of Physic, Harvard University; Physician in Chief to the Peter Bent Brigham Hospital, Boston, Mass., and Sir JAMES MACKENZIE, M. D., F. R. S. P., LL. D., F. R. C. P., Consulting Physician to the London Hospital, and Director of the Clinical Institute, St. Andrews, Scotland. In Six Volumes, Illustrated. Volume II, *Diseases of Bronchi, Lungs, Mediastinum, Heart, Arteries, and Blood*. London, Toronto, Melbourne, Bombay, New York: Oxford University Press, 1920. Pp. xv-817.

Practical Therapeutics and Preventive Medicine

A Compendium of Treatment and Prophylaxis, Original and Adapted

Operation for Spinal Fusion.—A. Mackenzie Forbes (*Journal of Orthopedic Surgery*, September, 1920) gives the technic of his operation for spinal fusion as follows: A flap of skin sufficiently long to expose the area to be operated on is reflected from the concave side as in the Albee operation. The muscles on either side of the spinous processes are separated and retracted, exposing the laminae. The supraspinous ligament, the interspinous ligaments, and other tissues between the adjacent spinous processes are removed. In the case of the dorsal vertebræ the following additional steps are carried out. The spinous processes and laminae are so gouged by means of a concave chisel that their cortical layers are separated from the medulla beneath and a series of chips of bone and periosteum are pried up along the superior and inferior surfaces of these parts of the vertebræ. These chips of bone are made to interdigitate with each other thus similar cortical chips or digitations from the adjacent vertebræ are so apposed that the new bone thrown out from the raw surfaces of the exposed medulla will unite in one bridge or band extending from vertebræ to vertebræ. In other words, the laminae and spines in this region are in such close apposition that the interval between them is easily bridged by pushing the elevated fragments adherent to the periosteum alternately upwards and downwards from the laminae and spinous processes, thus making a form of connecting trellis.

Chronic Acid in Suppurative Dacryocystitis.—L. Chenisse (*Presse médicale*, April 24, 1920) describes a plan of treatment recently recommended by Vacher and Denis and which, it is stated, permits of maintaining patency of infected lachrymal passages and removes the necessity for surgical excision of the lachrymal sac. Thorough anesthesia of the eye is first obtained with five per cent. cocaine solution and the sac cleansed with boiled water introduced by means of a syringe and fine blunt needle into the lower lachrymal canal. A few drops of the cocaine solution, with adrenalin, are then injected through the same needle, and patency of the lachrymal passages ascertained by means of a No. 3 or 4 probe, left *in situ* for a few minutes. One third mil of a two per cent. or even a 3.33 per cent. solution of chromic acid is then drawn up into the syringe and injected slowly through the lower lachrymal duct, an assistant meanwhile introducing pure hydrogen peroxide solution drop by drop into the eye in order to neutralize the small amount of chromic acid solution which frequently flows back through the lachrymal passages. In sensitive patients one may supplant the ophthalmic anesthesia by spraying cocaine into the nose, a little of the caustic solution sometimes passing into the nasal cavities. The chromic solution is permitted to act for two or three minutes on the mucous membrane of the lachrymal passages and the treatment concluded by injection of a few drops

of hydrogen peroxide solution into the lachrymal sac. On the succeeding days the lids and eyes are washed with warm boiled water and the sac emptied by pressure at the inner angle of the eye. After a few days the lachrymal passages are examined for permeability and, if necessary, a permanent probe of silver wire inserted to restore it. Where the first chromic acid injection fails to yield perfect results the treatment is repeated once or twice, sometimes with stronger chromic solutions.

Blood Sugar Tolerance as an Index in the Early Diagnosis and Röntgen Treatment of Hyperthyroidism.—Eric R. Wilson (*Journal of Laboratory and Clinical Medicine*, August, 1920) studied the blood sugar tolerance in five cases of hyperthyroidism in young women between the ages of twenty-three and thirty-three, all unmarried. The determinations were made before röntgen therapy, after two series of röntgen treatments, and after the completion of three series of these treatments. As a result of this study the following conclusions are drawn: The blood sugar tolerance test is of distinct advantage in the early diagnosis of hyperthyroidism. That seemingly advanced cases of hyperthyroidism will respond moderately only to röntgen treatment, as shown by the blood sugar tolerance test. An abnormal blood sugar tolerance curve when due to hyperthyroidism will tend to approach the normal under röntgen therapy, indicating that excessive toxic secretion is lessened. Clinical manifestations of hyperthyroidism may be lessened, but an abnormal blood sugar tolerance curve may exist after series of röntgen treatments. The blood sugar tolerance curve is an index to thyroid hypersecretion in those cases in which toxic secretion has manifested itself by a decreased glucose tolerance.

Influence of Calcium upon Glycosuria.—A. G. Phocas (*Bulletin de l'Académie de médecine*, March 23, 1920), mindful of Fischer's assertion that calcium chloride removes glycosuria experimentally induced by sodium ions and of the known dynamic antagonism between sodium and calcium ions, was led to think that administration of calcium might be of service in some cases of diabetes. He gives brief histories of nine cases, in all of which the quantity of sugar passed was considerably reduced, or even glycosuria completely checked by this measure. In one of the most striking cases a sugar output of sixty grams a day was wholly arrested upon ingestion of calcium chloride for one week. The best preparation of calcium for these patients is asserted to be lime water, given in a daily dose of 100 to 200 mils. Preference is given to this preparation because its alkalinity may be of value in combating acidosis and in improving the patient's power to oxidize glucose. In fact, lime water is in one sense preferable to sodium bicarbonate as a general remedy for acidosis because the latter supersaturates the organism with carbon dioxide,

which acts as an obstacle to organic combustion. An excess of lime, on the other hand, tends to fix a certain proportion of the carbon dioxide set free in combustion, and may thus indirectly improve oxidation, besides controlling any overstimulation of the nerve cells due to the action of the sodium ions. The strict milk diet in diabetes probably acts, in removing glycosuria, by restoration of balance between the sodium and calcium ions. While reducing the sodium chloride in the system, the milk introduces a considerable quantity of calcium in the highly assimilable calcium compound it contains.

Syphiloma Vulvæ.—Arthur Stein (*Surgery, Gynecology and Obstetrics*, September, 1920) presents the following conclusions in regard to syphiloma vulvæ: 1. In conformity with modern knowledge and in the interest of a better understanding of the disease, all misleading names such as esthiomène or lupus vulvæ should be exterminated from the literature. 2. Syphiloma vulvæ correctly designates the disease as a manifestation of tertiary lues. 3. A positive Wassermann test is not essential in view of the long standing character of the specific infection in the majority of the cases. 4. The treatment under all circumstances should consist of, 1, operative removal of all tumors, hypertrophied tissues and ulcers, followed in the same session by, 2, energetic cauterization and combined with, 3, intensive antisyphilitic medication.

Plastic Surgery of the Ear.—Julien Bourguet (*Bulletin de l'Académie de médecine*, April 13, 1920) describes surgical procedures appropriate in various kinds of deformity of the ear. In cases of excessively large external ear a wedge shaped piece, extending through the entire thickness of the ear, is removed. If the upper portion of the ear then seems too broad, two additional wedges are taken out, the one above and the other below and perpendicular to the first. The raw margins are then sutured together. The lobule may also be reduced by removal of a triangular segment. Where the lobule alone is too long, a lozenge shaped section is removed and the lobule reduced to its normal size by appropriate suturing. Where the external ear is flat, having no helix, a crescentic skin incision is made on the anterior surface of the ear, four millimetres from the flattened margin, the cartilage exposed, and at a distance of three millimetres excision of skin and cartilage is performed without injuring the skin on the posterior aspect. The band of cartilage thus liberated from the main cartilage falls forward to form a curled margin and is sutured in proper position. In triangular ears a T shaped piece of tissue is removed and the margins sutured. Undue protrusion of the ear is corrected by removing opposite crescentic pieces of skin on either side of the furrow behind the ear and also a sickle shaped piece of cartilage, carefully avoiding injury to the skin on the anterior aspect; skin sutures are then inserted. Sagging ears are corrected in nearly the same manner, with the exception that in these cases a sickle shaped piece of skin of varying breadth is alone removed; the skin of the upper and lower margins is dissected up and then sutured, thus straightening the ear.

Production of Hemolysins by Injection of Salts of the Rare Earth Metals.—Frouin (*Paris médicale*, March 13, 1920) was able to cause the production of hemolysins by intraperitoneal injection in rabbits of salts of the rare earth metals. This process constitutes an example of the production of antibodies in the animal system without previous stimulation of a defensive reaction by the corresponding specific antigens.

Heteroplastic Bone Formation in the Fallopian Tube.—Goichi Asami (*American Journal of the Medical Sciences*, July, 1920) reports a case of aberrant bone formation in the fallopian tube. Cartilage was undergoing ossification and was surrounded by an organization tissue, some of which had been converted into an osteoid tissue. It is assumed that a metaplasia of the connective tissue occurred with the formation of cartilage and the production of bone, but how it was done is left unexplained.

Arthroplasty of Knee Joint.—Putti (*Journal of Orthopedic Surgery*, September, 1920), from a report of ten cases of arthroplasty of the knee joint, gives the following as the lessons learned: 1. Complete removal of all intraarticular structures is necessary. 2. The knee operated upon is usually larger than the other from hypertrophy of tissues. 3. Operation too soon after acute inflammation in the joint has subsided means failure. 4. In gonorrhoeal knees with arthroplasty the postoperative care should be gentle. A longer time is required for good results.

Arthrodesis for Nontuberculous Hip Joint.—H. W. Spiers (*Journal of Orthopedic Surgery*, September, 1920) presents the following conclusions from a study of thirty-four operative cases from the orthopedic clinic of the Massachusetts General Hospital: 1. Arthrodesis for painful hips of traumatic origin gives a satisfactory end result. 2. Arthrodesis for painful hips of hypertrophic arthritic origin are less satisfactory but justified. 3. The time of convalescence is a long one, approaching a year. 4. The tendency of the extremity is to return to the position of adduction and little should be promised in this regard.

Blood Changes Following Röntgen Ray Treatment of Leucemia.—Charles L. Martin and W. Denis (*American Journal of the Medical Sciences*, August, 1920) report the results obtained in four cases of myelogenous leucemia in which the chemical changes occurring in certain of the nonprotein constituents of the blood during röntgen ray treatment have been followed. In the more severe cases the nonprotein nitrogen was extremely high; after treatment a gradual but steady fall was noted. In view of the fact that the creatinin values are invariably normal and that in the most severe case the urea accounted for only twenty per cent. of the nonprotein nitrogen fraction, instead of the usual fifty per cent., the suggestion is made that in leucemia there is present, possibly as a constituent of the white cells, some nitrogenous constituent not accounted for in the present scheme of blood analysis. The true acid content of the blood was much increased.

Proceedings of National and Local Societies

AMERICAN ASSOCIATION OF OBSTETRICIANS, GYNECOLOGISTS, AND ABDOMINAL SURGEONS.

Thirty-third Annual Meeting, Held at Atlantic City, N. J., September 20, 21, and 22, 1920.

The President, Dr. GEORGE W. CRILE, in the Chair.

(Concluded from page 788.)

Treatment of Abortion Complicated by Sepsis.

—Dr. GEORGE A. PECK, of New Rochelle, drew the following conclusions: 1. The conservative treatment of abortion complicated by sepsis is based on pathological entities and clinical end results. 2. Hemorrhage is the only symptom that may demand a prompt and thorough emptying of the uterus for its control. 3. Every intrauterine manipulation or procedure should be executed with the greatest care to avoid traumatizing and otherwise injuring the endometrium. 4. Late cases, and especially those in which the patients had already been subjected to curettement, are eminently suitable for this form of treatment.

Missed Abortion.—Dr. JENNINGS C. LITZENBERG, of Minneapolis, Minn., stated that missed abortion was the retention of a dead fetus before viability retained in utero more than two months after birth. It was a common condition and was dangerous, as temporary ill health until the uterus was emptied, or permanent ill health would result. The diagnosis was not unusually difficult. The uterus should be emptied before the condition became a menace to health and life.

Preparation of the Skin for Operation with Special Reference to the Use of Picric Acid.—Dr. H. W. HEWITT, of Detroit, Mich., stated that it seemed clear that a good preparation for disinfection of the skin should possess the following properties, namely: 1. It should be simple and easy of application. 2. It should be efficient, *i.e.*, have the power of destroying the common skin organisms in a comparatively short time (not over three minutes), and be sufficiently powerful to keep the skin sterile during the operation. 3. It should not macerate or injure the skin in any way. 4. In laparotomies it should not injure the peritoneal coat of the intestine, if the intestine accidentally came in contact with it. 5. It should be of universal application. 6. It should contain no proprietary preparations, since these were of unknown strength and could not be depended upon. 7. It should be standardized, so that its antiseptic value might be known. Solutions might be standardized by the Walker-Rideal method. Of all the methods and chemicals in use today, very few approached this standard. Bichloride of mercury in aqueous solution would not sterilize the skin; in Harrington's solution it was efficient, but this solution contained hydrochloric acid and injured the skin. Dr. Hewitt said that he had used this solution extensively, but had discarded it.

About three years ago his attention was attracted to picric acid as used in the British Army. Chemically,

ally, picric acid was known as trinitrophenol, its formula was $C_6H_2(NO_2)_3OH$, and it was soluble in ninety-five parts of water and sixteen parts of alcohol. It had been used to a large extent in the treatment of burns and was known as a parasiticide. It was also astringent and penetrated deeply the corneous layer of the skin. Its only disadvantage had been in staining the skin, an effect which would last from twelve to eighteen days but might be removed by the application of a five per cent. solution of carbonate of soda, or a twenty-five per cent. solution of ammonia in ethyl alcohol, provided this was done immediately after the operation was finished. The picric acid solution used in these experiments and in his clinic was made by saturating a seventy per cent. ethyl alcohol solution with picric acid, which made a six per cent. solution.

The merits of this method of preparation were many, namely, it was simple; it was cheap; it was efficient; it did not injure the skin in any way, and might be used on any part of the body; it did not injure the peritoneal coat of the intestine; it contained no proprietary preparation, and its antiseptic strength might be standardized. This was only a preliminary report. The staff of Grace Hospital, Detroit, had used this preparation, up to August 1, 1920, in 926 cases, and it was now the adopted method of skin preparation in that hospital. The number of cases reported was still too small to justify definite conclusions, but Dr. Hewitt said he hoped at some future time to report a series sufficiently large to be of clinical value.

Pathology of Common Puerperal Lesions.

Dr. JOHN OSBORN POLAK, of Brooklyn, N. Y., stated that in order thoroughly to grasp the physiological pathology which actually took place, one must appreciate that the uterus, during involution, was a puerperal wound. Its interior was undergoing the normal process of repair and inoculation of this wound would produce either a toxemia or a definite inflammatory reaction, depending largely on the character of the infecting organism. At first, this wound infection was a local process which might be illustrated in the infected perineum, or the infected cervix tear, or the infected endometrium. In each, there was an inflammatory reaction in the adjacent tissues, which limited extension of the infective process and confined it to a circumscribed area about the wound or within the uterus. In these localized lesions the pyrexia and other constitutional symptoms were due to two factors. The toxemia resulting from an absorption of the toxins liberated by the bacteria and second, to the tissue reaction excited. On the other hand, the process might be a spreading infection extending beyond the wound area. This was due either to the increased virulence of the infecting bacterium or to the diminished resistance of the tissues. This spreading infection might occur by extension through the lymphatics within the walls of the uterus, spreading to the lymphatics in the para-

metrium producing a parametritis, or a peritonitis, or even a bacteriemia, or the infection might extend through the blood vessels, in which case it manifested itself clinically as a thrombophlebitis, an embolic pyemia, or a bacteriemia.

Clinical experience had shown him that a well contracted uterus in normal anteversion was capable of emptying itself of its contents if infection was not introduced from the outside. Experience had taught him that any sort of trauma to the delicate granulation wall of the puerperal uterus which was confining the infection within the cavity, opened avenues of extension, and that lateral parametritis was a constant sequel of attempts at digital or instrumental evacuation. It was important to note that the encapsulated germs did not always lose their virulence, but might on the occasion of subsequent traumatism or operation break out with increased virulence and cause a bacteriemia.

In blood stream infections the local pathological reaction was considerable, consequently the local symptomatology was insignificant; for whether the bacteria entered the blood stream via the lymphatics, or via the veins, their transit was so rapid and the reaction caused so insignificant, that appreciable local lesions must necessarily be absent. For the entrance of bacteria into the blood stream, there must be a puerperal wound which was inoculated by bacteria. Broadly speaking, the treatment depended on the pathological diagnosis and might be considered under the following heads: 1. Local measures which secured drainage and uterine contraction. 2. General supportive measures that increased the patient's resistance. 3. Specific remedies, especially of value in blood stream infections. 4. Finally, surgical measures. These were only applicable to abscess formations and thrombotic lesions of the pelvic veins.

Factors That Determine Tissue Resistance to Cancer.—Dr. JAMES E. DAVIS, of Detroit, Mich., said that the life of a complex organism was the result of cell interactions and the internal metabolism of the individual cells. Factors altering cell interactions were tolerated by the high vertebrate forms only when it was possible to accomplish conformation within a limited period of time. Convincing examples of this fact were observed after amputations, resections, traumatizations, autotransplants and homotransplants and heteroplastic grafts. Loeb transplanted thyroid into subcutaneous tissue, removed it seven days later, and found the transplant surrounded by a connective tissue capsule rich in fibroblasts. Inside the capsule a large vessel was proliferating. In the capsule and about the vessel a few thyroid acini in contracted form were persisting. Necrosis, hemorrhage and organization were going on elsewhere conforming the transplant.

The transplantation of tumors in the higher species of animals had failed, excepting the infectious sarcoma of the dog. In the normal tissues resistance was adequate for control and destruction of inherent neoplastic dynamic growth power which was uncontrollable in its autogenetically prepared tissue. The cell and its surrounding fluid possessed interactive and retroactive properties. The most convincing proof of this was given by

Carrel who had grown connective tissue *in vitro* for almost eight years. The plasmatic jelly medium when used too long became liquefied, its fibrin disappeared and the air rarefied, effecting a marked slowing of growth. Fresh, unused plasma from the icebox promptly quickened the growth rate. The plasma from a chicken four to five months old caused a growth fifteen microns more extensive than did that from a five to six year old chicken.

The reactions following exhaustion, irritation and specific diet, gave acidity, toxicity, and cytoplasmic sensitization. Measurement of these states was a procedure of real scientific value to the clinician. The reaction of connective tissue to epithelial neoplasia before and after its invasion was significant and important. Epithelial cell disintegration stimulated phagocytic and proliferative connective tissue reaction and the latter in turn might possibly cause increase of dynamic growth power, without a corresponding increase of nutrition. The clinical recognition of long continued cell irritation and unbalance of tissue was too frequently delayed until after the expression of organic functional disorder. The determination of stressed or irritated tissue potentiality should have much attention. The determination of sensitization acidity and oxidation reactions were essentially quantitative tests which had relational value in this problem. It was mainly a quantitative difference in energy and time factors that existed between regenerating and cancerous cells and it was for this difference one should test. Physiological growth, regeneration and neoplasia utilized the same means to produce a product and resistance was an essential cause for all three. Normal growth was production under control, regeneration was production to control, and neoplasia was production without control.

BRITISH NATIONAL ASSOCIATION
FOR THE PREVENTION OF
TUBERCULOSIS.

*Annual Conference Held in Liverpool, England.
October 7, 8, and 9, 1920.*

The President, SIR ARTHUR STANLEY, in the Chair.

Prevention and Treatment of Tuberculosis.—A paper on this subject by Dr. E. W. HOPE, officer of health of Liverpool, was read by Dr. Musson, deputy medical officer. It presented a review of the various methods of prevention and treatment of tuberculosis, advocated from time to time, the extent to which they have been followed, and the results obtained. Dr. Hope pointed out that treatment had hitherto received an overwhelmingly greater amount of attention than prevention. In the case of the other great scourges of the human race in bygone days, plague, leprosy, smallpox, typhus, and malaria, the same phenomenon was observed, but prevention had come into its own at last. He thought that there was no doubt that the sanatorium had been introduced with an unfortunate flourish of trumpets, which resulted in inflated expectations among those who did not appreciate the precise functions of such institutions. Sanatoriums were necessary, but the benefits that they conferred

would be more effective and more lasting the earlier the patient could be brought under their good influences. The value of educational methods in the prevention of tuberculosis could hardly be exaggerated. The sanatorium, the tuberculosis dispensary, and the medical practitioner, all had their part.

Tuberculosis—a Social Problem.—Lieutenant Colonel NATHAN RAW, M. D., M. P., said that of all the diseases with which authorities were called upon to deal none was more difficult, perplexing, and unsatisfactory than tuberculosis. It was difficult because, unlike any other disease, tuberculosis was part and parcel of the social problem of the country. It thrived and was spread in insanitary housing conditions and in turn tuberculosis caused poverty and distress with unemployment and destitution. The problem was perplexing, because we had not yet an accurate knowledge of the disease. It was known that tuberculosis was caused by a germ, the tubercle bacillus, and was therefore an infectious disease, but they were not by any means certain as to how or when infection took place in the human body. It was known that tuberculosis was never hereditary, and that it was therefore a preventable disease, and, given proper and adequate treatment, it was curable. The results of treatment were at the present time unsatisfactory, due almost entirely to the fact that sufficient time could not be devoted by the patient to his cure. In his opinion, nothing less than six months' treatment under open air conditions was of much service, and many patients required one or two years. The provision of village settlements in which suitable men might permanently reside, earn their own living, and have their relatives live near them, was the most satisfactory method of treatment, but, of course, it was the most costly. He felt sure that the removal of tuberculosis, more especially in regard to treatment, from the provisions of the National Insurance Act, and its constitution as a special branch of the Ministry of Health, the responsibility for dealing with it being given to the local authorities with a substantial grant from Imperial funds toward the cost of treatment, would result in enormous improvement.

Sanatorium Treatment of Tuberculosis.—Dr. IAN STEWART STROTHERS, of Aberdeenshire, said that in his opinion people were not justified in being content with the results obtained from sanatorium treatment, and this belief was shared by others who had to deal with individual patients. He thought that there was a growing sense of dissatisfaction among the laity with the small number of cures turned out by sanatoriums. Nevertheless, experience showed that these institutions remained the best means at their disposal. What was most urgently needed was a national scheme of widely organized research directed toward the treatment of pulmonary tuberculosis. He suggested that every sanatorium should be a centre where students and graduates could have a few weeks of instruction to increase their knowledge of tuberculosis. Two factors militated against good results from sanatoriums, a, the large number of patients allocated to one medical officer, and, b, the late stage of the disease when patients arrived.

A Specific for Tuberculosis.—Dr. PAUL LEWIS, of the Henry Phipps Institute, gave a brief account of the experimental work in tuberculosis that was being carried on there, and said he felt confident that systematic trial would result in the finding of a specific chemical substance that would be as beneficial in tuberculosis as salvarsan was in syphilis.

Crowding in Tuberculosis Clinics.—Dr. H. HYSLOP THOMSON, county medical officer of Hertfordshire, County Council, referred to the undesirable crowding that existed in certain tuberculosis clinics, and of the necessity for coordinating home and dispensary treatment. Such coordination was most necessary in scattered rural districts. He suggested the appointment of medical practitioners as part time tuberculosis officers to work in cooperation with whole time officers whose duty would include attendance at the clinic at each session with the tuberculosis officer and the attending of domiciliary cases at their homes.

The Human Element in Tuberculosis Work.—Sir HENRY GAUVAIN, medical superintendent of Lord Mayor Ireloar Cripples' Hospital, said that money might be lavished on a scheme for tuberculosis control, but unless the human element was at work the money would be wasted or yield a poor return. The British Government had realized that important grants of money must be made, and was not only doing much, but was prepared to do much more. The Ministry of Health had recognized its responsibilities, was making increased provision for treatment, establishing more beds, founding colonies for the tuberculous, and straining every nerve by exhortation and grants of money to meet the needs of the unfortunate sufferers from tuberculous disease. But was it doing enough; was it getting or going to get the best value for the money and effort expended? If not, how could it do better? Were its energies being utilized in the best direction? If not, could they suggest better or more perfect methods? These were questions which those seriously engaged in solving tuberculosis problems must endeavor to answer. They were fighting an enemy more difficult to subdue than any human foe. They were spending vast sums of money; they were going to spend more, but they lacked a clearly defined policy. The remedy was reasonably clear. Intensive and well planned efforts to educate the public to the danger confronting it should be made. These were preventive and defensive measures, but the surest means of defense was offense. It was here, perhaps, that they could do much more. The neglect of adequate instruction in the prevention, diagnosis and treatment of tuberculous disease in the medical schools was serious. A few teachers did take some interest in the treatment of tuberculosis, but they appeared to be the exception and not the rule. Much more time should be devoted in medical schools to really intelligent instruction in tuberculous disease. It was imperative, if real and speedy progress was to be made, that thorough and systematic instruction in all forms of tuberculous disease should be given in the medical schools and facilities given for extramural knowledge to be obtained. In all the British Empire only one university had established a pro-

fessorship in tuberculosis. That was at Edinburgh, where the chair was held by the distinguished vice-president of the association council, Sir Robert Philip. As far as he was aware, in only one special hospital for nonpulmonary consumption was regular and systematic instruction given, and that was at Alton, where the wards were thrown open to medical men and students by the generosity of Sir William Ireloar and his cotrustees, and even meals were supplied to students attending the courses, all without a fee of any kind. He held strongly that their first line of offense against tuberculosis was held by the general medical practitioner. Too little had been done to enlist his powerful help.

When they came to the tuberculosis service an even worse state of affairs obtained. He realized that he was treading now on dangerous ground. He had the greatest admiration for those devoted men engaged on this thankless and comparatively unremunerative task. Only those who had had an opportunity of seeing their work closely, understanding the difficulties of their position, and the depressing nature of their duties, could realize the disadvantages under which they labored. Happily, a large proportion were men of vast experience in tuberculosis, experience acquired after many years of close study, but that was due to a combination of circumstances for which the public was to be congratulated and was not the result of generous or even good management. Only enthusiasm and a high sense of duty could sustain them in a thoroughly disheartening task. There was much discontent in the service, and the members of it would be more than human if there was not. That state of affairs should be remedied.

How could the necessary reform be effected? It might not apparently be so urgent now. But what about the time when these highly skilled and experienced men were no longer able to continue? It might be urged that they would be replaced; but by whom? It was not generally known and it should be known that not one single regulation had been framed governing the admission of recruits to the tuberculosis service. A man might have had no experience whatever in such work, might be unsuited by temperament or by training, but so long as he was a qualified medical man, he was eligible for appointment as tuberculosis officer. And when appointed it must be remembered that he was given no facilities whatever for becoming a real expert at the work. He was thrown straight into an appointment, and had to acquire knowledge of the work as best he could in a limited field. He had urged the establishment of a diploma in tuberculosis which would prove the holder's competence in the duties he had to undertake. If the Government was going to launch a great campaign against tuberculosis, half measures would not do; efficient work was essential and was obtainable. The tuberculosis service must be regarded seriously; the human factor required to achieve success must be fostered, encouraged, and given power to achieve substantial results. The tuberculosis service must be an attractive service, offering scope and substantial reward to those entering, and facilities for research and progress.

(To be concluded.)

Letters to the Editors.

THE MEDICAL PROFESSION AND THE HALL OF FAME.

NEW YORK, November 10, 1920.

To the Editor:

A few months ago I sent out a plea for recognition of the medical profession in the Hall of Fame and especially for Morton as perhaps the most outstanding figure in American medicine. This was published in many of our leading medical periodicals, and as yours was one which extended the hospitality of its columns to the cause, I am sure you have in no small degree helped in the election of Morton's name. The outcome of the recent election must be gratifying to every American physician who is familiar with Morton's life, his struggles for recognition, and the sad experience he was made to undergo by those who attacked him during life and those who up to this time wished to withhold from him the credit for his work.

Our never to be forgotten Osler, with his keen sense of justice, gave us the result of his profound study of historical medicine concerning Morton's share in the discovery and promulgation of ether anesthesia in the following words: "William T. G. Morton was a new Prometheus who gave a gift to the world as rich as that of fire, the greatest single gift ever made to suffering humanity." And Professor Welch confirms the investigation of his lifelong friend and in one of his recent letters to me says: "Surgical anesthesia has been America's greatest contribution to medicine and surgery and it would be a thousand pities not to have this recognized in the Hall of Fame. As only one name can be selected for this purpose, it is clear to me that this name should be Morton." Professor Welch was one of the electors and his influence was undoubtedly an important factor in Morton's final triumph.

It will doubtlessly interest the readers of the NEW YORK MEDICAL JOURNAL to know the exact outcome of this year's election of America's immortals for the Hall of Fame. Of the 178 names voted on the following seven were chosen: Samuel Langhorne Clemens (Mark Twain), who received seventy-two votes; James Buchanan Eads, the engineer, fifty-one; Patrick Henry, statesman, fifty-seven; William Thomas Green Morton, discoverer of ether, seventy-two; Augustus Saint-Gaudens, the sculptor, sixty-seven, and Roger Williams, the minister, a leader in liberal religion and founder of Providence, R. I., sixty-six. The only woman who received enough votes to place her name on the roll was Alice Freeman Palmer, the educator, who received fifty-three votes.

That Morton, together with our most beloved Mark Twain, should have received more votes than any other candidate, is a particularly good omen for the medical profession, and it is to be hoped that in future elections the names of our other great pathfinders in medicine and surgery may not be forgotten. Such names as Ephraim McDowell, J. Marion Sims, Benjamin Rush, Walter Reed, all deserve a place among the immortals in America's Hall of Fame. S. ADOLPHUS KNOPF, M. D.

THE THEORY OF THE PNEUMA IN ARISTOTLE.

BY JONATHAN WRIGHT, M. D.,
Pleasantville, N. Y.

The revolt of Hippocrates against the Nature philosophers is set forth in the opening paragraphs of the essay on *The Ancient Medicine*. They had indeed failed to solve the mystery of life and they had also failed to correct the erroneous and folly laden assumption as to the pneuma and the air, but in order to secure the resumption of that progress which the Nature philosophy had initiated and of which Hippocrates was the heir, this was a necessity. That was to begin, however, only after the passing of Hippocrates and Plato and Aristotle. Galen credits them, apparently only on evidence accessible to us still, with very much more knowledge of anatomy than is apparent to us in their writings. He says (1a) they did not write of what, by virtue of their manner of medical training, they had acquired in home instruction as boys, apprenticed to a preceptor who was often a father, but this is hardly convincing to the modern reader who easily perceives the cause of error into which before the time of the Alexandrians, the Greeks fell in the explanation of morbid phenomena they encountered in practice.

It would seem as though, if the pneuma entered the hollow channels of the body and was seen to pulsate in the heart and in the peripheral blood vessels, from which blood spurted when cut, that blood must accompany the pneuma. Indeed this is still further remarkable from a historical point of view. "Blood is the life" was a dogma accepted by primitive man and by civilization immeasurably older than Greek culture. It apparently had been modified by some of the orientals and had been thought of rather as the vehicle of life or of the pneuma, but it was apparently in Egypt that the vessels were first thought of as carrying it exclusively. One fails to be at all assured of any provision made for a distinction between those which did and those which did not carry blood. Until, therefore, there came a time when the purely objective differentiation of artery from vein began to be made, it was quite impossible for any theory to arise which separated the blood from the air. The separation of purely blood channels from gastrointestinal, from air channels and from other ducts and conduits of the body was probably never entirely complete in the anatomy of

the Egyptians (2). The confusion of the trachea and the other air channels with blood channels appears in the earliest of the Greek records and this lack of differentiation of the veins from the arteries was the origin of that school of pneumatists who declared the arteries contained both blood and air, when that differentiation was once made, but apparently by the time of Galen the majority believed the arteries carried air alone and the veins blood alone. I shall have occasion to discuss the doctrine as to this point, which obtained in the time of Hippocrates, but the state of belief may be inferred from the fact that Aristotle, who lived after him by a generation at least, knew, apparently, all that had been done by his predecessors, and yet made no mention of the differentiation, but himself advanced it so far only as to name the trachea the *aspera arteria*, instead of calling it simply *arteria* and giving the modern name to the aorta (3a), and saying some blood vessels have thicker coats than others.

Man had begun to reason that if, as was quite apparent, the pneuma was the regulator and director of all things in the body and directly continuous with the world soul outside of it, then all the emotions and intelligence of man must dwell in his heart, whence it could regulate all peripheral manifestations. I am not going to detail the urgent reasons he found in facts known to him and in the beliefs of the more ancient nature philosophers, but Aristotle believed this. He sought support in the facts. The greatest mind, not only of philosophy, for Plato also believed it with reservations and explanations, but Aristotle, the greatest observer perhaps of all time, believed it, just as Homer and Hesiod, the greatest of poets, believed it. We may laugh at Diogenes Apollonius, since we know little else about him except that Aristotle quotes (3a) his description of the veins, but no one laughs at Plato and Aristotle who has read a page of them, or at Homer, either, who has read a line of him. The intellect, as well as the emotions, was located in the heart, because the soul pneuma went there, and thither went the air when it was identified as the material part of the pneuma.

The belief in this basis fixed in the minds of men, the beating of the heart from fear or exultation, elated by love and distressed by sorrow, we can easily understand, was a suggestion of proof, if any were needed, which was weighty enough though it may seem to us trivial. The eructations of a

disordered stomach, accompanied by cardiac sensations, are a familiar phenomenon easily attributable to disturbance of the pneuma. The latter passes, it is true, into the mouth and down the windpipe to the root of the lungs, but there a complexity of structures was found that defied exact definition. If the pneuma was the regulator of life, if the brain was not yet known as the centre of thought, emotion and of sensation and the organ from which voluntary motion received its orders, then the pneuma which presides over all these must pass to the uttermost regions of the body and, in default of the nerves also unknown, must regulate matters on the spot or have its seat in the blood which reaches all parts. In the sensory centres is the heart which is the reservoir of the blood. Thus all concepts of anatomy and physiology hung upon the central belief in some material thing which traversed the conduits of the body with the blood or through certain of them which we now know carry arterial blood and which, at the root of the lungs or in their substance, was in continuity or in direct connection with what we now know as the air passages.

I have purposely referred to the pneuma as a material thing, despite the fact that philosophers identified it with the soul within the body and with the world soul or universal pneuma without the body. Those of us who think of the soul no longer connect it with material things. We no longer thus think of fear, joy, hate; they no longer have for us a local habitation as well as a name. All these concepts, however, for the ancients were realities. Galen, paraphrasing the way of Plato in the *Timæus* describes (1b) the Creator, or Nature, making the substance of the humors out of the dry and the wet. Out of the cold and the hot he constructed the pneuma, and this he used as an instrument to mold the humors into the shape of the organs of the body. Of course it is not difficult to find many passages in which we miss this materialistic acceptance of abstract ideas, but it nevertheless will be found to lie at the bottom of what, unless we realize its existence, would otherwise be quite inexplicable in the thought of ancient philosophers from Plato down.

Plutarch said the Stoics make the qualities which we designate as descriptive adjectives or attributes to nominal or actual objects, "bodies also." They must have their seat somewhere in the body, chiefly as parts incorporated with the pneuma or soul. We may call this mysticism, but it has a material connotation which we must not allow to escape us in the study of ancient anatomical thought. It is not sufficient for us to know that practically all medicine was originally written in the temples but we must see clearly the origin of the ideas which entered into the history of medicine after it left the temples. For more than a thousand years they bore the stamp of their birthmark.

Aristotle did not escape their influence. He had noted indeed the difference in the thickness of the tunics of the blood vessels. Herophilus after him said (1c) the pulmonary artery had walls six times as thick as the pulmonary vein. But the pneuma was still such a real thing to Aristotle,

though evidently the concept of the soul was a little separated in this thought from the pneuma, that he explains the voice (3f), in contradistinction to the other noises of respiration in the larynx, as the force of the soul striking on the respired air. We gain the impression from this that it is not the command of the brain sending a message through the laryngeal nerves for the larynx to produce a sound indicating what is going on in the brain. That, I take it, is the modern view in the simplest words. In the ancient view it is the pneuma on the spot which orders things so that the thought, in which it participates and which it connects with the outside world, finds expression. I may attempt to render it more plain by another illustration. Today, as of old, a cut made at the surface of the skin seems instantaneously apprehended by consciousness. We can now measure the time, it is true, but it seems still that we instantly jerk away the injured finger. We understand it as a fact now, but if we had had to explain it to an ancient Greek, that the sensation must travel up one nerve to the brain, or spinal cord, and then have its message translated and orders issued and sent down another nerve for the withdrawal of the finger, the Greek would have thought it one of Aristophanes's jokes. For him the pneuma was on the spot, in communication through the blood channels with the heart, it is true, but ready to act in an emergency on its own initiative reflex action, without waiting for orders from headquarters in the heart. This is the conception Galen in his turn, having discovered the laryngeal nerve, set himself to dispel. It took a thousand years and more.

Aristotle was not ready to go as far as the half mythical Orpheus, Simplicius says, and "call the aptitude of bodies to life respiration," but to the modern reader his attitude does not seem far removed from this pantheism of primitive man. In his *History of Animals* (3b) Aristotle refers to the heart, "or a part analogous to the heart," as the principle of motion and the principle of the senses and, therefore, of the whole animal; the brain only tempers the heat of the heart. Others, Plato and the authors of some of the spurious Hippocratic books, some supposed to be earlier, some certainly later than Hippocrates, also thought it was the pulmonary air that cooled the heart. In his treatise on the respiration (3g) Aristotle agrees with them that the function of respiration is the regulation of the heat and the moisture, because of the porous nature of the lungs and because the air is so attenuated. In his tract on *Sleep and Wakefulness* (3h) he says the intelligence is shut off from the head by the ligature of the jugular veins, but evidently, from what precedes, this is due to the pneuma of the blood having its communication with the heart interrupted, and not due to the blood stasis in the brain.

The soul of man includes the principle of sense and motion. As it has become clear that Plato (5), like the African and American philosophers of primitive man, was driven to the expedient of multiple souls or the manifold function of the soul, so Aristotle carries a full cargo of functions for it and evidently sails the seas, as they did, on a pneuma

ship. He adjusts his anatomy of the heart and blood vessels better than did Polybus and Syennesis and Diogenes Apollonius, whom he quotes; but the trachea remains the *aspera arteria*, with no indication, but a note on the variations in their calibre and wall thickness, that blood vessels are divisible into veins and arteries.

Aristotle is thought to have attended Plato's teachings in the Academy for some years succeeding 367 B. C., founding the lyceum at Athens perhaps thirty years later. The son of a distinguished physician, the Æsclepiad Nichomachus, and himself apparently versed in all the theoretical medical learning of the day, he knew much more of the internal anatomical structure of animals than of man. Galen said, despite his great knowledge, he knew little of dissection. We must keep this in mind in thinking out a consistent explanation for the persistence of the fundamental theory of life phenomena represented by the pantheistic conception of the *pneuma*. I have emphasized elsewhere (5) its intimate association with the very fibre of the thought of primitive man, but it could only persist as an interpretation of human anatomy in the absence of an intimate acquaintance with practical experience in the dissection of the human body. It is true we must accept this explanation with all its limiting modifications. There are abundant examples of the existence of a knowledge of the most elementary facts which are entirely inconsistent with long prevailing theory. The facts often fade from men's consciousness before they have destroyed the false belief and have to be discovered again. We may find one exemplification of this in Galen's attitude toward the *pneuma*. He was blinded by the prevailing belief, doubtless, to such an extent that he missed the evidence open to his sight in the dissection of animals, but nevertheless he was by virtue of that experience only a faint hearted believer and pointed out, not enough evidently to dispel all his prepossessions, but ample to allow us to perceive that had he had sufficient moral support he would have preceded Harvey in a proper understanding of the circulation. As it was Galen faltered and his mental process seems to have been: If there is such a thing as the *pneuma* then we must accept the following as the physiological fact; whereupon he proceeds (1d) with a scheme that was as preposterous then for him as it would be for the most experienced naked eye observer today. Galen, however, had a very mediocre, if very vigorous, mind. We may conjecture that the results would have been different if Galen's facts had been food for the intellect of a Plato or an Aristotle. But despite all the philosophy and notwithstanding the profound skepticism of the minds of these Greeks, in their day they were slaves, if not to the feelings of horror of the contact of the dead human body entertained by the common people, at least they were subservient to the laws and the public sentiment arising out of that primitive terror which to some extent is still with us. That real dissection of the human body should apparently have begun at Alexandria, on the continent of Africa, the birthplace and the domicile of religious faith and fanaticism, is explicable only on the reflection that the

Greek rulers were enlightened men, free from the dangers the superstitions of the masses create for those innovators living under more democratic forms of government. Every rose has its thorn, as we modern democrats often have occasion to reflect.

But we should not be blinded by the absence of freedom of thought which finds courage under the ægis of autocracy to fly in the face of popular prejudice. There was something more than the shudder at the sight of death, something more deeply grounded than the religious and legal formula based on it. Both Aristotle and Hippocrates were alike ignorant as to the number and arrangement of the sutures of the human skull, which in those days must often enough have offered itself for observation. It is plain that Hippocrates must have examined skulls, as in self criticism for a mistake in diagnosis he reveals an acquaintance with sutures, but he gives no coherent account of them, while Aristotle seems to have examined them in the most superficial fashion. There seems indeed to have existed an unconquerable repugnance even to look at the dead human body, which we can easily understand, but singular to say this coexisted with an indifference to what a careful study of its anatomy might have taught them which amounted to apathy and which it is more difficult to understand. Instead, therefore, of wondering at the errors of Aristotle's physiology of the circulation and the respiration we should realize his deep ignorance of anything in the hidden anatomy of man which differed from that of animals. This he manifestly was well acquainted with, yet even in animals he missed the obvious features in the thoracic viscera which should have given him a clear insight into the erroneous details of his theory of the *pneuma*. Fundamentally it rested on the truth which we still recognize in the chemical term, oxygenation. That we know lies at the basis of all animal life manifestations and the *pneuma* we may look upon as that indispensable and chief element in the air which must go everywhere in the body to maintain life.

Yet for Aristotle the chief function of respiration was to supply air and water to the heart for the regulation of the animal heat which had its chief seat there, the brain sharing the function of moistening the heart. We may find a sufficient explanation for the ignorance of anatomy in the few generations which cover the life spans of Hippocrates, Plato and Aristotle, if not for their apathy in the matter, but that Aristotle, with all his biological knowledge of bird and beast, including an unrivalled knowledge of their anatomy, with the advantages of the parental training and those of Plato himself, that a mind such as his thus equipped should on the whole have had less accurate ideas of human physiology than Plato's seems to me singular. It would seem that so long as a scientific man does not use his facts in a critical analysis of his theories, so long as he does not practise those rules of deductive reasoning which Aristotle himself formulated, so long as he does not combine induction and deduction in his every day thought, he is sure to go wide of the path of the truth.

Correct as the fundamental idea of the primitive

pneumatist was, it led astray one of the greatest minds of antiquity not only as to the physiology but as to the anatomy itself of man. Unaccustomed, as we must suppose Plato was, to study at first hand the facts of nature, untaught in the knowledge his eminent pupil brought into the world, he was still able to construct a less erroneous view of physiological processes than Aristotle. He arrived at a basis more in accord, crude as it was, with the principles which underlie the teachings of modern histology, than did the great naturalist. If I have read Plato aright he appreciated the necessity for the existence of the capillary circulation, if not for the lymphatics and his deductive reasoning supplied what Aristotle's facts failed to reveal. In his *History of Animals* (3) Aristotle declares: "When the trachea is filled with air, it distributes breath (pneuma) to the cavities of the lungs . . . it only inhales and exhales breath and nothing else either dry or moist." There is no germ here or elsewhere of a capillary circulation, no hint of the life giving oxygen, the real food of life, indeed he denies the idea of it. In his essay on *Respiration* he says: "It must not be considered that respiration is produced for the sake of nutriment, as if the inward fire were nourished by spirit, just as fire is nourished by combustible matter and the vital heat being nourished the relics of the nutriment are emitted by expiration." As a matter of fact this is in general outline just what occurs. His denial of it was in opposition to the views of others who had arrived thus far on the right path without the encyclopedic knowledge of the Stagyrte. He could repeat (3d) with apparent credulity the mythical view of an Australian savage, that impregnation with the pneuma is possible, telling of a hen partridge fecundated by a breath blowing on her from the male—but the biochemical significance of the pneuma when it is taken in by respiration he missed; not only that, he rejected any suggestion pointing in that direction. He criticized the passage in the *Timæus* on which in the last essay I dwell at some length, because it makes the inspired air take part in the process of digestion also and it is not confined to his idea of cooling and moistening the pneuma in the heart.

As soon as we reach Plato and Aristotle we find the soul quite a complicated affair. This is very likely because we have so much more of their work than that of other philosophers left to us. From others there remain to us only isolated sentences or phrases from which we are to infer their views, isolated and quoted by Aristotle himself or by Theophrastus, his successor or by others much later, but in all probability the views of others, as completely developed as those of Plato and Aristotle, would show a like confusion and, of course, a greater variety. To Aristotle, in his treatise on *The Soul* we owe what we have of the views of Thales and Democritus, of Hippo and Heraclitus, of Empedocles and of many others. To the extent with which he notices these is due our somewhat uncertain idea as to just what he believed himself. We get enough out of it all, however, to see that he entertained essentially the ideas of the Egyptians, as set forth in the papyri we now have. The soul, if not identified fully with the air of the breath, had its seat with it

chiefly in the blood. In referring to the heart or a part "analogous to the heart" as the principle of motion and the site where the apperceptions of the senses are interpreted, he is in opposition to Alcmaeon and Plato. That was the seat of the intellect, which Plato, doubtless influenced by the traditions of Alcmaeon's teachings in the Sicilian School, placed in the head, in his tripartite division of the soul of man. For Aristotle the regulation of the heat and the moisture of the system was the manifestation of the pneuma or the soul mingled with the blood near the heart, as we have seen in his treatise on the respiration, but in his *History of Animals* we read (3c): "Passages lead from the lungs to the heart and they are divided in the same way as the trachea throughout the whole lungs and the passages leading from the heart are at the upper part. There is no passage which is common to them both, but by their union they receive the breath and transmit it through the heart, for one of the passages leads to the right cavity and the other to the left." The contradiction and the obscurity here we have every reason to believe were due to the necessity that pressed upon him to get the pneuma out of one set of vessels and into the other. The union of them he had never seen and his conception of it is not suggestive of anything but his embarrassment when confronted by the theory and his inability to find support for it in fact. His imagination did not serve him as well as Plato's did him.

Aristotle is credited with having named the aorta. He seems to have used the word previously applied by some of the Hippocratic writers to the lower part of the air passages. Some have ascribed to Hippocrates the first differentiation of artery from vein, but his allusion to the fact that some veins have thicker walls than others is the only intimation that I find of it, while Galen ascribes the differentiation more specifically to Praxagoras, the instructor of Herophilus, but he makes the assertion without citation. The ascription of sensory phenomena to the heart does not seem to have been worked out very satisfactorily, but sensation for Aristotle, as Beare (6) thinks, seems to have been carried in the same vessels with the blood associated with the pneuma, just as we have seen the soul or the pneuma producing the voice in the larynx. It seems to me quite clear that the whole scheme in Aristotle's mind was blurred by his clinging to the pantheistic basis of primitive man's conception of the soul as responsible for all the details of bodily movement and sensation after his own observations had necessitated its modification.

STANDARDIZED ROENTGEN RAY IN THE TREATMENT OF SKIN DISEASES.

With Special Reference to Eczema.

BY HOWARD FOX, M. D.,
New York.

One of the greatest advances in dermatological therapeutics has been the standardization of the röntgen ray. Previous to the introduction of the Coolidge tube all routine röntgen ray treatment was attended with danger even in the hands of an expert. It was necessary for each operator to evolve his own technic, which varied according to the apparatus used. Only by radiometric measurement was it possible to compute the amount of ray given in any particular case. At the present time it is as easy to give a precisely measured amount of röntgen ray as it is to prescribe a measured amount of strychnine. To obtain this desirable result it is necessary to use a Coolidge tube and an interrupterless transformer. The dosage can then be measured by pastilles (of platinocyanide of barium) or by arithmetical computation. Measurement by pastilles is not very satisfactory as this method is difficult for some to learn and in any case introduces the element of personal equation. Through the splendid pioneer work of MacKee, Shearer, Remer and Witherbee, it is now possible to dispense entirely with pastilles and depend upon a simple arithmetic formula to standardize a röntgen ray apparatus.

THE QUANTITY OF THE RAY.

The quantity of ray depends on four factors, namely, spark gap (representing voltage) milliamperage, time and tube distance (from anode to skin). Within certain limits these can be changed to suit the convenience of the operator. In most of my work the following figures have been used: six inch spark gap, two milliamperes, three minutes and eight inch distance, for one so-called skin unit. A half unit was obtained in a minute and a half, and a quarter unit in forty-five seconds, the other three factors remaining unchanged. In cases of ringworm where short exposures were preferred the figures were, as follows: six inch spark gap, five milliamperes, a minute and nineteen seconds and six and one half inch distance.

The skin unit corresponds to one H (Holzknecht) unit with pastille lying on the skin (skin distance) or about five H units with pastille at middistance between anode and skin. This dose will epilate the scalp but will not produce an erythema except as MacKee says, "if given at one sitting, on very sensitive parts such as the face of a young girl." In speaking of H units or fractions thereof in the further course of this article, the words, skin distance, will always be understood.

Over three years ago I published some observations on The Coolidge Tube in the Treatment of Nonmalignant Diseases of the Skin. This was based on an experience of eighteen months with a standardized technic, though I had previously used the ray for a dozen years in the old inaccurate and unsatisfactory manner. It is not often that a paper on a therapeutic subject can be quoted three years later without making certain reservations if not repudiating much that was previously written.

In the present instance my feeling on the subject is best expressed by saying that I enthusiastically agree with my former statement as follows: "With the new apparatus and technic, my opinion of röntgen ray therapy has entirely changed and I may add that I have never made a change in therapeutic measures that compares in satisfaction with the change from the old to the new method of using röntgen rays." My subsequent experience has substantiated this opinion and enabled me to enlarge the usefulness of the standardized treatment. I also subscribe thoroughly to another former statement that "I feel certain that the next generation of röntgen ray therapists will all adopt the newer methods of treatment and think it likely that before long the question of having used the safer technic may have a medicolegal bearing in cases of röntgen ray burns."

What has been said will sound like the veriest platitudes to those who use a standardized technic. Unfortunately there are still many dermatologists who either continue to use the old methods in a desultory way or do not use röntgen ray at all. The profession as a whole is certainly ignorant of the possibilities of modern röntgen ray, while our patients (except those who have been treated by this method) are generally astonished to learn that the value of this agent is not confined to fluoroscopic or photographic work. The technic of giving measured doses is not difficult to learn, even for those who have had no previous experience with the ray. For the trained röntgenologist it is child's play.

In regard to filtration it should be said that practically all of my work has been done with unfiltered rays. I can see no advantage in using an aluminum or other filter in the great majority of skin diseases, situated as they are on the surface of the body. In a few cases, where deep subcutaneous lesions are present as in a case of true Hodgkin's disease, I have preferred to use a filter of three millimetres of aluminum. Filtration, of course, is necessary in treating lymphatic glands or carcinoma of the breast, etc., but this is hardly within the province of dermatological therapeutics.

PROTECTION OF THE SKIN.

Protection of the skin which is not desired to be rayed is amply afforded by lead foil of the thickness of one thirty-second of an inch. As a substitute for lead foil I have used rubber cloth one eighth inch in thickness. One advantage of the rubber cloth is that a single piece of it can be used to cover a considerable area of the body. It is also much more durable than the lead foil though less flexible. It supplements the lead foil as a protection, each having its use according to the locality treated. In treating large areas, such as the back, it often seems best to dispense with the protecting foil and give several exposures at different points and rely upon overlapping of the ray as described by Fred Wise. I still find it most convenient to treat my patients in the recumbent position on a wooden table. A metal table was early discarded after the tube had been punctured by accidental contact with the metallic portion of the tube stand.

An erythema should always be avoided except when treating malignant conditions where two H

units or even larger doses are given. It is only when an erythema is produced that there is any likelihood of future telangiectases. In nearly five years' experience with the new technic I have only produced an erythema (unintentionally) in one case (generalized psoriasis) in which I foolishly tried to accommodate the patient by expediting the treatment.

Pigmentation of the skin was noted in a small proportion of cases, even though the dreaded erythema had been avoided. Fortunately the pigmentation was never permanent, though at times it persisted for months. The tendency of the skin to become pigmented is most marked in brunettes and especially in negroes. One of my patients, from the Harlem Hospital, a young negro boy, was treated for chronic exfoliation of the lips. A few days after a single dose of only one quarter H unit there was a marked pigmentation of the adjacent portion of the lips which had not been covered by lead foil.

To safeguard the patient and to obtain the most accurate results the operator should remain at his post during the entire seance. Standing behind the leaded screen and looking through the lead glass window he should see that the patient does not move and that the milliamperage remains as constant as possible. He should also watch the anode, when it becomes white hot from a large quantity of ray and be ready instantly to throw off the current in the very unusual event of softening of the metal support of the anode and possibly burning the patient. It is best to use one hand for the milliamperage control and the other for the switch which discontinues the current. The practice of operating two or three machines simultaneously by one individual is, I think, improper. A clock may be used to shut off the current automatically at the desired time, but this should not relieve the operator of the responsibility of closely watching the patient and the apparatus.

TREATMENT OF ECZEMA.

Among the various diseases of the skin that were treated, eczema perhaps occupied the most important place. I am now as enthusiastic as before over the treatment of eczema of all varieties and in all stages, by the röntgen ray. With the exception of a very acute vesicular eczema with marked edema, etc., I think that all cases of the disease are amenable to röntgen therapy. In a very acute case (resembling rhus poisoning) I would prefer to use wet dressings of boric acid or a calamine and zinc lotion for a week or so till the swelling had largely subsided, when I would not hesitate to begin röntgen treatment. The general opinion seems to be that the ray is only suited for exceedingly chronic, thickened patches of eczema. While it does clear up patches of this kind the most brilliant results are seen in the subacute cases of papular and vesicular type. The cases that are most resistant to the ray as well as to other methods of treatment are those of the erythematous type. I have also had disappointing results in a few cases of vesiculosquamous eruptions of the hands which I had classed as eczema. I now feel it is quite possible that some of these cases were examples of epider-

mophyton infection, though the demonstration of the fungus in this region is always difficult.

It is of course realized that in treating an eczema by the röntgen ray that we are not attempting to remove the cause of the disease. As a matter of fact we do not know the essential cause of what is called eczema. I had hoped that some light might be thrown on the subject by the protein sensitization tests. The results of some recent work along this line, in conjunction with Dr. J. Edgar Fisher, were, however, most disappointing in eczema in adults. Whether the röntgen ray removes the cause of eczema or not it certainly clears up the lesions in a large proportion of cases in a much more satisfactory manner than by any other therapeutic measure with which I am acquainted. In a few cases a single treatment effects a permanent cure. In a large number of cases, from four to eight weekly exposures are followed by permanent removal of the disease, without the necessity of any local application or internal medication. The röntgen ray treatment is not only quicker and surer in its action but is infinitely more agreeable than salves, such as tar, ichthyol, or chrysarobin. Two hundred and sixty-nine cases of eczema were treated, the patients varying in age from fifteen months to eighty-five years. The dose was a one half H unit for the first and a one fourth H unit for successive treatments given at weekly intervals. An improvement was generally noted after the first and almost invariably after the second exposure. The anti-pruritic effect of the ray has also been quickly shown in treating eczema.

PSORIASIS.

In regard to psoriasis my former opinion remains practically unchanged when it was stated that "the lesions themselves were easily cleared up but they returned with discouraging frequency. The röntgen ray appears to be especially useful for lesions of the hands and face where chrysarobin is objectionable. . . . Its value in psoriasis is certainly below that in eczema." I formerly felt that the ray was "a less valuable remedy than chrysarobin in the treatment of psoriasis," but now consider the two methods of treatment about on a par as regards efficiency. There can, however, be no question that röntgen therapy is a less disagreeable procedure than inunctions of chrysarobin ointment. It is often difficult with any method of treatment to clear up an attack of psoriasis entirely, while it is impossible to prevent future outbreaks of the disease. Arsenic is undoubtedly of value at times, while treatment by a low protein diet is of very little value in my experience, an opinion that is now shared by many dermatologists. For the solution of the problem of psoriasis we must for the present depend upon the röntgen ray or chrysarobin. It might be mentioned in this connection that the ray should never be applied to a region that has been recently treated with strong irritants such as chrysarobin, iodine, phenol, or other similar drugs, on account of the danger of a possible erythema. An interval of two or preferably three weeks should elapse between the employment of a local irritant and the röntgen ray.

It is hardly necessary to say that the ray is not

sued for treating psoriasis of the scalp, though in a few cases I have cautiously given a one fourth H unit followed by improvement. In my series there were sixty-seven cases of psoriasis treated by the ray. The dose, as a rule, was one H unit (at monthly intervals), six areas, as a rule, being the maximum number treated at one sitting. In my experience I have obtained much better results with large than with fractional doses, and in this respect differ from some of my colleagues.

Good results were obtained in the majority of cases (thirty) of so-called seborrheic eczema. The ray was fully as effective as ointments in this disease and certainly a more agreeable method of treatment for the patient. It was particularly useful where the disease was limited in extent. The usual dose was the same as that given for eczema. In some of the more deeply infiltrated cases one half H units at intervals of two weeks were given.

THE X RAY IN ACNE.

Acne is one of the few skin diseases that has been treated successfully by the röntgen ray for a considerable number of years, and I still feel as before that the ray is "the most efficient agent for the treatment of acne, and, with the modern measured dose, do not hesitate to treat any case of acne, whether occurring on the back of an older person or the face of a young girl." In point of efficiency and comfort of the patient the röntgen ray should be the method of choice. I am willing to admit that good results can be obtained by mechanical methods such as the dull curette and comedoextractor combined with soap frictions. Such treatment, however, is often disagreeable for both patient and physician, and its results are not as permanent as when the ray is used. The ordinary lotio alba so commonly used for acne has little more value than that of a placebo, while vaccines of the so-called acne bacillus I feel sure are utterly worthless from a therapeutic viewpoint. One hundred and thirty-eight cases of acne of the face, chest and back were treated. The usual course of treatment consisted of twelve exposures of one fourth H unit given at weekly intervals. At times it has seemed advisable to follow the suggestion of MacKee and omit every fourth treatment and extend the course over a period of four instead of three months. As a rule there was not any noticeable improvement until after a half dozen or more treatments had been administered.

Rosacea did not respond very well in my experience to röntgen ray, eighteen cases of various types having been treated with rather unsatisfactory results. While some of the pustular cases were improved, there was naturally no improvement in the telangiectases or large masses of rhinophyma.

LICHEN PLANUS.

Lichen planus of the ordinary type is another of the group of inflammatory skin diseases that is favorably affected by the röntgen ray. When treated by this agent the pruritus is quickly relieved and the lesions gradually disappear, though much slower than in eczema. I still feel sure that the röntgen ray is the only local remedy that causes involution of lesions of ordinary lichen planus.

Other local remedies simply relieve the itching. In the hypertrophic type of the disease my experience has been limited, one case, however (previously quoted), responding favorably. Eighteen cases of lichen planus were treated, the dose being the same as that in eczema.

Lichenification (*lichen circumscriptus*) also proved very amenable to röntgen therapy, nine cases of this chronic obstinate condition having been treated. In two cases the eruption disappeared quickly after a single treatment, while in others the results were not so rapid. The best effects were obtained by doses of one H unit at monthly intervals or one half H unit given every fortnight.

SYCOSIS AND FOLLICULITIS.

The results in twenty-four cases of sycosis (*staphylococcic*) and folliculitis were fairly satisfactory. In many cases of sycosis nothing but röntgen ray (or radium) seems to have any permanent effect at all. Some cases were cured or improved without causing the fall of hair, while in others epilation was necessary. The obstinacy of the disease was shown by a case which I treated twelve years ago by the old method of giving large numbers of unmeasured fractional doses. The patient who had suffered from this affliction for nine years had been previously epilated by an experienced colleague and in spite of this a second epilation was necessary to effect a cure. Needless to say, I could not be induced at the present to repeat such a procedure with any but the modern technic.

Three cases of the unusually obstinate condition known as cheilitis exfoliativa were treated with very satisfactory results. The scaling which had not even been temporarily helped by any other remedies was entirely removed in two cases, after five and in another after nine treatments of one fourth to one half H unit. The cases were treated recently, one patient remaining well for five months.

RINGWORM AND FAVUS.

The great therapeutic value of the röntgen ray is shown by the variety of conditions in which it can be employed. The fact that a certain quantity of the ray will cause a fall of hair is utilized in treating ringworm and favus of the scalp. In these conditions the result is certainly brilliant. Instead of treating ringworm with salves and mechanical epilation for months or even years, we are now able to cure permanently nearly every case of ringworm and the majority of cases of favus of the scalp in three months. The modified Kienboeck-Adamson technic as described by MacKee and Remer, Hazen and others, is not at all difficult, though it requires considerable patience on the part of the operator in treating young and restless children. The patient's scalp is previously clipped (not shaved) and after the preliminary markings with a blue pencil, one H unit is given at right angles to the five intersecting points upon the scalp. In about two or three weeks the hair falls completely or is loose enough to be removed with gentle traction. The scalp then remains bald for the following six to twelve weeks, after which the hair returns completely and the disease is cured. As

pointed out by Hazen it is advisable to epilate the entire scalp even when the disease is not widely disseminated, as the new hair may have a somewhat different color and consistency. Occasionally there is a reinfection and a second epilation six months later is necessary. My series includes seventeen cases of ringworm and four of favus. A few of these have been treated recently and the patients are still in the stage of temporary baldness. The others made an uneventful recovery in about three months. One of my cases was in a child three and a half years of age. While the treatment of ringworm of the scalp is not difficult, it is a satisfactory proof that the standardization of the apparatus is accurate.

Other classes of cutaneous diseases in which the röntgen ray is of great value include hyperidrosis, pruritus, the leucemic affections, and carcinoma. Localized sweating of the palms, soles and axillæ is a disease in which the ordinary remedies are only palliative. The röntgen ray, on the other hand, is the only agent with which I am acquainted that can effect a permanent cure. My experience has been limited to the treatment of seven cases. I am convinced that large doses such as one H unit every month are necessary to produce results. At the suggestion of a colleague I recently treated two cases by small doses (one fourth H unit) weekly, giving a total of ten to twelve treatments respectively, and failed utterly to obtain any appreciable results. On the other hand, a complete and permanent cure was obtained in a cello player who had suffered for two years from hyperidrosis of the palms. He was given eight exposures of one H unit at monthly intervals.

The antipruritic action of the röntgen ray is well known in inflammatory diseases such as eczema, psoriasis, lichenification, etc. In both localized and generalized pruritus without visible cutaneous lesions its effect is often most striking, as in a case (previously quoted) of pruritus of the vulva and anus of four years' duration. After a single exposure of one H unit the pruritus disappeared completely and had not reappeared at the end of nine months. At times the ray was only palliative, while in one case of general pruritus, after persistent treatment, no appreciable relief was obtained. Fourteen cases of pruritus were treated, the best results being obtained by a dose of one H unit.

LYMPHATIC DISEASES AND CARCINOMA.

That the röntgen ray has an important place in the treatment of the lymphatic diseases and carcinoma is, of course, well known. In the lymphatic diseases involving the skin, such as leucemia, Hodgkin's disease, and the allied condition of mycosis fungoides, the röntgen ray is the only remedy that has a favorable, if only palliative, effect on the lesions. There can be no doubt that the ray alone will cure a large proportion of cases of epithelioma of the basal cell type (rodent ulcer), though it must be admitted that this relatively benign form of cancer can be easily eradicated by a number of other methods of treatment. The ray will also cure a small proportion of cases of metastasizing type (squamous cell) epithelioma. In my treatment of epithelioma I have combined the röntgen ray treatment with a preliminary vigorous curettage under

local anesthesia. Immediately after curetting, the ray has been given in doses of two H units, including a border of a quarter to a half inch of normal skin, the neighboring parts being carefully screened. In some cases a second similar exposure has been given a month later.

LESS FAVORABLE RESULTS.

In a number of miscellaneous affections, my results have been disappointing, including some in which beneficial effects have been asserted by others. Although the röntgen ray is supposed to have a favorable action upon diseases characterized by warty lesions, such as common warts, senile keratosis and Darier's disease, it has not been a brilliant success in my hands. It is quite possible that my dose has been too small. In all events I have seen better results in some cases from the use of radium. I have not been impressed with the usefulness of the röntgen ray in lupus erythematosus, having personally, however, only treated three cases with little benefit. I have found radium more effective in this extremely obstinate condition. The result in five cases of dermatitis herpetiformis, two cases of sarcoid, and one case each of keloid and pityriasis rubra pilaris were very disappointing. In certain nail conditions, notably ringworm and paronychia, the results were equally bad, with the exception of a single case of ringworm involving two nails, in which the disease completely cleared up after five exposures of one H unit given at monthly intervals.

As the gamma rays of radium and the röntgen ray have similar physical qualities, it is natural that their effect upon certain skin diseases should also be similar. Owing, however, to the limited areas that can be treated in reasonable time by radium, its practical utility in dermatology is decidedly less than that of the röntgen ray. In a few conditions, such as nævus (of various types), lupus erythematosus, leucoplasia, and possibly warty and keloidal lesions, it is of much more value than the röntgen ray.

CONCLUSIONS.

1. The röntgen ray is probably the most useful therapeutic agent for the treatment of skin diseases.
2. Its versatility is shown by the great variety of conditions in which it can be used, including inflammatory diseases, those depending on epilation, pruritus and hyperidrosis, lymphatic disease and cancer.
3. It is only by means of accurate standardization that its full value can be realized and its dangers eliminated.
4. Standardized treatment requires the use of a Coolidge tube and interrupterless transformer. The quantity of ray can then be measured by pastilles or by arithmetical computation.
5. The routine use of pastilles is unsatisfactory, as considerable experience is required and as they introduce the element of personal equation.
6. By means of the simple method of computation devised by MacKee and Remer, the treatment of skin diseases by the röntgen ray has been revolutionized and a great contribution made to dermatological therapeutics.
7. The most brilliant results in my experience have been attained in eczema and in ringworm of

the scalp, where the röntgen ray is certainly the method of choice.

8. It has also been of great value in acne, psoriasis, seborrhoeic eczema, lichen planus and epithelioma.

9. In chronic sycosis, localized hyperidrosis and some cases of localized pruritus it is the only remedy (except radium) that can effect a permanent cure.

10. Leucemic conditions and mycosis fungoides cannot be even temporarily improved by anything except the röntgen ray (or radium).

I wish to express my thanks to my former associate, Dr. S. J. Nilson, and my office assistant, Miss Ruth Kane, for continuing this work during my absence in the military service, and to my associate of the past year, Dr. J. Edgar Fisher, for his assistance.

PHYSICAL DIAGNOSIS VERSUS THE X RAY IN DISEASE OF THE LUNGS.

BY GEORGE WILLIAM NORRIS, A. B., M. D.,
Philadelphia,

Assistant Professor of Medicine in the University of Pennsylvania;
Visiting Physician to the Pennsylvania Hospital; Fellow of the
College of Physicians of Philadelphia; Colonel
M. R. C., U. S. Army.

Among the numerous advances in diagnostic accuracy within recent years, the x ray is by common consent accorded a high place. Its successes, however, have been much greater in some fields than in others. In the following discussion we shall limit ourselves to a consideration of the x ray in relation to diseases of the lungs.

DISEASE OF THE PLEURA.

Pleural adhesions can often be determined by careful inspection of the chest, by the observance

of the diaphragmatic shadow, and by percussion and auscultation of the lower pulmonary margin. A far greater degree of accuracy is possible, however, if the fluoroscope or plates are used. Associated with the recent influenza epidemic, cases were noted in which great thickening of the pleura occurred. These cases presented the physical signs of a pleural effusion and an x ray picture which could hardly be differentiated from that presented by fluid in the pleural cavity. It is usually impossible by means of physical diagnosis to demonstrate the presence of pleural effusions until four hundred c. c. have accumulated. The x ray will usually show the presence of fluid in smaller amounts and with a greater degree of certainty. In regard to loculated fluid collections, the advantage of the x ray is still more greatly enhanced.

Radiographic studies have confirmed the clinical suspicion that localized pneumothorax is much more common than was at one time believed and, as a rule, enables us to outline accurately the region involved. Interlobar collections of fluid are also often located with greater precision than is possible by physical diagnostic methods. The x ray also has a useful field in connection with artificial pneumothorax, since it enables one to detect adhesions which may make the procedure useless, and it also enables one to determine accurately the degree of lung compression which has been attained.

PULMONARY ABSCESS.

In this condition great help is usually afforded in determining the exact site, size, and proximity to the surface of deeply situated pus collections.

FOREIGN BODIES IN THE BRONCHI.

Another signal triumph is here accorded to the x ray. Not that foreign bodies are never overlooked, because they are, especially when organic substances, such as peanuts, have been inhaled. Nevertheless, x ray results are infinitely better and more accurate in this field than physical diagnosis is, or can ever hope to be. Without a history of a foreign body having been inhaled, the elusive peanut may readily be overlooked, but when such a history exists the foreign body can nearly always be localized by radiographic methods.

Attention has properly been called by David R. Bowen (1) to the necessity of an x ray examination in all cases of persistent bronchitis, without demonstrable cause. More frequently than one would suspect such cases are due to the presence of a foreign body.

PNEUMONIA.

By means of x ray observations our knowledge of the gross pathology of lobar pneumonia has been advanced. We have learned that many, if not all, pneumonias begin as central lesions and spread toward the periphery. As a result of this knowledge we know definitely why early pneumonias often yield no definite physical signs and why bronchial breathing often appears several days after the onset, if not actually after the crisis.

While an acute process in the lungs is under way, no clinician will venture an opinion as to the degree of antecedent pulmonary lesions. Nor will the radiologist. But later, when it may become a

question of unresolved pneumonia, interlobar abscess, pleural exudation—fibrinous or fluid—or of chronic pulmonary tuberculosis, the clinician is often immeasurably aided by the radiologist.

MEDIASTINITIS, ADENITIS, ETC.

The clinical methods of determining the presence of mediastinal abnormalities before they have reached an advanced degree, are but meagre. Spinal percussion, d'Espine's sign, Eustace Smith's sign, and others, are of doubtful value and uncertain significance. The presence of mediastinal adenitis or neoplasm, or their differentiation from thoracic aneurysm, is usually, if not always, determined definitely by the x ray.

ADVANCED TUBERCULOSIS.

The actual degree of involvement and the exact location and size of cavities, although often of secondary importance, are often more accurately established by means of the x ray. In patients dying of tuberculosis, involvement is often more extensive than physical signs would lead us to believe.

BRONCHIECTASIS.

In the early stages of this condition the uncertainty of x ray diagnosis equals that made by clinical means. In the later stages, when bronchial thickening, glandular enlargement and cavity formation occur, a doubtful clinical diagnosis can often be substantiated.

"Röntgenograms, although invaluable in certain cases, may be very misleading at times when the disease has spread so as to affect the upper as well as the lower lobe. When showing clear apices the plate is of extreme diagnostic value in ruling out tuberculosis. Slight shadows at the base, however, which are all one frequently sees in typical cases of bronchiectasis, cannot usually be correctly interpreted, and very often definite sacculations, found on physical examination and confirmed by anatomical investigation, cannot be seen either on flat or stereoröntgenograms" (2). The fault most commonly committed is that of insufficient observation. If repeated examinations over prolonged periods are made—before and after expectoration has occurred—many more cases will be demonstrable by means of the x ray.

PNEUMOCONIOSIS.

Clinically the differentiation between dust disease of the lungs and tuberculosis, or the coincident presence of both conditions, is usually made with difficulty and after prolonged study. In this study the x ray may be a useful adjuvant, but in many cases, especially those in which the apices are involved, the radiograph may leave us quite as much in doubt as before the examination was made.

Concerning the foregoing statements there can, it would seem, be no difference of opinion, but when we come to early pulmonary or lymphatic tuberculosis, the question of its activity or latency, its differentiation from anthracosis, syphilis, or fungus disease, opinions differ widely.

Some time ago a number of clinicians in Philadelphia, who were interested in pulmonary diseases, examined the patients in a series of cases of suspected early tuberculosis referred to them by an

independent observer at the Phipps Institute. Later these patients were examined radioscopically by a number of x ray specialists in the city, and finally all met together to discuss their findings. The procedure was a most instructive one. As a general rule, the more experienced the examiners in each branch, the more closely did their findings tally. The two facts which most forcibly impressed us clinicians were, first, the different interpretations of the same plate by different radiographers, and, second, the greater conservatism of the more experienced radiographers.

From the discussion which took place, it became painfully evident that some of the x ray specialists had not even the haziest conception of the pathology of tuberculosis. It was doubtless some kindred experience that once led Sir William Osler to remark that no class of the medical fraternity was so much in need of the "salutary lessons of the dead house."

In a recent article based upon a study of about six hundred cases at Camp Lewis (3) it is stated that tubercle bacilli are inhaled deeply into the distal bronchioles of the lower lobes. Thence infection travels with the lymph stream to the hilus, but from there it travels against the lymphatic flow to the apices.

In defense of the radiologist, however, it should be stated that too often the clinician, especially the man who has been poorly schooled in the subject, insists on a positive answer from the radiologist. Naturally, in many cases, if a definite yes or no is demanded, mistakes are the inevitable result.

There are scattered through the land a great number of x ray stations where much good and useful work is done; but relatively few of the men who operate them have or can have the careful, prolonged, intensive training and the correlation of autopsy material to make their x ray plates, or the deductions they make from them, of any great value. To their credit, be it said, some of them admit this.

Nor is it necessary to state that relatively few internists are expert diagnosticians of early tuberculosis. Our war experience, which showed the necessity of reeducating physicians by means of special courses in the elements of physical diagnosis, is a sad and sufficient commentary. Nevertheless, one finds as a rule far less cocksureness in the average physician than in the average radiologist, when the diagnosis of early tuberculosis is in question. Mistakes are common to all. In one case of which I have knowledge, the x ray diagnosis of acute miliary tuberculosis, which was scoffed at by an eminent physician, was corroborated at autopsy within two weeks. And several times I have seen an x ray diagnosis of extensive tuberculosis of both lungs, made on fat, fever free, hard working, and practically symptomless patients. Quite recently, in Philadelphia, a patient in whom a diagnosis of tuberculosis was made at a well known sanatorium and corroborated by the radiologist of the institution, was cured by the surgical drainage of an interlobar empyema undertaken on the advice of an internist. Again I have known of cases which were clinically diagnosed emphysema to be shown by x ray and autopsy to be miliary tuberculosis.

Between the two extremes of x ray being everything and physical diagnosis nothing, and vice versa, there must be a middle ground of truth. No one who has received x ray reports from competent radiologists during the last five or six years, but feels that the technic is better, the observations more accurate, and the pronouncements more conservative. One does not now hear so much about root shadows, areas of congestion, calcified lymph nodes, and other visionary interpretations, to use another expression of Sir William's. That the x ray can demonstrate incipient tuberculosis before it is clinically possible, has, to say the least, not been proved. Other types of acute infection may produce a reaction in the lymph channels and in the fibrous tissue surrounding the arteries, veins, and bronchi. Further, it is in just such cases that diagnostic aid is most desired. Nor has it been shown that the activity or nonactivity of a tuberculous process can be radiographically determined.

Some influenzal infections may cause a slight clouding of the apex, slight flattening of the first rib, a shrunken apex, and small areas of apparent pulmonary consolidation. Such findings are identical with those often presented by pulmonary tuberculosis. The x ray findings are characteristic of tuberculosis only in the later stages. It may show very slight changes which cannot be detected by ordinary clinical methods, as well as the exact site of the lesion, but not the gravity of it (4). The stethoscope will remain the chief instrument of pulmonary diagnosis, because it gives a better idea of the activity and nature of the process, though not the exact extent of it (5).

In the vast majority of early cases the old methods of diagnosis yield satisfactory results. Only rarely is the x ray essential. Occasionally the x ray gives positive information not otherwise obtainable, and at times it helps to corroborate evidence in suspected cases, but, on the other hand, one finds cases clinically definite in which the x ray reveals nothing. A few conglomerate tubercles and a local increase in moisture do not show upon the plate.

There can be no question that the accuracy of the x ray diagnosis of pulmonary tuberculosis has advanced greatly within the last few years, this relative advance being far greater than has that of physical diagnosis in the same time. The use of anterior or posterior stereoscopic plates, of plates made at different angles, of observations made during an arrested inspiration or expiration, as well as the use of serial records made at intervals of weeks or months, has added greatly to our diagnostic ability. The combined study of a case by means of physical methods and the x ray has such manifest advantages over either method singly, that they should be jointly employed whenever possible, but if only one method is to be chosen, the older method is still the preferable one. This was tersely emphasized in a remark made not long since by one of the leading radiologists of the country: "No x ray man shall ever send me to a sanatorium."

In closing, it may not be out of place to say a word regarding the isolation of the radiologist. Too often, I fear, he is called upon for a report, which we receive and file, and thereafter he dis-

appears from the scene. Regarding the antecedent history of the patient he may be but scantily informed, and regarding the future progress of the case or the findings at the autopsy he is often left in entire ignorance. It may be his fault, or it may be ours, but it would seem that the point is worthy of consideration.

ROENTGENOTHERAPY.

BY J. THOMPSON STEVENS, M. D.,
Montclair, N. J.

Fellow of the American Röntgen Ray Society.

The success that is being obtained in various parts of the country at present with röntgenotherapy is due to four factors: 1, The interrupterless transformer; 2, the Coolidge tube; 3, filtration, and, 4, crossfiring in deep work.

The first interrupterless transformer was put out about thirteen years ago by H. Clyde Snook, of Philadelphia. Owing to the construction of this machine it is possible to deliver large quantities of electrical energy over long periods of time without variation in voltage. Since the advent of this machine others have appeared from time to time, all being more or less efficient in röntgenotherapy.

With the invention of the Coolidge tube, we had, for the first time since the appearance of the interrupterless transformer, a tube which was able to receive the heavy output of the transformer over long periods of time without variation. From this time on, röntgenologists were able to give massive doses of the rays at will. Doses are now given at one sitting which formerly were impossible. And so the instruments were at last supplied whereby we were placed in a position to do great good, and also great harm by imperfect technic.

Filtration has received a superabundance of attention from all and, as might be expected, is still being improved from time to time. About the only point upon which all agree is heavy filtration for deep work and lighter for superficial work. Sole leather has been used, aluminum, glass, various papers, felt, and combinations of any or all of the materials just mentioned. At present in this country, sole leather, aluminum, and glass are favored, usually in combination. Personally, I use for superficial work a layer of sole leather and either one millimetre of aluminum or two millimetres of pure glass. In deep therapy, I use as a routine four millimetres of aluminum, two of glass, and a layer of sole leather.

Crossfiring has for its purpose the application of a sufficient dose of the rays to a pathological process lying well under the superficial structures without injuring the skin. We attempt to deliver

into the diseased area enough of the rays to destroy it. This is done by blocking out areas on the skin, through each of which is delivered as much of the rays as the skin will stand. Over each area the tube is tilted so that an enormous amount of the rays is delivered to the diseased area.

In spite of the fact that most writers describe at length the technic used for each disease treated, I find that with slight variation of the technic, at times, that all röntgenotherapy naturally falls into three groups, viz: 1, superficial; 2, deep, and, 3, superficial and deep combined. In superficial work we want our maximum dose to be absorbed by the skin. We may use a light filter made up of a layer of sole leather or one of either aluminum or glass. Generally I make use of a layer of sole leather together with one millimetre of aluminum or two millimetres of pure glass. In superficial work we do not make use of crossfiring but if the diseased area is too large to cover with one exposure we must block off areas on the skin, and then administer a dose of the rays to each, until we have covered the entire area. To give a dose of the rays to any one area we can make use of one of two methods: 1, The massive dose method in which an erythema dose is given at one sitting, or, 2, the fractional dose method. As all skins do not respond equally to a given dose of the rays, I prefer the fractional method in superficial therapy, as by this method we can keep close watch on our patient and can give just enough. Enough is generally an erythema dose. This is done by setting the machine so that the tube will back up five inches and will draw two milliamperes (at a focal distance of eight inches). The exposure should last three minutes. This is repeated every other day until the erythema is seen on the skin. Ten such treatments will produce a marked erythema, and sometimes as few as four will give the desired result. In a month's time we can repeat the series if necessary. The parts not under treatment must of course be protected with lead sheeting and leaded rubber sheeting.

In deep röntgenotherapy we deliver into the diseased area a sufficiently large dose of the rays to destroy the disease. This must usually be done without harming the skin, although at times, when the pathological process is not too deeply located, we may, with advantage, continue our treatment to the point of ulceration. An ulcerated area generally clears up as readily after röntgen treatment as does the burn following massive doses of radium. To do this we make use of a heavy filter, a hard tube, and crossfiring.

According to Pfahler, of Philadelphia, the filter should consist of six millimetres of aluminum or the equivalent of glass. I generally use two millimetres of glass, four of aluminum, and a layer of sole leather. The tube should be made to draw five milliamperes and to have a parallel spark gap of nine inches or the equivalent of 90,000 volts. At a focal distance of eight inches with the Hampson radiometer it will require five minutes to give an erythema dose to a given area. In treating malignant disease I sometimes give as much as two and three times the pastille erythema dose, that is, fifty to seventy-five milliampere minutes respectively.

Owing to the fact that the tissues overlying the diseased area will absorb the rays, we must crossfire in order to get the required dose to the disease. This is done by blocking out on the skin areas as large as can be covered with an exposure protecting the other areas with lead strips and so passing from one area to the next, giving to each area at least an erythema dose or as much as is indicated by the disease under treatment. Crossfiring is done by so tilting the tube that through each area the rays will be focussed on the seat of the disease. Unless I am treating malignancy, which I treat as just mentioned, I let the tube deliver to each area forty milliampere minutes. As said before, the areas not under treatment should be covered with lead sheeting, i. e., the parts directly under the tube, and the remainder of the patient's body should be covered with rubber sheeting heavily impregnated with lead.

In conclusion I wish to state that nothing that is not positive fact has been put into this paper; that it is free from anything that is in the experimental stage of development. I have tried to make it understandable by the practitioner and the specialist other than the röntgenologist so that they might have in one small paper the facts of röntgenotherapy without being bored by voluminous reading in order to get a little meat. For this reason I have tried to cut down the detail as much as is possible with a basic understanding of the principles involved.

ILLUSTRATIVE CASES.

CASE I.—Mr. F. K., came to me on June 6, 1918, with a large eczematous spot upon his right foot which had been present for years. Technic, routine superficial; result, vivid erythema resulted following the fourth dose and treatment was stopped. Eruption has never reappeared.

CASE II.—Mr. A. M., referred with a large spot of psoriasis upon the left elbow. Disappeared before an erythema dose had been given. Technic, routine superficial, one series of ten treatments being given.

CASE III.—Mr. T. D., came to me with a large ulcer on the right temple which had been diagnosed as lupus. He had had x ray treatment elsewhere but as no erythema was present I subjected him to the usual superficial treatment. The fifth dose was the last, as the lesion had entirely healed and patient stopped treatment in spite of the fact that he was earnestly advised to continue. Final result I cannot report, as I have lost track of this patient.

CASE IV.—Mr. L. H. E. was referred with a small ulcer on the lower lip, a section of which showed it to be epithelioma. Technic, removal of diseased area with the actual cautery; routine superficial therapy; deep therapy over front, back, and both sides of neck. Result, patient was well eleven months after last treatment.

CASE V.—A. E. came to me with a cervical adenitis and fistula which was probably tuberculous. Technic, routine deep. Result: Two months after last treatment swollen glands had disappeared, fistula was closed, and there was very little induration at that time.

CASE VI.—Mrs. J. Mc. had had x ray treatments for a long time for an exophthalmic goitre, but with-

out result. Symptoms of hyperthyroidism gradually increased in spite of treatments. There was no evidence of there having been an erythema. Technic, routine deep. Several series of treatments were given once a month over the tumor and down over the mediastinum, five series in all being given. Result: Two months after first series patient felt well, ate and slept well; pulse was normal; tumor a little smaller, possibly. After three more treatments tumor became the size of a large marble; it was the size of a grape fruit at the beginning of treatment.

CASE VII.—Mrs. P. S. C. was sent to me for x ray treatment of a fibroid on the posterior wall of the uterus. The tumor was about the size of an orange and the patient suffered from severe menorrhagia and metrorrhagia so much that she was seldom free from the discharge for more than three days out of each month. Technic, routine deep; seven series. Result: Bleeding stopped entirely two weeks after first series and at present the tumor is barely palpable.

CASE VIII.—Mrs. A. A. J. had been operated upon for cancer of the right breast. Two months later recurrence in mediastinum was diagnosed. Technic, deep, front, back, and both sides of chest. Five series were given, one series each month. Result: Deposits in mediastinum disappeared, but patient died of a recurrence in the rectum which I was not permitted to treat.

CASE IX.—Mrs. C. A. C., referred for palliative treatment of an inoperable cancer of the uterus and pelvis. Technic, deep, fifty milliamperes minutes given through each of ten areas from navel to pubes, front and back. Treatment resulted in a marked tanning of the skin. Result: Well two years after last treatment.

FOODS AND RACES.*

BY J. S. LANKFORD, M. D.,
San Antonio, Texas.

Of the two great hungers of the human race the desire for food is paramount. Extreme scarcity leads to grave contention; at the point of starvation all the primitive instincts are aroused, and the individual may steal or rob to satisfy hunger; the group will lose sight of justice, and use every compelling force for relief; in the last extremity the individual will turn to cannibalism.

Anthropological and biological investigation point clearly to the unity of aboriginal man. A single species of a single genus, influenced by varied environment, became the divergent races we now see, and one of the strongest factors in the causation of racial variation is the quality and quantity of food. Of course divergence has been in part due to climate, but the greater climatic effect is through the influence of local food production with geographical isolation.

In considering racial distinctions in relation to food, it is not sufficient to compass the life and environment of man within historical knowledge; nor does it suffice to study the evidences of the less remote prehistoric times of the Cro-Magnon,

Neanderthal, or Piltown man. We must run back the line to earlier prehuman forms, even beyond the Javanese ape-man, and think of the painful and precarious evolution before the mind of man had developed sufficiently to utilize the products around him, or to travel far in search of food, when geographical restrictions and ignorance were cruel factors in life. In this way we can understand the small stature of island peoples, limited to little space, with sparse supply of food; and the same conditions among people of larger areas of infertile, overpopulated territory, suffering hunger for long periods of time.

The subject is so broad, and touches so many phases of the development of man, that it is proposed to limit consideration mainly to racial stature and some allied subjects; and to suggest a probable cause of the emotionalism of certain races.

In order to understand the effects of food supply on racial evolution, it is necessary, first, to note the requirements of the individual. A well balanced and safe ration is composed of fifteen per cent. of proteins, twenty-five per cent. of fats, and sixty per cent. of carbohydrates, with a daily allowance of forty calories to the kilogram of weight, a range of two thousand to three thousand calories, according to size and vocation. In occupations of hard physical labor, an addition of one thousand or fifteen hundred calories of carbohydrates and fats are necessary to furnish energy. The haversack ration of the American soldier in the recent war had a fuel value of four thousand four hundred and forty-eight calories.

The individual must be well nourished to thrive, as can readily be seen in any community; the progeny of the poor develop slowly and growth is inhibited; the children of the well to do grow rapidly and attain a larger size. In the growing years it is highly essential that the dietary contain an ample supply of lime and phosphorus for the skeletal frame. Another item of great importance is the vitamins, only recently discovered, and found in the covering of grains, fresh vegetables, milk, citrus fruits, probably animal proteins and other products.

It is well to understand how food is utilized in the process of growth and repair. This is one of the many functions of the wonderful system of ductless glands, especially the pituitary, the thyroid, the sex glands, the pineal, and the thymus. This physicochemical or electrochemical system is known to perform this service through countless cases of arrested development, where one or more of these glands were diseased, and by the direct and remarkable development that occurs in glandular feeding in such cases. No more interesting fact is found in the whole field of medicine than the influence of the endocrine glands in physical and mental development. The growth of the body may be retarded, or decidedly altered, by deficient working of any one of these glands, or even by unbalanced function. It is known that the pituitary governs the development of the frame; overfunction leads to gigantism and underfunction to dwarfing. It is definitely settled that the thyroid is concerned in stature also, and that it determines the traits of hair, skin, features, and mentality, thus

*Read before the San Antonio Scientific Society.

differentiating races. The pineal, suprarenals, and sex glands, all play an important part in growth and the maintenance of function. This is all accomplished by utilizing the minerals in the food supply, applying them to the appropriate tissue. So vital is this fact that it has probably been the chief means of race divergence. It is not improbable even that it is at the root of the cephalic index of races; that the brachycephalic and the dolicocephalic heads date back to some very remote period of anthropogeographical isolation for ages when the endocrine glands were working industriously with the poorly differentiated material available in the food supply. The dwarfing of races has evidently been caused in considerable part by lack of proper stimulation of the pituitary body and other glands by proper food supply.

In studying the stature of races, the Japanese Empire furnishes us the best example of insular island life. The area of tillable soil is only about fifteen per cent., and a considerable part of this by expert terracing and by irrigation. The rest of the surface is mountainous, volcanic, nonproductive, and even unfavorable to the propagation of wild animal life for sustenance. The lowlands in many places are untillable on account of the rocks washed down from the mountains by torrential rains. Pasturage vocations have been impracticable because the arable land must be used for agriculture; and the volcanic wastes and the bamboo in the lowland is a further barrier, and stock for food cannot be raised, fish being the main supply of animal proteins and fats. It is conceivable that the Japanese have lived on this restricted territory for countless ages, and have suffered from food shortage for long periods, and from recurring famine; and the population has likely run beyond possible production at different periods. We may get some idea of what this race must have suffered in food deprivation in earlier time by our knowledge of the incidents of the two hundred and fifty years of seclusion. From sheer necessity agriculture in Japan during that period attained a degree of perfection found nowhere else at any time. Less than three acres were allotted to the family, and every foot of arable land was kept under intensive cultivation by skilfully fertilizing the individual plants, by constant manual turning of the soil, by irrigation, and by every possible artificial aid to nature; and those things were planted that promised the greatest returns, as rice, beans, and other grains, and nourishing vegetables and fruits. And in spite of the greatest production by these ingenious people, during one known period of one hundred and twenty-three years, from 1723 to 1846, the nation made little progress, and the population declined at times. Infant mortality was high, and means were employed to limit population because of the scarcity of food. It is believed that racial stature was affected to some extent during the seclusion period, though this is a slow process and probably depends upon long ages. During the next fifty years, after the policy of seclusion was abandoned, living in intimate association with continental peoples, and with ample food supply, including a large quantity of Australian cold storage meats, the population of the

Empire made tremendous gains, and it is asserted that the stature has improved, though this is doubtful, and intelligent progress in every department of life is one of the startling things in history. Another thing of great importance in fixing the stature of the Japanese is the lack of animal proteins. For the reasons given, they have been without the animal proteins so essential to full development of stature. It is a notable fact that in moderately cold countries, where large quantities of meat are consumed, other things being equal, man is of large stature, as the North Chinamen, some of the Russians, the Teutonic peoples, Anglo-Saxons, and other north country mixed breeds.

Notwithstanding the contention of vegetarians, science has proved the great value of animal proteins in tissue building and in the sustenance of life when consumed in reasonable quantity. It is remarkable with what unanimity all people, both savage and civilized, have unconsciously adjusted themselves to something like an even ration of protein foods, usually about ten to twenty per cent., and the most eminent physiologists of the world have uniformly contended that the proteins are essential to physical wellbeing. There is a quality in animal proteins that stimulates cell life and function, and promotes physical and intellectual development that does not exist in fats, carbohydrates, or minerals, unassisted, probably operating through pituitary stimulation. The population of the Central Powers in the recent war suffered intensely from the lack of fats and proteins especially, and now it is found, after the starvation period, that an abundance of fats and carbohydrates does not rebuild without the addition of meats. Even when inbreeding, selection and restrictions of climate are considered, we must admit that the Japanese stature has been limited by the several causes mentioned.

The same proposition applies to other island peoples similarly situated, and many less striking examples can be found. A fact of singular interest is that where Oriental races have drifted away in early periods to more productive lands, where game and fruit were abundant, a larger growth has been attained. No finer physical men exist than some of the Pacific Islanders, especially the Polynesian New Zealanders.

The small stature and slender build of most Asiatic peoples, such as the Chinese, the Hindus, and others, as related to food supply, is due to several causes; overpopulation and hunger over long periods; a monotonous rice diet; the lack of animal proteins, the meat animal in the Orient being absent or held sacred, aesthetic tastes barring animal foods.

The races that have attained the best development and made the greatest intellectual and commercial progress have been favorably located, with ports open to all the world, attracting ample supplies of a great variety of foods including proteins, as the Greeks and Romans, and the well favored modern peoples.

A monotonous food, though of animal protein, is not wholesome, for the Arctic peoples, the Eskimoes, Laps, and others, whose food is highly nitrogenous, are of short stature. It is probable, however, that

this is in part due to the hunger of the long winters, recurring famine, and the age long conflict with the cold. Dr. Helen Churchill Semple, a profound student of races and a distinguished authority, says that the dwarf races of Africa live almost exclusively on meat, a monotonous diet, and that the supply is often precarious. She is referring to the Bushmen who are desert hunters, the Watmas who are hunters of big game, and to the Hottentots who are herders on uncertain grass lands. These races have all suffered much from scant supply and monotony of food, and while they have not had to contend with intense cold, they may have had to endure a good deal from climatic disease.

Alpine people are of short stature, and the higher the altitude the shorter the measurements. In the more moderately high altitudes they have a little meat and some vegetables, but in the higher altitudes the lack of pasturage makes it too expensive to raise food stock, and they subsist largely on dairy products.

Many examples might be cited showing the influence of the food supply on racial growth of island, continental, mountain, desert, and coastal peoples. The Jewish people have suffered a decided shortening of stature from two causes, prolonged persecution and hardships in various countries, and from the inhibiting influences of city life; and yet they are singularly long lived on account of their custom of carefully selecting food, and the sanitary precautions taken in their food, especially meat.

It is probable that the influence of heredity and environment operating through biological law, using the materials at hand in various parts of the earth, has permanently fixed the stature of the various races. Transportation facilities will furnish ample and varied food supply, except when interrupted by war, and there will be no further radical change. Nevertheless, there will be some modifications, and the advantage will be with those people who for reasons of location, soil, water, climate, etc., have a large and varied supply of food with a good lime, phosphorus, and chlorophyl content, and whose marvelous workshop, the endocrine gland system, is not handicapped by disease. It would be interesting here to speculate on the probable degree of the leveling up of the human races in the future. We started as one, we separated into many, and the trend will be to unite again, in spite of strong ethnical tendency. Anthropogeographical limitations will no longer bar any branch of the human family from a good varied food supply long at a time. Napoleon started something greater than his wars when, urged on by his great necessity, he originated the canning and preserving industry and beet sugar, for this made possible the universal feeding of all races at all times. Trade and the intercommunication of peoples will favor the equal feeding of all, and the interbreeding of the past indicates that races will tend to vanish under the stimulus of a broader democracy and greater facilities of transportation of foodstuffs. We shall move back a considerable point toward our original place in the ages to come, in blood and in stature, but the mark of progress will never be lost, and the present racial traits will persist.

The agonizing hunger and suffering of millions on account of the recent war, illustrates what might happen if the Malthusian idea is correct; but the possible supply of food in the world is now enormous, rendering that theory untenable. New items are constantly being added to man's dietary. It was long after the conquest of Peru that the white potato spread out from the land of the Incas to the uttermost parts of the earth nourishing all races, and now it is threatening the horse with its alcohol power; the universally popular tomato was growing wild in South America and little known scarcely more than a century ago; grain culture is constantly improving and extending, and everything is Burbanked; the growth of banana cultivation and the possibilities of banana flour are immense; the cattail is coming into its own, and plants of thousands of kinds are under investigation, and we have but touched the vast supply of food in the sea and the mighty rivers. And the synthetic process in the chemical laboratory promises marvelous things. There can be no danger of a starving world till that very remote time when the earth itself shall perish for lack of moisture, as foreshadowed by the immortal Byron.

One point we want to emphasize especially in this discussion of food in relation to races is that the emotionalism of the Latins and other people of the temperate zone, and of tropical peoples, is due to the large intake of sugar, which has always been available in abundance. Not only is sugar always at hand, but the natives consume large quantities of raw ribbon cane in sugar growing countries. We will lay it down as a definite proposition that this large consumption of sugar, a quickly acting fuel, stimulates and overdevelops the pituitary body and its functions. This little organ at the base of the brain is a partly glandular and partly nervous structure, and it is known to be the centre of all sensation and emotion, and at the same time it rules and directs all the activities of the whole system of ductless glands, and the vegetative nervous system, governing all the functions of organic life. It also serves as a communicating centre between the brain and the other organs. The constant stimulation of sugary products over centuries of time has overwrought this important organ and overdeveloped it in some of its functions, and thus races have been permanently affected.

As a proof of this contention, the difference between the Romans of two thousand years ago and their Italian successors might be cited. The Romans were a peculiarly stoical, strong, and unshakable people, and we know the Italians of the present day are very emotional. The Romans had no sugar, for it was not introduced into the Mediterranean Basin by the Saracens till about the eighth century, and was not abundant till it came from the West Indies later. The Romans of course had honey and raisins, but the quantity was limited, and not in such universal use as to affect the race. Sugar has been pouring in a stream down the throats of the Mediterranean peoples for hundreds of years, not only from the table, but in candy and drinks. History will show that the French have undergone a similar change, and perhaps the Spanish. The emotional

mentality of tropical peoples is well known. It is not only a reasonable belief, but a fact easily demonstrated by scientific observation and will be proved, that the excessive use of sugar could produce such results. Only recently a Bengalese scientist has found that the blood of tropical peoples contains a higher per cent. of sugar than others. The rapid increase in the consumption of sugar may portend evil for our own country. The American people are now consuming annually eighty-five pounds per capita, an increase of sixty-seven pounds in forty years, and still there seems to be no limit. In fact, it is increasing more rapidly since we have prohibition, and many are using it unconsciously as a stimulant. Its almost universal excessive use threatens serious detriment to the various organs with impairment of function and degenerative disease. And ultimately it will affect the emotional side of life and tend to make us unstable as a people. It would be well for those who think to give some thought to this proposition, and warn others of the dangers ahead.

Perhaps increased emotionalism has enriched the world in romance, poetry, art, and music. It were better that the human race suffer some deterioration than to have been without the rich romance of French literature, the entrancing stories of Ibanez, the passionate truth in the art of Italy, France, and Spain, and the matchless melody of Mexican music. But it is wise to moderate our excesses in the use of this valuable food and safeguard the health and stability of our people.

STERILITY, SEX STIMULATION AND THE ENDOCRINES.

BY THOMAS W. EDGAR, M. D.,
New York.

In presenting this paper to the profession I feel that it is my duty to preface what follows by a few words in reference to the subject, in order that conditions regarding the contained facts be realized. Almost thirty years ago, Brown-Séguard published in the *Archives de Physiologie* a treatise dealing with his research on testicular organotherapy. He went so far as to offer himself as a medium, and had injected into his body a preparation prepared from the testes of a dog. He reported that almost instantaneously he was endowed with renewed vigor and virility: in his own words, "Considerable laboratory work produced hardly any fatigue, and to the astonishment of my two assistants I was able to work for several hours in a standing position."

Unfortunately, the charlatans of Paris commercialized this fact by promptly seizing Brown-Séguard's announcement; as a result the real significance of the facts established by this master was drowned by the acts of these unethical practitioners to mulct their susceptible patients of more money. Thus his work and its result fell into disrepute, and up to the present this bad reputation has stayed with organotherapy, whether it be testicular, or what not. Nevertheless, to those of us who have become interested in endocrinology, the facts presented in rough form in 1888 have formed a

basis on which to work miracles in spite of the ever unfortunate and cold reception given the perpetrator of any new method of procedure of robbing life of its degenerations or bringing back the sex instinct with its consequent happiness of mind and healthiness of body.

Volumes have been written on the subject, and there have been many criticisms offered. Testicular and ovarian organotherapy have suffered most. In my estimation three fourths of the unkind things said about this branch of endocrinology have been the result of expecting the miraculous to happen, and the setting of one's hopes too high. Again, many failures have been due to slipshod methods and treatment. Results have not been obtained in short intervals, and as a consequence the treatment has been abandoned.

AN INDIVIDUAL IS AS OLD AS HIS OR HER INTERNAL SECRETIONS.

Senility and presenility, in my estimation, are nothing more nor less than a waning of the endocrine function, accompanied by functional cellular inactivity, with the resultant increase in toxemia, which poisons and degenerates; repair, if it does take place, is slow, and the organs gradually fall into disuse, followed by atrophy. Ideals, ambitions and desires are but memories, while procreation is impossible.

When the ability to procreate wanes, the individual is then to be considered senile, unless the causative factor is a specific disease. This hypogonadism may exist at any period. It is seen during early adult life and is then due to indiscretion, or is the result of presenile changes in the internal glandular system, as portrayed by malnutrition, wrinkling and shrinking of the skin. The eyes become dull and the movements slow, while the spermatogenic function, as well as the ovarian sequence, disappears. This presenile stage may be also initiated by indiscretion, as shown by the sex glands becoming functionally inactive, and the case may present the same hypogonadism that is found in pathological conditions.

I quote the following from an author who is evidently of the same opinion as myself:

"The diagnosis need not be discussed further, and its successful control through a mythical *elixir vite* has been the goal of many from time immemorial, and from Ponce de Leon to the present day. Hypogonadism may be amenable to organotherapy even in elderly men, and the fundamental principles of homostimulation holds good in proportion to the responsiveness of the glands thus stimulated. It is a broader matter than the gonads alone, as the thyroid, pituitary and other endocrine glands all play their part. Senility then is hypocrinism rather than hypogonadism alone, and if we must treat it, it should be treated in the larger sense, and when organotherapy is in mind, it should be pluriglandular therapy.

Thus the failures of the past have acted as stepping stones to a more thorough investigation and firmer understanding of the subject. The solution of the vital functioning of the body depends on endocrine secretion, as do the senile and presenile phenomena.

Senility or old age is inevitable. It is the logical termination of the human organism. The allotted time of threescore years and ten, however, is only traditional, and there is no scientific reason why the human being must wither and cease to become a functioning factor after this time. We have accepted the age of seventy as the time for dysfunction, because we have had no specific therapy to combat its ravages. In other words, we have accepted the ultimatum because we have had no argument in the form of resistance to combat its ravages.

Senility is not dependent on the age of tissue, but on the condition or nutrition of that tissue by internal glandular functioning. Lack of functioning is inevitably followed by atrophy, while atrophy is followed by death. Dysfunctioning of the endocrine system regardless of age is followed by senile or presenile changes. In the young we find these conditions simulating changes that take place in late life, all due to singular or pluriglandular dysfunction of the internal glandular system.

The internal glandular system throughout life is capable of rendering its specific stimuli against a certain amount of resistance. If called upon, or taxed at any period of time, beyond its maximum output, fatigue results, with a retardation of function. Following this senile changes occur: a concrete example being in the roúé whose spermatogenic function is at a minimum, also as shown in the neurotic individual who suddenly flares into tempers, only to call forth the adrenal secretion which in the end fatigues the gland, and due to a decrease in pressure caused by said fatigue the patient becomes asthenic. Again the unconscious dysfunction, such as decrease in the secretion from the anterior or posterior lobes of the pituitary, the thyroid persistence of the thymus, all have their effect on tissue nutrition. Activity of mind and body are registered on the dial of life in proportion to the nourishment of said tissue (not the age of tissue) which is dependent in great part by activation by the endocrines.

Death in the broad meaning of the word as applied to the animal organism is always specific; it is due to lack of internal secretions to prevent their atrophy and death. Death is always due to cessation of vital function, caused in each and every case by the absence of that factor which under normal conditions activates or keeps active vital function, the endocrines. Disease, aside from severe traumatism, causes in the organism a toxic condition which retards by action of the degenerative changes produced the delicate metabolic equilibrium, and as a result death ensues either from paralysis of the respiratory centre or a failure of the myocardium. In other words, the endocrines are reduced to a minimum, activation ceases and death ensues.

In nineteen hundred and fourteen it was my privilege to be in Bahia, Brazil, at the time Dr. Fernandez, a Spaniard, was using with some success a serum (pluriglandular) in treating sex conditions, such as sterility in the young female. His method was to give an injection of his product intramuscularly twelve hours previous to the act of inter-

course. He was able in a series of twenty cases to induce pregnancy in two women so treated. All applicants were examined previous to injection, and any visible gynecological condition, such as atresia, or malpositions of the uterus were eliminated.

Dr. Fernandez's work on the internal secretions interested me, and as I was personally interested in metabolism, I devoted my time to its study: not, however, from the viewpoint of sterility, but metabolism in general, especially diabetes mellitus. In March, 1919, I published a paper dealing with the treatment of diabetes by the Edgar serum. At a later date a second paper was presented dealing with cases treated. At this time I was impressed with the number of patients who showed improvement in their sex relationship. Other patients manifested improvement in their mental condition. I became interested and found that many patients had regained the power of erection and ejaculation. I became interested in the surprising results and immediately studied a series of cases that were not diabetic, in order to check up my results.

My idea in presenting this short paper is simply to place myself on record as being interested in sex stimulation and at present using a pluriglandular endocrine serum with success in the treatment of this condition. It was not my intention originally to depart from the specific therapy of diabetes, but my unusual observations in the cases treated have been so promising in producing a state of wellbeing in my elderly adult patients, that I feel entitled to state that I have a distinctly beneficial serum for the alleviation of presenile and senile deficiency: and that my product is capable of producing a new lease of life in those whose functions have been reduced to a minimum.

Previous to reviewing several cases, I may state that as I did not decrease the diets of these individuals, or try to build up their tolerance by starvation, I do not feel that their improvement was due to this form of therapy. Secondly, the last three patients were not diabetic, and presented no evidence of any objective or subjective disease, aside from their presenile conditions.

CASE I.—Male, aged eighty-four. Consulted me because he was losing weight and becoming weak. Complained of frequent urination, loss of memory. The patient had been employed by one of the large periodicals as a political writer on account of his intimate knowledge of politics. For the past six months he was unable to deliver any speeches, and because of his inability to concentrate was unable to write. Physical examination revealed a remarkably well preserved individual, skin ruddy and moist. The radial and temporal arteries only slightly sclerotic; eyes clear and moist; knee jerks absent; venereal history negative; fine tremor of hands present; musculature flabby; weight 210 pounds. The patient consulted me on account of his mental condition, thinking it might be due to diabetes, which was sapping his strength, and causing him loss of sleep. I informed my patient that I did not think it wise to treat the diabetes heroically, as we might upset his metabolic equilibrium, as is often done in elderly diabetic patients when the diet is radically changed. He persisted,

however, in his desire for treatment, and it was administered with reluctance. The injections took place as follows: September 10th, September 25th, October 4th, October 18th, October 27th, November 7th. At this time my patient voiced the opinion that he was feeling ever so much better, and that his memory had greatly improved, so much so that he had written an article for a Washington paper which had been accepted. He then received injections on: November 18th, November 28th, and December 15th. The patient was so much improved mentally that he was busy writing every day; his mentality was that of a man of forty. He was able to express himself in definite terms, and recall past events that had happened in the political world years ago; sleep was undisturbed. He informed me that he did not become fatigued on exertion, either physically or mentally.

During the course of treatment his sugar output remained unchanged, although the polyuria and weakness disappeared. This is a remarkable case in that definite results were produced in a man of this age, as evidenced by a dismissal of all symptoms that might be referable to a final waning of all endocrine functioning.

CASE II.—Young man, aged thirty-four, instrument maker by trade; venereal history negative. A history of diabetes extending back three years. Complained on visiting me of general weakness, loss of weight and ability to concentrate. Sexual instinct at a minimum; erection impossible. Physical examination revealed a prematurely old man. Skin dry with beginning wrinkles; heart and lungs negative.

First injection October 17, 1919, continued for a period of four months at intervals of seven days. There was no dietetic treatment advised, and none indulged in. On discharge, the patient was sugar free, had gained thirty pounds and, as he expressed it, was feeling like a new man. He also gained back the power of erection. His spermatogenic function, which had been absent for two years, returned gradually. His wife became pregnant in May, 1920, seven months after the patient received his first injection, but unfortunately miscarried at the third month. He now enjoys better health than at any time during the past five years, and is doing hard manual work without any appreciable fatigue.

CASE III.—Female, married; no children. Menstruated at the age of fifteen. Periods remained regular until the age of twenty-seven, usually lasting four or five days; no pain. At this time the patient came home one evening to find her cousin dead in bed. Following this shock she swooned, was revived and continued in her usual good health, but did not menstruate. She had suffered from amenorrhea for the past two years, previous to consulting me. Physical examination revealed no obstruction or malposition of the uterus. There was no tenderness over the ovarian area, nor was there any leucorrhœa. Skin was lightly icteric, and drawn in appearance. Frontal headache was complained of. The patient presented an apathetic appearance.

A specimen of the husband's semen examined on a warm stage microscope showed very active spermatozoa. His Wassermann was negative, as was that of his wife. I advised routine injection of my serum. The patient received one injection

weekly for a period of four months. During the middle of the fourth month she menstruated. I visited her the following day, and found that she was losing a normal amount of menstrual blood. The flow continued for two days and subsided. The next period was regular, and they have continued so to the present. This patient had been curetted previous to the administration of the serum, without result. Undoubtedly her ovarian dysfunction was due to the sudden shock she received over two years ago, and as a result her endocrine equilibrium was disturbed and normal stimulus did not take place.

CASE IV.—Male, aged fifty-seven; hatter by trade. History elicited the fact that the patient's skin was becoming dry and rough. The sexual function had been impaired for the past four months, with inability either to ejaculate or maintain erection. The patient was unable, at times, to sleep more than two hours a night. He became uninterested in his work, lost weight and strength, and presented an apathetic appearance. The physical findings were negative throughout, except for a slight hypertrophy of the prostate. There was a definite mental obsession due to anxiety over his condition. After receiving ten injections of the serum the patient had improved greatly and had resumed business. His nights were comfortable, and he felt much improved. Three months after beginning treatment he gained back the power of erection and ejaculation. Microscopical examination of the semen, however, revealed the fact that the spermatozoa were not motile. The psychological stimulus coincident to the return of the function was indeed wonderful in that it changed the mental aspect entirely, allowing him to dispel the pseudoobsession under which he was laboring. This patient is well and working eight hours every day. His mental attitude is cheery, and he looks and acts twenty years younger.

CASE V.—Capitalist, aged fifty-four, past history negative as to medical and surgical illness. Has always indulged in alcohol to excess. History of sexual indiscretion dates back for the past twenty years. Consulted me June, 1919, because of inability to maintain erection, with partial loss of ejaculative powers. This condition had been present for a year. Physical findings negative aside from hypertrophied prostate. Administration of serum commenced June 15, 1919. Received ten injections in all. On discharge function had returned. I may state that there was no medication aside from the serum used in this case. This patient was of the roué type and the condition was the result of fatigue of the endocrine secretion which responded to specific stimulation in the form of activating substances.

In none of these cases was there any evidence of disease of the interstitial cells of Leydig. In each case electric stimulation caused a slight erection of the penile musculature, with a short contraction of the sphincter muscle. The patient in Case II did not react in any way to large doses of strychnine, which lead me to believe that neurological conditions existed. In spite of this fact endocrine stimulation produced results. Last but not least, the

psychological effect produced by the renewing or revitalizing of a dormant function was capable in these five cases of so changing the outlook on life that bodily vigor and mental acuity were substituted for morbid forebodings.

The question of grafting or implanting testes is a satisfactory procedure in the majority of cases, but as sex dysfunction is pluriglandular in its entirety, it is necessary to ascertain the metabolic rate and function quotient of the other secretory glands before operative procedure is advised. In a testicular implant case in which operation was performed some time ago, it was necessary to resort to thyroid feeding after the implantation in order to coordinate the *vis a tergo* of the secretory equilibrium, the patient being myxedematous as well as suffering from hypogonadism.

I am now working with a solution composed of the salts of the blood, the concentration being isotonic with the blood serum, into which the gland of the donor is placed to facilitate its state of resistance, during the interim between removal and implantation. By this method the functioning power of the gland may be kept in a highly nourished state. The spermatogenic function of the testes is not endogenous, but pluriglandular in its sequence. In other words, sex dysfunction, or testicular dysfunction, is hypoadocrinism, rather than hypogonadism.

766 WEST END AVENUE.

CHRISTIAN SCIENCE AND SEX.

BY THEODORE SCHROEDER, M. D.,
Cos Cob, Conn.

It might be interesting to see if some of the more fundamental doctrines of Christian Science can be explained as the intellectualization of psychoerotic states and attitudes. My own past observation impels me to seek the interpretation of all mystical philosophies of like tendencies in terms of the emotional conflict over sex. Intensified sexual impulses are often accompanied by an equally intense and often inefficient urge to exclude the physiological aspects of sex from consciousness. Thus it often happens that nymphomania or erotomania manifests itself to the rest of the world as erotophobia. When this becomes formulated according to various degrees of intensity and with varying cultural development, we find a great variety of resulting metaphysical theory and theological morality. Let us restate a little of Christian Science doctrine just to see if it lends itself to explanation from this viewpoint; that is, in terms of the internal erotic conflict.

First let us remember that Mrs. Mary Moss-Baker-Glover-Patterson-Eddy had more husbands than she had children. This is some evidence of her having been afflicted by sexuotional conflicts. Without the satisfaction of the biological impulse for progeny, she became afflicted with the compensatory psychological urge to become the "mother" of all who are "born of truth and love" (1). God "is the universal father and mother of man" (2), perhaps because bisexual impulses in

herself required the projection of these dual qualities into her God. She discoursed glibly about "the womanhood as well as the manhood of God" (3). Probably because with this concept she could achieve a needed compensation for her feeling of inferiority, due to her femininity (4). This compensation consisted in identifying herself with God, in the rôle of being his feminine part.

Though differently expressed and perhaps differently theorized about, she yet laid claim to the same perfectionism asserted by Mormons and the free lovers among the Bible Communists of Oneida. Sin is but "an error of mortal mind," and Mrs. Eddy having come to a realizing sense thereof, to her all "evil is unreal" (5). That is to say, all her own "shameful" past had to be pushed out of consciousness; had to be treated as unreal, in order to neutralize her feelings of shame, of inferiority. Of course, one who needed such a psychological remedy for a feeling of depression had to abolish "the erring testimony of mortal sense" so that she could receive into consciousness no evidence of her own sin. She could not commit an unreality which alone is sin. Those who are excessively burdened by the feeling of their own sinful flesh tend to find compensations in rising above the flesh, in identifying themselves with the supernatural generally, or with God. So they argue that God, being the "all in all," one like Mrs. Eddy is herself a part of God, and how could she, a part of God, commit any sin so long as she rejects the "erroneous belief" that "evil is real" (6)? No. She is "no longer obliged to sin" (7). To such persons all is pure, even though to unspiritual vision it may still seem both real and evil. Having herself experienced that "spiritual birth" which "opens to the enraptured understanding" (8) many things, she readily discovered (perhaps with the help of her many husbands) that lust is "always wrong" (9) unless the physiological factors can be excluded from consciousness. Then we can oppose to the "material sense of love" a purely psychological erotism, that is a "spiritual law of love" (10) and "spiritual love" (11) with "spiritual oneness" (12), with God or anyone else in the universe, either dead or alive (13).

Thus, through Christian Science ideals will "the attraction between the sexes be perpetual, bringing sweet changes and renewal." So it can be described if we succeed in excluding from consciousness all the physical sexuality, and enjoy approximately the continuous ebb and flow of ecstasy due to erotomania. Since the "material sense of love" is but an "error of mortal mind" it follows that all erotic love is wholly psychological, that is, spiritual. If it is unceasing, as in extreme erotomania, then we can say that God is love and love is all there is of God. It follows that celibacy is nearer right than marriage (14), because normal marital relations tend to dilute the psychosexual ecstasy. Now generation "rests on no sexual basis" (15). In all climes and times, neurotics have found their way to celestial exaltation, through spiritual connubiality, heavenly bridegrooms, and offspring begotten by ghosts. Mrs. Eddy had experienced the pains of parturition at least once, but under the inhibiting

compulsion of her neurosis she could exclude even that from memory and consciousness, and she may have believed herself to have begotten her child on no sexual basis. The psychiatrist can give her a sympathetic understanding if he cannot agree with her. When the "spiritual creation is discerned and the union of male and female apprehended as in the Apocalypse," (16) then will marriage be abolished. In the meantime those of us who continue to suffer from the error of mortal mind that sex is real and some of its lusts are wholesome will continue to mate on a physical instead of a purely psychoerotic basis. "But to force the consciousness of scientific being before it is understood is impossible." (17) So Mary Moss-Baker-Glover-Patterson-Eddy leaves us, to our physical illusions and refuses to disclose any more of her vagaries on the spiritual process of begetting offspring, which "rests on no sexual basis," perhaps because such exposure might reveal too much of the psychoerotic mystery of bisexual attributes of God in herself.

Eddyism proves the correctness of Father Noyes of the Oneida Community when he concluded that a celibate church is a woman's church. Christian Science with its feminine predisposition to celibacy has seventy-two per cent. of women in its following (18). For many more wholesome women in other churches, a virile pastor and the glorification and sanctification of heterosexuality as expressed in conventional, parsonized marriage constitute the lure. Not so in a church that discredits marriage. Here we should expect to find a haven for the victims of inhibitions against normal heterosexual relations, who wish to make a virtue of their misfortune. Those whose impulses tend toward perversion and inhibition need a compensation and thus find it in the "spiritualization" and glorification of the resultant psychoerotic states, that are alleged to rest on no physical basis.

Here, as always, the development is the same. From some abnormal sex tendencies through sexual allegories to a firm belief that all lust is evil. Hence celibacy, spiritual love, eternity of sex attraction through piety, and finally the overthrow of the reason upon the subject of the mania as shown in the illusions about the spiritual generation of flesh and blood offspring which "rests on no sexual basis." This belief that some day either men or women will beget human offspring without the help of the other sex, is an oft recurring symptom of psychoneurosis. Its most distinguished victim was probably Auguste Comte. (19) Recently I saw a letter from a male physician—not yet confined in an asylum, but asserting that soon men without the aid of women would propagate the human species. So the male homosexual may formulate the logical outcome of his conflict. The late William T. Stead assured me that he had seen (but only with his spiritual eyes of course) children begotten without a fleshly father. Every asylum has its inmates who have sufficiently imperative emotional needs to enable or compel them to create in the objective world what others cannot see there, or to enable or compel them to ignore and deny objective realities that most of the rest of us have to admit the reality of, both in our theories of life as well as by our conduct.

For a few the denial for a part or all of the time, of some or all of the objective realities is made possible by such a relatively complete obsession by the erotic ecstasy that it excludes from consciousness, at least for a time, both its sexual origin and the related objective realities. Under this obsessing erotic ecstasy, the sensations derived from objectives do not register in consciousness, or only so faintly that all seems unreal. "The testimony of mortal sense" is weakened or abolished. As the state of erotic ecstasy approaches continuity with relatively small variations of intensity it is readily formulated in: "the attraction between the sexes is perpetual." But since the physical causes of this attraction are (because of shameful experiences) excluded from consciousness, the material sense of love is also abolished. Yet we are here. If now you unite with our consciousness of existence the theories necessitated by the erotic inhibitions we come logically to the conclusion that human beings can be begotten on some other basis than that of sexual methods of reproduction. For all those who need that sort of theory, I should think it is just the sort of theory they need. Obviously there are many such persons. Hence Christian Science and its popularity. There is one "error of mortal mind" that Mrs. M. M. B. G. P. Eddy did not abolish either in herself or her followers, and that is an adipose belief in dollars as real substance.

UNDERLYING FACTORS IN GOOD POSTURE.*

BY C. WARD CRAMPTON, M. D.,
Battle Creek, Mich.

(Concluded from page 816.)

The neck is one of the most important and most neglected regions of the body. The cervical spine holds up the head. It surrounds and protects the spinal cord, which in this locality controls the body processes of circulation, respiration, heat production, and to a great degree digestion and nutrition. Yet these bones are frequently badly adjusted to each other, and frequently the spinal column of the neck sags forward and downward. The debutante's

*Address of Temporary President of the Association of Institutions Giving Normal Instruction in Physical Training delivered at Waldorf-Astoria, New York City, April 10, 1920.

slouch is characteristically weak necked, quite typical of the young girl graduate who has had no physical exercise, no vigorous games, and has received all of her instruction in health from books on anatomy and physiology instead of from daily life.

In the neck are the four great arteries which bring blood to the brain and the big jugular veins through which it is returned from the head. The thyroid gland is saddled across the front of the neck, and this has an exceedingly important function in maintaining the nutrition of the body. Tucked away on either side of the throat, in a fold between the larynx and the lateral neck muscles, are three sympathetic ganglia which have much to do with the circulation and respiration. It will be seen that the neck is an important segment of the human body. Necks are as characteristic as faces, and they tell the story of weakness, power, vitality, illness past and present, and even prophesy illness to come.

That neck which has fine, strong muscular pillars on either side running from the ears down to the junction of clavicle and sternum, and heavy posterior masses of powerful muscle running from the occiput back to the spine and scapula—that neck is, indeed, likely to be surmounted with a head worth while in this generation of high deeds and great events. Few people realize what tremendous value there is in a well muscled neck. It holds the head high. The circulation in the neck itself is improved in all its various important parts, the spine, the cervical central nervous system, the sympathetic ganglia and even the larynx and the esophagus. The high held head puts these various parts in their proper position. The low drooped head falls in upon itself and allows each part to discommode itself and its neighbor. The exercise of the muscles of the neck not only improves the power and tone of the circulation but it also mechanically massages the throat and related parts. Exercise of the cervical muscles will do more to correct a bad condition of the tonsils than anything else except the surgeon's knife. Therefore, for the sake of the high head and of all of the body processes that are affected for good or for ill by the condition of the neck, the muscles of the neck should be strengthened.

Exercise No. 1.—1, Press the chin down on the chest as low and as hard as possible, raising the chest to meet it; 2, Scrape the chin along the neck as closely as possible, making as many double chins as you can; 3, Raise the head, look upward, and press far back; 4, Hold this position, emphasizing it as vigorously as you can. Try to look at the back of your head. In doing this exercise it is important at first not to press too hard with the chin nor to strain too hard in going backward, lest the untrained and anemic muscles become overworked and made sore. This dampens ardor and diminishes determination. Begin by doing the exercise five times, quietly and easily. Increase one or two a day to ten times. The four counts should take four full seconds. This means that it should be done at the rate of fifteen times a minute. Under no circumstances should they be done more quickly, but when one becomes accustomed to the exercises, they should take at least six seconds. There should be three to six seconds between each repetition.

The name of this exercise, neck massage, is very well justified; for there is an alternation of strongest possible compression and stretching of the whole of the neck within physiological limits, and if this exercise did not have the additional effect of strengthening the posterior muscle masses, it would be sufficiently useful for the massage effects alone. When the muscles relax, the head will fall forward, because the greater part of the weight of the head is in front of the spine upon which it rests. These muscles are in constant contraction when the head is held up. They relax when one gets sleepy and begins to nod. The nodding is merely due to the

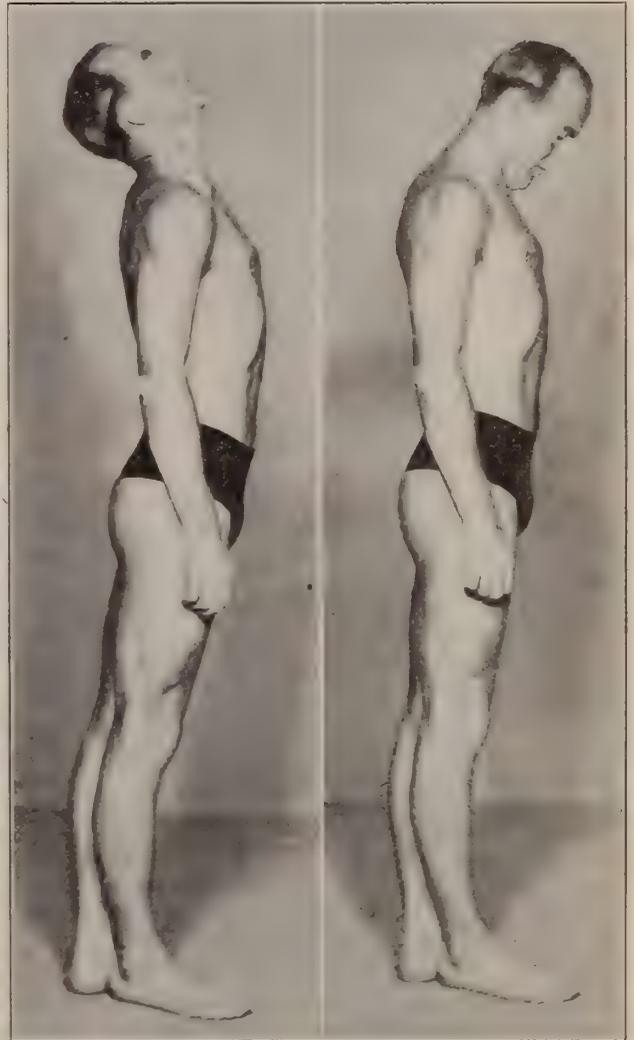

FIG. 4.—Cervical exercise No. 1. Neck massage.

temporary relaxation of these muscles, which are brought back to contraction again when we awake with a start. The extent of the contraction of these muscles is great.

This exercise is unusual in more than one respect. One of its peculiarities is that the fourth count does not change the position but merely emphasizes the position taken on the third count. This is for the specific purpose of shortening the neck muscles and illustrates the application of an important physiological principle frequently used in physical training, as follows: A muscle tends to assume the position it occupies during its work. The operation of the

principle may be seen in the resting position of the fingers of the farm hand or coal heaver who habitually uses a shovel, a pick or some implement which must be grasped and held tightly. This work requires the muscles of the forearm to be kept continually shortened, with the result that during rest

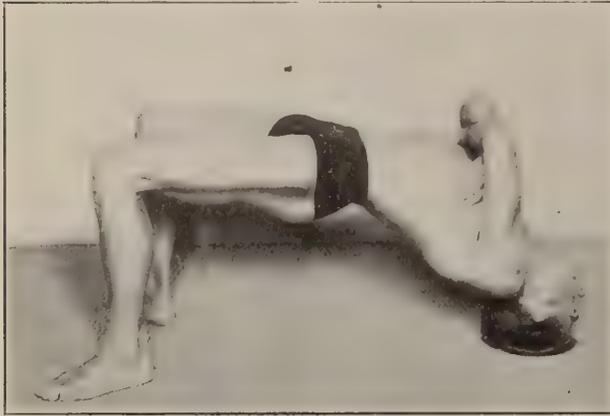

FIG. 8.—Test exercise, "The Bridge"

when the hand is no longer at work, the hand still maintains the position in which it worked, and remains half closed. This is why we emphasize the hard overcontraction of the posterior muscles of the neck, being confidently assured that if we practise it often enough, they will surely tend to remain shortened and the result we desire will be obtained; just as the fingers of the farm laborer are kept bent after their hard work, so the head will be held up. This principle is just becoming recognized as an integral part of physical training and is essential in procedures involving the change of posture relation or position of parts of the body. Other exercises which strengthen the muscles of the neck and should be used diligently, are as follows:

Exercise No. 2.—Position: Raise the arms in a half forward bent position with the wrists rigidly straight, the hands flattened, palms toward the face, thumb at side of index finger, the pads of the index and middle fingers resting lightly upon the chin. The shoulders, arms, forearms and hands are straightened upward and backward. This position in itself straightens the spine and lifts the chest and constitutes an excellent static exercise. 1. Head turning to the right. The head is turned squarely to the right as far as possible, tilted slightly but very slightly backward. 2. Return to position. This exercise should be done both right and left, six to twenty times. It should be noted that the head turns away from the hand and is held well back of it. This is important, for the head should be held back both in position No. 1 and in position No. 2. This is again putting into operation the principle given above in discussion of the first exercise, and one can see why it is necessary to keep the posterior muscles contracted and the head held well back. Keeping the head well back is necessary to keep the muscles of the neck shortened while they are working, and thus to put into operation the principle indicated above.

Exercise No. 3.—Position: Chin resting on right shoulder. Do not lift the right shoulder to the

chin, but use every effort to place the chin down and far back. Do not permit the shoulder to come forward. 1. The head is thrown back and toward the other shoulder in an endeavor to place the back of the head upon it; 2. Return to position. The exercise continues in an alternate endeavor to press the chin on one shoulder and the back of the head upon the other shoulder. It should be done slowly from ten to twelve times on each side. This exercise keeps the posterior muscles of the neck in a contracted or semicontracted state.

The posterior triangle of the neck extends from the ear along the line of the sternocleidomastoid muscle to the top of the sternum and is prominently shown. The base of the triangle extends from the insertion of the muscle of the sternum along the clavicle to the point of the shoulder. The other side of the triangle extends in a line not quite straight from the point of the shoulder upward to the rear. Incidentally the anterior triangle is massaged in a way similar to Exercise 1. These three exercises should be practised daily by every man, woman and child in the United States. The most favorable time is in the early morning on arising, for they form a part of the regular daily morning life-prolonging exercises.

The results of these exercises are as follows: Good posture of the head, good posture of the chest and back, stronger muscles of the neck, improved circulation in the important structures of the cervical regions and a general improvement in the whole body metabolism. The muscles of the neck of every man, woman and child should be strong enough to do the test exercise, the "bridge." The man who can do this has a set of muscles sufficiently strong to hold his head up, and it is perfectly clear that the exercise taken to make the neck muscles strong must have done his whole system a marvelous amount of good. This test should not be attempted within a month from the time of beginning the exercises indicated above, or strained neck will result.

Good posture is a three storied affair. It concerns the head, the chest, and, perhaps most important of all, the abdomen. We have noted the methods of raising the chest by simple static exercises and the great importance of the tone and development of the muscles of the neck in holding the head high and raising the chest. The abdominal features of both good and bad posture are perhaps the most important of all.

ABDOMINAL EXERCISES.

Biologists tell us that the normal attitude of pre-Adamic man was on all fours. This placed the spine and ribs above the abdominal contents, which were suspended from them by strong ligaments, the kidneys snugly attached behind the peritoneum, the intestines hanging like a bunch of grapes from the mesentery, and the liver, stomach, spleen, all with appropriate sustentacular ligaments. Man, on rising from this horizontal position, found his abdominal contents attached to the rear wall of the abdominal cavity, instead of hanging from above.

The liver soon obtained an attachment to the diaphragm, from which it now hangs suspended as it did previously from the posterior abdominal wall. The other organs still retain their posterior attach-

ments. This constitutes a hereditary disharmony, which is constantly causing trouble. The kidneys are prone to leave their moorings and slide down the back, sometimes behind their peritoneal coverings and sometimes pushing the peritoneum in a pouch before them. The small intestines hang down from their attachments and occupy as low a space as possible in the abdomen, flowing down into the pelvis, their weight pressing upon the pelvic contents, i. e., rectum, bladder, and generative organs, the lower layers of this mass of intestines being pressed upon by the weight of the upper layers.

This is bad for the pelvic organs, for they are crowded, congested, and generally discommoded in action, and it is bad also for the intestines themselves. This condition results in constant pressure being exerted upon the abdominal wall from within outward. In the erect position, this outward pressure is greatest at the lower levels of the abdominal walls and decreases gradually as we go upward until the ribs are reached, where the dragging effect of the abdominal contents begins to pull it in, instead of pushing it out. Hence, when the abdomen is weak, the trunk assumes the shape of the ancient leather water bottles which when filled were bulging and round at the bottom, but sloped to a thin neck above. Not only is the upper part of the abdomen drawn in, but the chest itself is dragged down and sinks inward. The weighty liver pulls down the diaphragm, which in turn pulls downward and inward the lower ribs which in turn pull down the upper part of the chest, and the bottle shaped appearance extends from pubis to neck.

This is the picture so frequently presented by the chronic invalid, the man in bad posture, the man who has never taken exercise. This is the effect of gravity, that constant force which constantly drags us down toward the earth. It is a picture of gravity victorious over the strength and vitality of a man, the picture of a man defeated by the forces of Nature. He is still erect, still possessed of a certain amount of vigor and muscular strength, but Nature is dragging him down piecemeal and has proceeded a long way toward the winning of the ever waging tug of war, which finally and inevitably she must win, for gravity brings us all at last to rest.

GOOD TONE.

The strong abdomen is a flat abdomen; therefore, make it flat and keep it flat. All that is necessary in the normal individual is merely an effort of the will, calling upon the abdominal muscles to contract. As a rule, however, men are not normal, and the abdominal muscles are incompletely under the control of the will, and in many cases are half paralyzed. For ninety-nine per cent. of the people it is necessary to reeducate as well as to strengthen these muscles.

ABDOMINAL CONTRACTION AND RELAXATION.

Exercise 1.—Position: Leaning forward with the hands on the knees, which are slightly bent. 1. Contract the abdomen, pulling it in and up as far as possible. 2. Relax the abdomen, allowing it to fall down under the pressure of the abdominal con-

tents; one count to the second; two seconds to the exercise. Repeat ten to thirty times.

ABDOMINAL CONTRACTION WITH BREATHING.

Exercise 2.—Position: Hands on the knees the same as in No. 1. Count 1. Abdominal contraction, the same as in Exercise 1; Count 2. Breathe in (abdomen contracted); Count 3. Breathe out (abdomen remains contracted); Count 4. Breathe in (abdomen remains contracted); Count 5. Breathe out (abdomen remains contracted); Count 6. Breathe in (abdomen remains contracted); Count 7. Breathe out (abdomen remains contracted); Count 8. Breathe in. (Abdomen remains contracted. Keep it contracted). Two seconds to each count; sixteen seconds to the exercise. Repeat six to twelve times.

These are probably the best of all the abdominal exercises and are the results of many years of patient research and experience. The first exercise gives a training in the voluntary control of the abdominal muscles, improving their circulation and strengthening them. It forces the abdominal contents up into the upper part of the abdomen, decreases the circumference of the lower segment and increases the circumference of the upper segment. In a well trained athlete, this is readily seen. *Chest expansion is important, but abdominal contraction is a far more significant measure of vital power.*

The relaxation of the abdominal walls permits the viscera to fall again, the alternating contraction

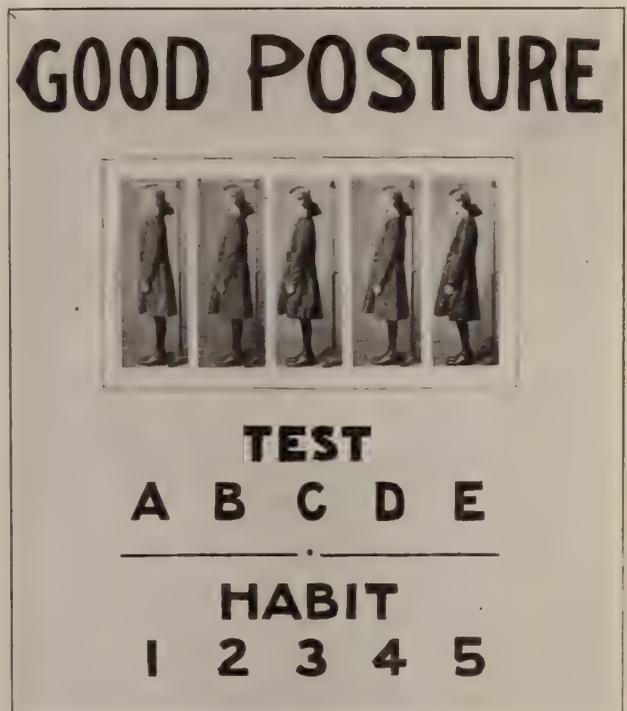

FIG. 6.—Posture chart for schoolroom.

and relaxation causes a churning kind of massage which stimulates the living tissues which form the abdominal contents, heightening their activity. The muscular structure of the bowels becomes less lax and more active, the glandular lining of the intestines, the actuating nervous ganglia, the arteries, veins, and lymphatics receive their appropriate

mechanical stimulation, all of which is conducive to health.

If the diet is even approximately near the biological normal, and the condition has not lasted long enough for the intestinal muscles to become semi-paralyzed or spastic, this exercise will completely relieve intestinal stasis. The improvement which this makes in the taut and strengthened abdominal wall gives it sufficient power to support the abdominal contents. Such power is tested, practised, and improved by Exercise 2. This exercise, breathing with a contracted abdomen, simulates the normal tonic condition of good posture. The abdomen is first contracted and held taut while the breath is taken in and allowed to go out of the lungs. This is the state of affairs which should obtain at all times during the day when a man sits or stands erect, particularly when he is standing still.

In the first exercise, the lower and inner wall of the abdomen was acted upon. In the second exercise, it is held normally contracted while it is put under a rhythmical strain by the movements of the upper part of the chest. It remains in static contraction, which is exactly the position in which it must remain during daily life. These two exercises are given in a position in which the trunk is nearly horizontal, a return to Nature, with a simulation of the natural mechanical strains on the trunk and abdomen.

THE MEASUREMENT OF POSTURE.

The measurement of the posture of children in school should be made as simple as possible. It should be based upon sound scientific principles but it should be relieved from the necessity of painful accuracy of scientific method. All measurements of posture whether scientific or merely practical should be based upon the recognition of the fact that good posture is an evidence of good gravity resistance, for bad posture is on the other hand a submission to gravity. If the child is standing as tall as it is possible for his physical frame to stand, he is in good posture. If gravity pulls him down an inch or two or three, he is in correspondingly bad posture.

Bad posture may be, therefore, measured by decrease in height. This may be shown by actual measurement of height or by observation of the contour of the body in profile for a poor posture will show various displacements forward and backward. If, for example, we take a piece of wire thirty-six inches long and lay it upon a yard stick in a vertical position, it will, if the wire is perfectly straight, measure just thirty-six inches. Now let us take this wire and bend it slightly at the middle and call this the position of hips forward. Bend it also at twenty-four inches from the ground making an increased dorsal curve. Bend it again farther up, corresponding to the "head forward" position, and then lay it alongside the yard stick and we will see that the wire, although it is thirty-six inches long, only measures thirty-two or thirty-three or possibly thirty-one inches, depending upon how much we have bent it at the various points corresponding to the hip, back and neck. This then is the way to measure how bad posture is.

Other measures of posture may be obtained by

noting actual visceral ptosis, i. e., the depression of internal organs below their normal positions. If the abdomen bulges and the chest is flat, there is bad posture and visceral ptosis.

We should be able to arrive at an index of comparative girths of chests and abdomens. In a healthy young man the average chest girth should be from twenty-five to forty per cent. greater than the smallest abdominal girth; in woman it might be less. The proportions of five to four are approximately normal. This measurement is complicated by the amount of abdominal fat and other factors. Circulatory ptosis can be determined by the author's test, which is based upon an observation of the systolic pressure and heart rate in the horizontal and vertical positions.

For the school room, however, we wish to measure posture merely to stimulate improvement. For this purpose there is offered a chart showing successive photographs of the same individual ranging from perfect posture to very poor posture. This indicates that a child may have excellent, very good, fair, poor or bad posture, that it is possible for any child to be either good or bad in this regard. It is evidence on the one hand that good posture is not impossible for any one if effort and application are brought to bear and, on the other hand, it is evidence that those who have good posture may if they are not careful tend to lose it.

In this respect, an important distinction must be made. Many children can assume good posture during a posture test, but make no effort to keep good posture at any other time. Hitherto they have been placed in the good posture division, but they deserve this distinction far less than the B posture children who try very hard all the time. I strongly recommend that good posture tests should be continued in a standard fashion, i. e., while standing, marching and exercising, but that in addition a rating should be given for habitual posture, and I suggest the following set of instructions for the teacher:

THE POSTURE RATING.

1. The teacher should be provided with posture charts showing a child appropriate in size to her grade showing the five posture positions.

2. She will conduct a test in posture, including standing, marching, and exercising with half of the class acting as assistant judges while the other half is being tested.

3. The pupils will be graded on this test with the letters A, B, C, and D corresponding to the pictures on the chart.

4. The teacher will observe the posture habit of pupils in their daily work, particularly upon standing for recitation of lessons, writing at the blackboard, marching to assembly, and, in short, rate the pupils on their habitual posture.

It is preferable to have one or more posture monitors selected because of their superiority in physical training and in good posture, and it should be his or her duty to record the ratings and relieve the teacher of the time and trouble rather than to nag and browbeat their fellow pupils, as monitors are sometimes prone to do.

The rating for habit in posture should be in nu-

merals, 1, 2, 3, 4, and 5, referring to the values exhibited on the chart. Thus we will have each pupil rated by letter and by number very much as business organizations are rated in financial reports. A will stand for the best posture on test, but the pupil in order to get in A 1 must stand in good posture all of the time, otherwise if he slumps he may get a rating of A 2 or even A 4, or A 5. A pupil in C posture may be C 4, or C 5, depending upon his posture habit. It is theoretically possible for a pupil in C posture to be 2, or even 1, on habit, because some pupils during the test have an inconquerable tendency to assume rigid overstraightened posture, which cannot be rated perfect; but when they are unconscious of observation sit and stand perfectly. Pupils and teachers alike take quickly and easily to these ratings, for A 1 has a well understood significance the world over and all departures from it have a common meaning.

CARDIAC MANIFESTATIONS IN INFLUENZA.

BY CHARLES GREENE CUMSTON, M. D.,
Geneva, Switzerland.

Although some attention has been given in the past in France, England, and the United States, to the cardiac manifestations of influenza, it is probable that the most important work on the question has been done by that veteran clinician, Professor Eichhorst, of Zurich, and his school. We know at present that during the evolution of influenza some one or all of the structures of the heart or its elements of innervation may become involved, the endocardium, the pericardium, or the myocardium, and this means that there exists a vast variety of symptoms, according to the cardiac structures involved. Cardiac influenza, therefore, may manifest itself as an endocarditis, pericarditis, or myocarditis, likewise by disturbances of nervous origin, such as syncope, bradycardia, tachycardia, or arrhythmia. It is also probable that these influenzal lesions are far more frequent than is generally supposed or as given in the classic textbooks on medicine, and if the disturbances in cardiac contraction are compared with organic lesions it becomes evident that their frequency is about equal, although Eichhorst maintains that the innervation system is more frequently involved than the histological structures of the heart itself. Sex or age appear to play no part as the bulbocardiac accidents have been met with in infants as well as in the aged, but I would point out that the majority of recorded cases have been encountered in subjects varying in age from twenty to forty-five years.

It also appears probable that hearts already the seat of lesions, the result of previous infections, become more readily the prey of the virus of influenza than normal hearts, and the grippe may likewise either awaken old lesions into activity or create new ones in a neighboring valve; it also attacks the system of cardiac innervation, destroys the cardiac equilibrium, and forces the condition of affairs toward a systolia. It must be frankly admitted that the causative factor of the cardiac pro-

cesses is unknown, although bacteriological research work has occasionally revealed the agents of secondary infection, such as Pfeiffer's bacillus, the pneumococcus, or the streptococcus. But just as frequently no bacterium has been found, in which case the lesions can only be explained by the action of a filtrating virus, which Prof. Bard, of Geneva, and others regard as the probable agent of influenza, or by the action of a toxin acting indirectly as in the case of diphtheria.

The symptomatology of the cardiac manifestations of influenza will depend upon the variety or type of the cardiac involvement, but often in the same subject a combination of several types of symptomatology may exist. One of the tissues composing the heart's walls can never be morbidly involved without reacting upon other component structures so that a series of general symptoms must inevitably result which are found in all cases.

The onset of the symptoms may be very sudden, a syncope, a paroxysm of angina pectoris, or dyspnea revealing the influenzal attack. But frequently these startling accidents only arise some days after the onset of the disease, or occasionally during convalescence when all danger is supposed to have been passed. Huchard insisted upon this latent period—which may be long—between the influenzal infection and the onset of the first cardiac manifestations.

But all forms of influenzal heart do not offer this sudden onset; the lesions develop quietly and it is only by mere chance that an examination or the development of serious complications, such as embolus or asystolia, reveals them. Among the more constant subjective symptoms should be mentioned a severe acute pain in the cardiac area or a sensation of cold or crushing in the retrosternal region, extending to the neck and arm. The asthenia and prostration are very evident in this clinical form of influenza, while the suddenness of their onset is rather characteristic. The dyspnea is intense and cannot be explained by the slight pulmonary lesions found on auscultation. It is accompanied by cyanosis, algidity and peripheral coldness. Hypotension is constant and very marked. The weak, small pulse is very unstable; arrhythmia is frequent. The evolution of the process varies and occasionally all morbid manifestations subside without leaving any trace, or the subject recovers with a well compensated valvular lesion and this is perhaps the most common occurrence in practice. On the contrary, in other instances the process becomes aggravated and the patient dies either from asystolia or collapse.

In referring to the syndromes that are commonly met with in practice it may be well to follow Eichhorst's division as follows: The pericarditic syndrome, the endocarditic syndrome, and the myocarditic syndrome, as well as some special forms which have been recently described by Minet and Legrand, of Lille, under the name of grippal bradycardiac heart, grippal tachycardiac heart, grippal arrhythmic heart, and grippal cynopal and neuralgic heart. The pericarditic syndrome offers two principal forms, namely, dry pericarditis and pericarditis with effusion. There is nothing which can

help the physician to distinguish these influenzal pericarditides from the same morbid process encountered in other infectious diseases. A fibrinous deposit arises on the serous membrane, giving rise to the friction sound, or the pericardial sac may be distended by a serous or purulent collection. The latter may reach a considerable amount, and the late Professor Grasset, of Montpellier, had a case under his care in which the amount of fluid was seven hundred cubic centimetres. A fact to be noted is that in this syndrome the myocardium is very frequently simultaneously involved.

The principal symptoms that may be encountered are the intensity of the general phenomena, the oppression, distress, increase of the area of cardiac dullness, the smallness of the pulse, the weakness of the heart sounds, and the presence of friction sounds, symptoms common to all types of pericarditis. The outcome of the process is often fatal, particularly when a fluid collection develops.

Among the cardiac manifestations accompanied by an organic lesion, the endocarditic syndrome is by far the most commonly met with in practice, and generally makes itself evident during the progress of the influenza or at the time of convalescence, and in the latter case it would seem to assume a much more serious aspect since all the valves may become involved. Nevertheless, influenza is more prone to attack the left heart, attacking both valves with about the same frequency and occasionally becoming located on both at the same time. However, cases have been recorded in which lesions developed on the tricuspid and even on the valves of the pulmonary artery. The morbid process may also involve the parietal endocardium or invade the intima of the large vessels.

From the viewpoint of pathology, the ulcerating and vegetating types of endocarditis have been found to be about equally frequent. The onset of the process is ordinarily silent, but frequently there is a recrudescence of the general phenomena, the dyspnea and tachycardia attracting the clinician's attention to the heart. The temperature chart assumes the pyemic character, the percussion dullness of the cardiac area increases, infarcts may occur and the pulse is poor in equality. The diagnosis will, however, be made by the detection of a soufflé, and in influenzal cardiac phenomena the soufflés possess two distinctive characters, namely, roughness and an early onset. They are fully developed in a few days and it is not at all uncommon to find them within four or five days after the recrudescence of the general phenomena. Such cases of endocarditis are serious when not fatal and when death does not ensue a serious lesion of the valves remains. The lesions are never limited to the endocardium alone, and are invariably accompanied by a process in the pericardium and myocardium.

Perhaps more than in the two preceding forms, the word syndrome should be employed for the clinical disturbances originating from the myocardium. In point of fact this syndrome includes a great number of most varied phenomena which point to an undoubted disturbance of the cardiac contractions. Nevertheless, this disturbance is not of necessity dependent upon an anatomical lesion of

the muscle, so that the term myocarditic syndrome is to be preferred to that of influenzal myocarditis. Eichhorst maintains that he has never observed myocardic lesions, even microscopic. But for all that myocarditis exists and lesions of the muscle have been frequently found at necropsy, but they are often hidden by a coexisting endopericarditis. It would seem that this pathological involvement of the cardiac muscle has a predilection for hearts which have been attacked by an antecedent infection. The lesions found are those of acute myocarditis.

The clinical signs are classical: precordial pain and a weak, small and irregular pulse. The arrhythmia is important to detect, as well as a special "trotting sound" described by Huchard, found by auscultation. This consists of a three time rhythm, the result of a systolic effort which takes place between the two principal times. It should be mentioned that the myocarditis may undergo its evolution silently, and it is only upon the occurrence of an effort that syncope arises, which may be fatal, and gives an indication of the true state of affairs. The accidents which will now be referred to as special syndromes, combined with those given above, will allow the clinician to come to a correct diagnosis.

The influenzal bradycardiac heart has been known for some time and is looked upon as frequent, although some maintain the contrary to be true. It may appear at various periods of the influenza, sometimes at the onset and in other cases it may develop during the progress or at the end of the disease, or even during convalescence. Should it be continued it usually presents a paroxysmal character, in which case it may bring about serious disturbances. The lowest pulse rate averages from forty to fifty beats, but it has been known to be as slow as nineteen or even fifteen beats to the minute. These disturbances of the heart contraction are accompanied by asthenia and intense prostration which may persist for a long time after the patient has recovered. Although some of these disturbances rapidly subside, there are others that persist for some time, as much as a year or fifteen months after recovery from the influenza. However, the bradycardia is not often fatal *per se*.

Influenzal tachycardia is considered frequent by some, while Eichhorst maintains that it is uncommon, and others uphold this view. The time of its onset varies; it may be very early in the disease or not arise until defervescence or convalescence have taken place, and this a very long time after the acute accidents have disappeared. Usually intermittent, it may be continued, the beats averaging from one hundred and twenty to one hundred and forty a minute. These attacks are accompanied by thoracic pains, distress, and stasis in the pulmonary circulation. Instances have been recorded in which paroxysms occurred which brought the pulse rate as high as three hundred beats a minute.

The evolution of this clinical form is essentially variable. The tachycardia may suddenly subside after a more severe paroxysm than the previous ones, or it may persist for a long time after recovery from influenza, as much as eight months in a case recorded by Sansom. The prognosis is serious in all cases and a fatal outcome is not uncom-

mon. The coexistence of phenomena similar to those encountered in Basedow's disease is not infrequently observed with postinfluenzal tachycardia, to which the name of vagus storms has been given.

The arrhythmic influenzal heart is another form, designated by Eichhorst as influenzal extrasystolic heart. Some English observers maintain that there is no relationship between the cardiac disturbance and the subjective sensations experienced by the patient. A severe arrhythmia may not be accompanied by any subjective symptom, while a very mild form can very well be accompanied by serious accidents of precordial distress. The arrhythmia may be bigeminate, trigeminate, alternating, or complete. The characteristic unstableness of the influenzal pulse is here to be found in its highest degree. The numerous extrasystoles which characterize this form appear during the same phases of the disease as the bradycardia. The process undergoes an evolution toward recovery or to chronic myocarditis and asystolia.

The syncopal heart of influenza is rather more of an important symptom than a clinical entity and in reality indicates a profound disturbance of the heart's contraction. It appears at times as an initial symptom announcing the onset not only of the cardiac complications, but of the causal infection as well. At others it is a complication of convalescence, or as a frequently fatal accident arising during the evolution of some other form of influenzal heart. It occasionally completely occupies the clinical picture on account of its repetition and with the instability of the pulse, presents the only sign of the cardiopathy present. The prognosis is invariably extremely serious.

Influenzal cardiac neuralgia has been known for years and many instances have been recorded in the Anglo-Saxon medical press, but Eichhorst, on the contrary, regards it as of extreme rarity and only to be encountered in young people. It would seem that this opinion of the eminent professor of Zurich is exaggerated because if one regards it as a mere symptom, it will be found noted in nearly all cases recorded. Often early in its onset, the pain appears with the beginning of the cardiac accidents. It is a violent, sharp pain, a crushing sensation or one of torsion at the anterior portion of the sternum, shooting to the back, neck, shoulder and arm. It is prone to occur in paroxysms, its evolution in some cases being in the form of a series of neuralgic crises. It also may arise very late in convalescence. Usually benign, it has been known to cause death in a few instances. Huchard was of the opinion that these cases are often instances of old angina pectoris, aggravated by influenza.

As to the pathogenesis, so far as the endomyopericarditic lesions are concerned, the lesions met with at necropsy show unquestionably that it is in the heart itself that the cause of the clinical signs met with are to be found. In those instances where no lesions can be discovered at necropsy, Huchard explained them by a cardioplegia resulting from involvement of the pneumogastric nerve as well as by an involvement of the motor centres of the heart in the bulb. Cardiac influenza is a bulbar process; alone, the arrhythmia is the result of a morbid

change in the muscle fibre. Huchard also attributed an important part to an influenzal coronary endocarditis which remains latent for a long time until one fine day it sets up a degeneration of the myocardium. Other observers believe that there is an irritative lesion of the accelerator nerve of the heart in cases of tachycardia and a neuritis of the vagus in cases of bradycardia. It has also been maintained that there is a possible action from thyroid hypersecretion on account of the phenomena of basedowism sometimes met with. As to the pain, it has been attributed to an involvement of the ganglions of the cardiac plexus or to a phenomenon similar to visceral neuralgia.

Althaus is of the opinion that there is a neuritis of the vagus and also a lesion of the bulbar centres, but given our present knowledge of cardiac anatomy and physiology, other explanations may be put forward. The bundle of His and the various cardiac ganglions, the relation existing between the ganglions and their motor and regulating action over the movements of the heart, might very properly lead one to suppose that there may be a single pathogenesis for all cardiac influenzal processes.

If the infection involves the heart *en masse*, then we will have the classical forms of acute myocarditis, endocarditis or pericarditis. But let us suppose that there is a milder action of the infective matter, which attacks only the more noble elements of the heart, either the ganglions and conducting fasciculi, automotors of cardiac contraction, or the neuromuscular cells scattered throughout the cardiac muscle and which, when irritated, may be the starting point of cardiac contractions which are extrasystolic in nature. If the toxin acts on the former of these elements an arrest will take place in the conduction of the excitations, the ventricles will have a tendency to take on their own rhythm and the result is a bradycardia.

Now, let us suppose that the infection produces very small isolated areas of myocarditis in the midst of the muscle; these can be the starting point of extrasystoles which, according to their frequency, will give rise to either arrhythmia or tachycardia. All of these accidents of influenzal cardiac processes can be explained, either by a massive action of the influenzal toxin on the heart or by a milder action acting upon more differentiated elements. This is merely an hypothesis. On the other hand, the symptoms common to all forms of influenza with cardiac manifestations, viz: hypotension, unstable pulse, asthenia, collapse, prostration and sudden death, represent the clinical picture of suprarenal insufficiency. In certain infectious diseases—diphtheria for example—myocardic syndromes are occasionally observed which may be due to an acute suprarenal insufficiency, and it seems rational to suppose that the toxin of influenza may act in the same way in this respect as that of diphtheria. The cases of basedowism observed in influenza would seem to support this view.

I believe that in this brief summary I have covered the subject of influenzal cardiac complications sufficiently to give the present views held on the subject in France and Switzerland and need merely add that the prognosis in all cases is serious.

Editorial Notes and Comments

NEW YORK MEDICAL JOURNAL

INCORPORATING THE

Philadelphia Medical Journal
and the Medical News

A Weekly Review of Medicine.

tation through the mail as second class matter.

NEW YORK, SATURDAY, NOVEMBER 27, 1920

ESTIMATING EMOTIONS.

The doorways of Man's existence have been thrown wide open. He is as neatly exposed as a child's doll's house with the front off. Doctors, surgeons, alienists, theologians, psychoanalysts, lawyers, philosophers, have crowded in and left no room unexamined, and no theory concerning it unwritten. They pursue the owner to his bedroom to steal and analyze his dreams, they describe his wilful waste in kinetics as he gets into his clothes, and his repressed emotion, finding an oathly outlet as he struggles with hyperstarched buttonholes. In vain he protests, they solemnly produce cards and file a list of his every possession with brain racking charts showing horrible probabilities because he has forgotten how to solve simple tests which his kindergarten progeny regard as a very small matter. In fact there is a report that British working men are attending evening schools so as to keep up to their children and not be shamed by them. An industrial commission set out recently to ascertain whether employees' thoughts were on their work while they were employed. About only two per cent. were. One woman said she was "thinking of nothing," a deceptive statement, because the commission declared this an impossibility and commissioners are always right! Now comes along Dr. Waller, director of the laboratory in the London University, who puts you in a chair, fixes up an electric apparatus which includes a pair of electrodes, a Wheatstone bridge and a galvanometer. Opposite the patient is a strip of linen bearing measurements. The in-

ventor asserts that it will throw a new light upon many important physiological and psychological problems, for a doctor can understand his patient's temperament with its help as the betraying beam of light traces its way accusingly across the record. The spoken word may be controlled and looks disguised, but few can control the sudden ceding of the mind to an emotion, not even a Scotsman or a Red Indian. Dr. Waller hopes in time to make the instrument record will power. At present he admits its limitations. Hatred or love may produce an equal wave of emotion, also the hearing of a crime or being accused of it; dread of pain or efforts to endure it.

What's done we partly may compute,
We know not what's resisted.

A doctor does not generally require any electric device to ascertain emotionalism, for those who come are usually somewhat unbalanced by disease and the flushed face, nervous fumbling with articles of attire, shifting of position and uncertain replies give him as much information as he requires. For ordinary use we do not need—indeed, had better not learn what our acquaintances are thinking. The profane sailor, who resolved to give up swearing at his mates, used to say: "God bless you; you know what I mean." It may be that the recording light beam would have been slightly modified even by the more temperate form of expression as it indicated a slightly disciplined emotion.

THE PROGRESS OF INDUSTRIAL MEDICINE.

Industrial medicine is making great headway and more so in America than in any other country. Most of the large industrial concerns here have their medical staffs, their hospitals, convalescent homes and so on. It has been found to be true economy and quite as much in the interest of employer as of employee, to keep the latter in good health and to afford him or her competent medical or surgical attendance when sick or injured.

While the practice of industrial medicine of the future will be more and more in the nature of prevention, there will still be plenty of scope for the practice of curative and healing medicine. In industrial businesses there will always be ample opportunities for the practice of the surgeon's art. The injuries and sickness brought about by industrial work more than rival similar disabilities produced by war. There is a machine shock resulting in neurasthenia and nervous breakdown as well as shell shock of war occasioning like affections. In fact, most of

the injuries and illnesses produced by war can be duplicated in industrial civil life. Recently, in Great Britain, a good deal of work was done in this direction. A medical research council and department of scientific and industrial research have been formed, the annual report of which has been issued recently. The investigations of this body are of great interest and have borne good fruit. The latest development of this kind, however, is contained in an appeal which St. Mary's Hospital Medical School, London, has issued asking the heads of industry to endow a Chair of Industrial Medicine. The holder's duty would be to visit heads of great industries throughout Great Britain and to find out from them what special diseases are leading to the loss of working hours. He would investigate the effect of fatigue on workers and their efficiency and also all trade diseases. Further, he would be responsible for the instruction of students in this branch of medicine. It is hoped in this way to provide a service of doctors thoroughly conversant with industrial health problems. It has been shown already what can be done in this field by the work of Dr. Lister Llewellyn on miners' nystagmus. The causation of a disorder which is costing Great Britain five million dollars a year, according to a recent estimate, has been discovered by this physician.

In the last years of the war a quarter of all casualties were gassed men; that is the number of men gassed in the British Army ran into six figures. For several months nearly ninety per cent. of these patients that came to the base were evacuated to England. It became obvious that if the war were to be won by the Allies that this loss must stop. The matter was grappled with in earnest, and a hospital at Boulogne was set aside to discover a means of checking the wastage. In a short time eighty-seven per cent. of all gassed men coming to the base marched half a mile in their equipment to convalescent depots within a month of their gassing, and the percentage evacuated to England from one hospital dwindled from nearly ninety per cent. to two per cent. Wastage of a similar nature occurs in the labor world. Every year sick workers lose wages amounting to millions of pounds, and they become a charge on the State for treatment and insurance amounting to millions more.

The object of the appeal of St. Mary's Hospital is to deal with this problem as the war hospital at Boulogne dealt with gas casualties. It is only necessary that first class men be afforded the facilities that exist in medical schools for investigating these problems. The trend of the practice of medicine is changing, and medical students of the present day must be so trained that they will be able to adapt themselves to the altered conditions.

PHYSICIAN-AUTHORS: DR. SILAS WEIR MITCHELL.

There are two ways of classifying Dr. Silas Weir Mitchell—the most celebrated Philadelphian since Benjamin Franklin—for he attained international distinction in two widely separated lines. It is purely a matter of choice whether you call him an eminent physician who was also a prominent author or a prominent author who was also an eminent physician. Mitchell was, in fact, a master mind in several distinct circles of intellectual activity. In literature he was not only a novelist of the first rank but also a poet of high distinction, and in medicine, although his specialty was neurology, he also was a recognized authority on toxicology (particularly snake poisons) and his researches on the reflexes of the lower limbs were the most comprehensive made in this country. On these and other medical subjects in which he conducted elaborate experiments and made exhaustive research, he wrote more than one hundred and fifty monographs, many of which are still the last word of authority in the medical profession. Medical work was distinctly Dr. Mitchell's chief life work, though one might be inclined to doubt it after a glance at the long list of volumes of poetry and fiction which bear his name. There are thirty-five of these and practically all were written in the last thirty-five years of his life, after he had turned the age of fifty. Few writers who begin at twenty are more fruitful.

Dr. Mitchell always gave first importance to his medical duties and never let literary work interfere with his practice and research. At a reception in his honor at the University Club in Philadelphia he once said that if he had to choose between literature and medicine he would abandon literature. "If I could be remembered for but one thing," he said, "I would rather it would be for the work I've been able to do for my fellowmen in the practice of medicine." Practically all of his writing was done during his summer vacation period. It was his custom in June to go to Canada for a month of salmon fishing and camping, after which he went to his summer home at Bar Harbor, Me., to devote himself to writing during the remainder of the summer. His contention was that the best rest is acquired by a change of work.

It was as the author of *Hugh Wynne, Free Quaker*—called by many critics the "best historical novel of the American Revolution ever written"—that Dr. Mitchell is best known. *Hugh Wynne* is a faithful picture of Philadelphia life during the War of Independence and many of the characters in it are historic personages. One of these is George Washington. The rise and fall of Benedict Arnold is a

tragic element in the story and the chapter on the death of Major Andre is a classic bit of writing. *Hugh Wynne* was the first of a series of novels from the pen of Mitchell dealing with various periods in American history. *In War Time* also dealt with the Revolutionary period and *The Red City* portrays life during the second administration of Washington as President, with Philadelphia as the background. *The Youth of Washington* was, of course, pre-Revolutionary, and is told in the form of an autobiography. *Roland Blake* and *Westways* are Civil War novels. Many of Dr. Mitchell's short stories had Revolutionary and Civil War settings. Throughout the latter conflict he served as an army surgeon and was in charge of the military hospital at Philadelphia.

Mitchell's other novels dealt mainly with contemporary American life, with the notable exception of *The Adventures of François*, a lively story of the French Revolution which paralleled *Hugh Wynne* in popularity. *François* is the only one of Dr. Mitchell's novels in a foreign setting, but several of his dramatic poems have backgrounds in other countries, or at sea. *The Cup of Youth* deals with Galileo, the astronomer and philosopher; *Philip Vernon* is a metrical tale of the Elizabethan period and *Francis Drake* recounts in verse an episode in the life of that well known seafaring man. All of Dr. Mitchell's novels, whether historical or not, were strongly psychological, and this applies to his poetry as well. He was particularly successful in the portraiture of women characters and through his writings can be noticed the strong influence which the medical profession exerted. To a greater or less extent nearly all his stories are pathological portraitures with plots based on episodes from his life as a practitioner. There are physicians as characters in practically all his novels and in *Dr. North and His Friends*, *The Autobiography of a Quack*, and others, physicians and their experiences and problems are the chief motifs. His first story—aside from a few juveniles written in the sixties—was *The Case of George Dedlow*, which appeared in the *Atlantic Monthly*, when that publication was under the editorship of Edward Everett Hale. It described a case in what he called the Stump Hospital of a man who had lost his legs and arms, and it undertook to diagnose the effect of this on the man's individuality. So realistically written was this fragment that the public supposed George Dedlow to be a genuine case, the newspapers took it up and subscriptions began to pour in.

But it was not the entertaining pathological information which made Dr. Mitchell's writings popular. His popularity was due to his imaginative virility,

his deep comprehension of human nature and human thought, his fascinating analyses of character and the fact that he always had a good story to tell and knew how to tell it. Although he never was a best seller (except in the cases of *Hugh Wynne* and *François*) his books still have a steady sale and more than a million copies have been sold.

Dr. Mitchell was born in Philadelphia on February 15, 1829, and died there on January 4, 1914, of influenza, after six days' illness, at the age of eighty-four. He derived his medical and literary gifts from his father, Dr. John Kearsley Mitchell, who was for several years a professor in Jefferson Medical College and was a poet of note. It was in Jefferson Medical College that the son obtained his medical degree in 1850. He also studied at the University of Pennsylvania. In 1887 he was president of the Association of American Physicians and in 1908-9 was president of the American Neurological Association. His eminence in science and letters was recognized by universities and societies all over the world which conferred degrees and honors upon him.

FREE ASSOCIATION AND ITS RIGHT TO USE.

The use of free association in psychoanalytical therapy meets with familiar forms of criticism. There are some who boast an intellectual modesty, which has, however, a stale odor of intellectual and moral laziness. To them any feature of the psychology of the unconscious seems too deep, too obscure. Others, with a more openly acknowledged superciliousness, consider the seemingly random memories brought into view by free association too trivial for serious technical attention. Would it aid in obtaining a truer valuation of the patient's free associations and of the method which deliberately makes use of them, if a psychological appraisal could be found for both classes outside of psychoanalysis? Perhaps such an estimate would also throw light where the employment of such apparent vagaries of memory seems too obscure a procedure. Bergson never laid claim to being a psychoanalyst. The matter of his *Mind-Energy* was written or spoken independently of the teachings of Freud. He has a fondness, nevertheless, for delving into psychic facts and a keen sense of the practical implication of psychic actualities in each moment of life.

Bergson has already made classic the statement that the function of the past, stored in memory, is to illumine the present moment, to direct and further the action in hand. The task of mental therapy is surely the freeing of memory to such service, memory that has been too long held back—repressed.

In order to release energy at such a point, energy painfully caught and held in the repressed matter, is it effective to turn upon the situation the logic of intellect? Is any patient ever reasoned out of an incessantly haunting obsession, compulsion, phobia?

Bergson suggests a different sort of light. He says that memories are recalled "in order that the circumstances which have preceded, accompanied, and followed the past situation, should throw some light on the present situation and indicate the way out of it." Bergson is talking of memories which flood upon a new perception but it is not amiss to apply his appreciation of the service of memories to such a particular point, the blocked up issue which has appeared like a new perception in a dream phenomenon or a stubbornly unchangeable one in a symptom.

This philosopher-psychologist at any rate finds room in theory and practice for a thinking process which reaches in two opposite directions, and counts each of equal dignity. Thought forms and follows a directed scheme but this is meaningless, yes impossible, unless there is "a descent of the scheme toward the image, and a moving of the mind among the images themselves."

A careful reading of Bergson's chapter on Intellectual Effort convinces the reader that to this thinker at least all intellection makes use continually of the method of free association. There is no word either of exclusion on the ground of triviality or any other quality. The only criterion of selection is serviceableness to the matter in hand.

LET THERE BE LIGHT.

We are ceasing to regard fresh air with suspicion. It is no longer regarded as poisonous after sunset or dangerous if encountered as a draught. We have even a Fresh Air Fund, out of door sleeping places, and now a big campaign is going on to get light. Not bursts of light as on the Fourth of July, not like illumined Broadways, not glaring ballrooms, but steady light for workers, without glare, without flickering.

Eyestrain means headache, and headache has a hundred little devils called minor ailments dancing in attendance. Strained eyesight means that the pretty eyes of our girls are hideously bespectacled; strained eyesight in youth means almost sightless old age and no occupation which accentuates the dreariness of the long days. So now there is cropping up in every city long titled municipal bodies which demand light, but graded light for employees. Light not only in the rooms but on staircases, in basement passages, on fire-escapes. Some of us can recall the revolting odor of a work room, gas illumined, and used all

day, the single gas jets on dark staircases, and now we see the harsh glare of unshaded electric light. These things cannot be trusted for rectification to the uncertain humanity of employers. Wise municipal law spells industrial efficiency, industrial efficiency would mean a good strikebreaker, because it would mean efficient brains. New York, New Jersey, Pennsylvania, California, Oregon and Ohio have excellent codes based on a tentative code drawn up by the Committee of the Illuminating Engineering Society, afterward adopted by the Committee of National Defence. There will be a sensible diminution of young patients at our eye clinics if all the good these codes hold out is brought to bear on the tired-eyed, painted, powdered, high shouldered, narrow chested girls who trip mincingly along in tight skirts after work to halls and movies to further strain their pretty eyes.

A MEDICAL LUNCH.

The English are becoming as clever in their ways of getting money as their American cousins. Who could refuse an invitation to a lunch given by one hundred clever women to one hundred clever men? The object was to get money for the Royal Free Hospital School of Medicine, where, sixty years ago, Elizabeth Garrett achieved distinction as the first Englishwoman to take a medical degree. There are now five hundred women students in the school. The air must have been rather too exhilarating, with the powers of two hundred clever men and women let loose. Fortunately, there were no discussions or the roof might have been blown off. Sir Alan Garrett Anderson, M. D., said that the best places of the profession were reserved for the consulting staffs of the great teaching hospitals, and the Royal Free was the only general hospital in the kingdom to admit women to the desired top platform. Princess Louise was the guest of honor, and had at her table women doctors of Harley Street fame. The home secretary was one clever man. Some others were Sir Eric Geddes, M. D., Sir George Newman, M. D., and Sir Owen Seaman, of *Punch*.

THE EYEBROW.

There is hardly a feature today which is not subjected to strict examination by the ubiquitous psychologist. An Italian doctor has been making a study of the eyebrow, and he has found that in dementia præcox there are nearly always short, bushy hairs nearly meeting in the space between the eyebrows and a noticeable thinning toward the external side. In epileptic women the eyebrow is made up of two portions, the inside is in the form of a comma, of which the tail enters in the two branches of the external portion in the form of a Y. In epileptic men one often sees large tufted, heavily haired eyebrows, united at the median line. In maniac depressive cases the absence of the outer third of the eyebrow is common.

News Items.

A Police Hospital in Tokio.—A hospital is to be erected in Tokio, at a cost of \$300,000, for the benefit of the city's 8,000 policemen and their families.

State Consultation Clinics for Tuberculosis.—The State Department of Health of Massachusetts has established a series of consultation clinics for early pulmonary tuberculosis.

Jewish Hospital Clinical Society of Philadelphia.—Dr. Myer Solis-Cohen has been elected president of this society to serve for the ensuing year. Dr. Irwin S. Meyerhoff was elected vice-president, and Dr. Joseph P. Besser, secretary and treasurer.

Woman's Hospital Society Gives Dinner to Dr. McGinnis.—The Woman's Hospital Society, of New York, gave a dinner to Dr. E. L'H. McGinnis on Tuesday evening, November 16th, in recognition of the work done by him during his many years' service at the Woman's Hospital.

Antituberculosis Crusade in Japan.—According to press dispatches from Tokio, Japan has inaugurated a widespread crusade against tuberculosis and a general campaign for public sanitation. Important social legislation has recently been enacted and national and municipal authorities are cooperating to enforce the new laws.

Dr. Baruch Honored.—A dinner was given in New York on Sunday evening, November 21st, in honor of Dr. Emanuel de Marnay Baruch, organizer of relief work for Germany and Austria. Two thousand persons attended the dinner, among them being Dr. Royal S. Copeland, commissioner of health of the city of New York, and other city officials.

Chicago Physicians Receive Honorary Degrees.—Dr. Ludvig Hektoen, of Chicago, had conferred upon him the honorary degree of Doctor of Laws at the centennial celebration of the Medical College of the University of Cincinnati. The honorary degree of Doctor of Science was conferred upon Dr. Dean Lewis and Dr. Edward O. Jordan at the same time.

Hookworm Infection in Australia.—Reports to the United States Public Health Service, dated August 24, 1920, state that a vigorous campaign against hookworm disease is in progress in Australia. In one district in the northeastern section of Queensland, out of 1,433 natives examined 216 were found infected, and in another district in the same section out of 1,592 natives examined 182 were found infected.

International Public Health Journal.—The first number of the new *International Public Health Journal* has just been issued by the Department of Medical Information, General Medical Department of the League of Red Cross Societies at Geneva, Switzerland. The journal will be devoted to all phases of public health work and preventive medicine and will be published every two months in four languages, French, English, Italian, and Spanish. Dr. Thomas R. Brown, of Baltimore, is editor, and Dr. William F. Francis, of Montreal, is associate editor.

Married.—Dr. Arthur Lewis Root, of New York, to Miss Edith Dow Merrill, in New York, on Wednesday, November 17th.

Dr. Harold F. Cleveland, of Holyoke, Mass., to Miss Regina B. Madden, at Brockton, Mass., on Sunday, November 14th.

Medal of Honor Awards.—Among the thirteen men in the Navy and Marine Corps who were awarded the Medal of Honor are the following: Lieutenant J. Boone, Medical Corps, United States Navy; A. G. Lyle, dental surgeon, Medical Department of the Navy; Lieutenant Orlando H. Petty, Medical Corps, R. F.

Lectures by Dr. Kenyon.—The Federation for Child Study announces three lectures by Dr. Josephine Hemenway Kenyon on The New Ideal of Health, Wednesday afternoons, at 2 West Sixty-fourth Street, as follows: December 1st, Influence Before Birth; December 8th, The Vital First Three Years; December 15th, The Neglected Preschool Period.

A Merger of Psychological Journals.—Announcement is made that, commencing with the January, 1921, issue, the two journals, *Psychobiology*, and *Journal of Animal Behavior*, will be merged under the new name of the *Journal of Comparative Psychology*. The new journal will be edited by Knight Dunlap and Robert M. Yerkes and will be published by the Williams & Wilkins Company, Baltimore.

Spanish Physicians Appeal to Government to Bar Foreign Competitors.—Press dispatches from Madrid state that the physicians and surgeons of Spain are greatly perturbed over the recent invasion of their country by foreign practitioners, more especially Austrians, who have been unable to find sufficient means for subsistence in their own country. In consequence, it was decided to appeal to the Government to make regulations under which foreign practitioners would have to acquire a medical degree in Spain before being allowed to practice.

St. Louis University Centennial Endowment Fund.—St. Louis University has asked its alumni and friends to raise the sum of \$3,000,000 as a Centennial Endowment Fund, in commemoration of the one hundredth anniversary of the founding of the institution. The anniversary occurred in 1918, but because of war conditions existing at that time, with over three thousand of the undergraduates and alumni of the University having answered the call to arms, the celebration was postponed until conditions were more nearly normal.

St. Louis University holds the distinction of having established in the great Louisiana Purchase tract the first colleges of medicine, dentistry, law, and commerce. Of the \$3,000,000 asked, the income on \$1,500,000 is for salaries of the teaching staffs of the colleges of medicine and dentistry; the cost of a new laboratory for the school of medicine is estimated at \$250,000; new buildings and clinics for the schools of medicine and dentistry will cost an additional \$550,000. The remainder of the \$3,000,000 will be applied to the needs of the Institute of Law, School of Commerce and Finance, and the College of Arts and Sciences.

New York Neurological Society.—At the next meeting of the New York Neurological Society, to be held Tuesday evening, December 7th, under the presidency of Dr. Walter Timme, the work of the Memorial Hospital on the radium treatment of tumors of nerve tissue will be presented, with lantern slide demonstration, as follows: Dr. Halsey J. Bagg, Experimental Study of the Effects of Radium on the Brains of Animals; Dr. James Ewing, the Structure of Nerve Tissue Tumors with Reference to Radium Therapy; Dr. Douglas Quick, Clinical Results of Treatment of Nerve Tissue Tumors by Radium. Dr. Walter M. Kraus will present two cases of Friedreich's Ataxia, and Dr. Charles Rosenheck will read a paper on Juvenile Tabes.

Associate in Clinical Psychiatry and Psychotherapy.—The United States Civil Service Commission announces an examination for associate in clinical psychiatry and psychotherapy, to fill a vacancy at St. Elizabeth's Hospital, Washington, D. C., at \$2,500 a year and maintenance. The duties of the appointee will be to act as consultant to the different medical services of the hospital, with the particular end in view of assisting in analyzing and understanding their patients. He will specifically undertake analytical and therapeutic measures in special functional cases that it would appear possible to benefit in this way. In addition to this work the appointee will be expected to avail himself of the clinical material and laboratory opportunities for special observation and research. It is desired to secure the services of a person familiar with the modern therapeutic movements in the practice of mental medicine. The appointee must not only be familiar with these movements, but he must be capable of an analytical and interpretative application of psychological principles to the individual case.

Personal.—Dr. W. A. Bridges, for the past year acting medical director of the Maryland Tuberculosis Association, has resigned to become superintendent of the Eudowood Sanatorium, Baltimore.

Dr. Walter Dill Scott, professor of psychology in Northwestern University, has been elected president of the university.

Dr. Alfred L. Gray, of Richmond, has been elected president of the Medical Society of Virginia, succeeding Dr. Fletcher J. Wright, of Petersburg.

Dr. Rudolph Matas, of New Orleans, has been elected vice-president of the American Medical Association to fill the vacancy caused by the death of Dr. Isadore Dyer.

Dr. Frederick W. Johnson, of Boston, has been appointed professor of clinical gynecology at Tufts Medical College, and Dr. Louis E. Phaneuf, of Boston, associate professor of gynecology.

Dr. William C. Braisted, surgeon general of the United States Navy, and Dr. Robert E. Le Conte, of Philadelphia, have been awarded the Navy Distinguished Service Medal for meritorious service during the war.

Dr. Lewis W. Fetzer has resigned as professor of physiology and pharmacology at the Baylor University College of Medicine and will take charge of the laboratories of the St. Paul Sanatorium at Dallas, Texas.

Women Physicians in the Orient.—The Woman's Foreign Missionary Society of the Methodist Church has just commissioned four women physicians and eleven women nurses for work in their hospitals in the Orient. The twenty hospitals under their care were depleted by the call for medical workers during the war and seven of them had to be closed, but these are now to be reopened. Among the physicians whom the society is sending is a young Chinese woman who has been studying medicine in this country for the past eleven years. She is to be at the head of one of the mission hospitals in her own country.

Meetings of Local Medical Societies.—The following medical societies will meet in New York during the coming week:

WEDNESDAY, *December 1st.*—New York Academy of Medicine (Section in Historical Medicine); Bronx Medical Association; Harlem Medical Association; Psychiatric Society of New York; New York Urological Society; Society of Alumni of Bellevue Hospital; Brooklyn Society for Neurology (annual).

THURSDAY, *December 2nd.*—New York Academy of Medicine (stated meeting); Brooklyn Surgical Society.

FRIDAY, *December 3rd.*—New York Academy of Medicine (Section in Surgery); New York Microscopical Society; Practitioners' Society of New York; Society for Serology and Hematology; Alumni Association of Roosevelt Hospital; Gynecological Society of Brooklyn.

SATURDAY, *December 4th.*—Benjamin Rush Medical Society.

A Medical Unit for Overseas.—Announcement is made by the Joint Distribution Committee of the American Funds for Jewish War Sufferers that a medical unit will be sent overseas next month to fight disease in Eastern Europe.

Dr. Harry Plotz, of Mount Sinai Hospital, medical adviser of the committee, has asked for \$2,000,000 to cover the first year's work and to provide for payment of the medical personnel, the purchase of medical supplies, the construction of bath houses, etc. Medical and hospital supplies will be distributed in connection with an educational health campaign. Dr. Plotz will be in charge of the work and will head the unit, which is to be made up of physicians with military experience. Applications for volunteers for the unit will be received by Dr. Plotz.

Died.

CHASE.—In Brooklyn, N. Y., on Monday, November 16th, Dr. Walter B. Chase, aged seventy-eight years.

DEVOR.—In Chambersburg, Pa., on Monday, November 15th, Dr. John H. Devor, aged sixty-three years.

DE LIGUORI.—In Waterbury, Conn., on Tuesday, November 2nd, Dr. John de Liguori, aged seventy-four years.

GERE.—In New York City, on Friday, November 19th, Dr. James Belden Gere, aged forty-eight years.

HAYES.—In New Bedford, Mass., on Tuesday, November 2nd, Dr. Stephen W. Hayes, aged seventy-two years.

JAMES.—In Lexington, Ky., on Monday, November 15th, Dr. Robert C. James, aged fifty-five years.

MURRAY.—In New York City, on Friday, November 12th, Dr. Elizabeth C. Murray, formerly of Cleveland, Ohio, aged sixty-five years.

SALTER.—In Buffalo, N. Y., on Friday, November 12th, Dr. Albert E. Salter, aged seventy-three years.

WHITE.—In Florence, Miss., on Saturday, November 13th, Dr. E. K. White, aged sixty-three years.

Book Reviews

NEW X RAY MANUALS.

Röntgen Interpretation. A Manual for Students and Practitioners. By GEORGE W. HOLMES, M. D., Röntgenologist to the Massachusetts General Hospital and Instructor in Röntgenology, Harvard Medical School, and HOWARD E. RUGGLES, M. D., Röntgenologist to the University of California Hospital, and Clinical Professor of Röntgenology, University of California Medical School. Illustrated. Philadelphia and New York: Lea & Febiger, 1919. Pp. xviii-211.

X Ray Observations for Foreign Bodies and Their Localization. By Captain HAROLD C. GAGE, A. R. C., O. I. P., Consulting Radiographer to the American Red Cross Hospital of Paris; Radiographer in Charge, Military Hospital V. R. 76, Ris Orangis, and Complementary Hospitals. Illustrated. St. Louis: C. V. Mosby Company, 1920. Pp. i-83.

Radiography in the Examination of the Liver, Gallbladder, and Bile Ducts. By ROBERT KNOX, M. D., Hon. Radiographer, King's College Hospital, London, England. A Series of Articles Reprinted from *Archives of Radiology and Electrotherapy*, July, August, September, and October, 1919. Illustrated. St. Louis: C. V. Mosby Company, 1920. Pp. i-64.

The x ray has invaded so many fields and engaged so many specialists in the task of perfecting technic and of working out new interpretations, that no general textbook covering the entire subject is available. For this reason the various manuals and monographs, of which the following are excellent examples, are of particular service:

An extensive territory is covered in Dr. Holmes's small volume *Röntgen Interpretation*. First the reader is cautioned against the errors he is likely to encounter, such as confusing shadows and artefacts. These have frequently led to faulty diagnosis in the past and will no doubt continue to do so in the future, but if the operator is on guard the possibility of error may be reduced to a minimum. Then some of the anatomical variations are presented. These, too, have led to error. Diagnoses of fracture have been made when the condition was merely one of delayed union of symphysis and diaphysis. We are then presented with a résumé of the most common usages of the x ray, fractures and dislocations in various parts of the body, the pathology of bone lesions and disorders, then the more common uses of the x ray on the skull. The chapter dealing with the joints is especially good, the illustrations being extremely clear. This is followed by chapters on the chest, the gastrointestinal tract, and the genitourinary tract.

The work is not complete and some of the illustrations, such as those illustrating pathological changes at the roots of teeth, are not satisfactory, but on the whole it is a most useful little guide book for the practitioner, showing him the many uses to which the x ray may be put as an aid in diagnosis.

* * *

Mr. Gage was associated, for the greater part of the war, with Dr. Joseph Blake. He devised many useful methods for the localization of foreign bodies and these are described rather concisely in his small manual. No more painstaking worker could be found and his constant aim was to devise methods that were as simple and practicable as possible. He did away with many of the cumbersome meth-

ods that on account of their complexity gave the impression of great precision and substituted devices which were far simpler and at the same time no less exact. He was aided in his work by following the patients into the operating room after the foreign bodies had been localized and seeing his methods put to practical application. He presents a minimum of theory with a maximum amount of utility.

* * *

This compend by Knox consists of a series of articles reprinted from the *Archives of Radiology and Electrotherapy*, and are worthy of being brought out in book form. The illustrations are the most valuable part of the book. They help clarify many of the hazy points in the none too simple problem of x ray examination of the gallbladder region. Among the photographs are several stereopticon views, which may be removed from the book and examined through a stereoscope, giving the exact relationships of the technic described. Surgeons are prone to place little reliability on radiographic findings in the gallbladder region. Perhaps this presentation will establish confidence in the method.

PHYSIOLOGY AND BIOCHEMISTRY.

Physiology and Biochemistry in Modern Medicine. By J. J. R. MACLEOD, M. B., Professor of Physiology in the University of Toronto; Formerly Professor of Physiology in the Western Reserve University, Cleveland, Assisted by ROY G. PEARCE, A. C. REDFIELD, N. B. TAYLOR, and Others. Third Edition, with Two Hundred and Forty-three Illustrations, Including Nine Plates in Color. St. Louis: C. V. Mosby Company, 1920. Pp. xxxii-992.

Most important changes have been made in the section on the nervous system in this, the third, edition of Macleod's book. This work was done by A. C. Redfield and he has succeeded in presenting the subject in a manner best calculated for practical application in a therapeutic sense. Fortunately, the striving shown here is constantly toward the clinical usages to which the researches of both laboratory workers and clinicians may be put.

Other subjects which have called for changes in the text due to the progress made in their respective fields are the chapters on vitamins, surgical shock, and capillary circulation. While the endocrines have come in for their share in the revision it seems as though, in a book of this character, more could have been said without going beyond the borders of safety. For example, little is said about the pineal or thymus. Perhaps the authors have not dared to venture in this little explored field in a work of this kind, yet a beginning should be made, and it might be well to present what is known of the more obscure subjects rather than rehash and elaborate some of the physiological phenomena merely because there is less divergence of opinion regarding a special subject. The parts dealing with the chemistry of respiration are entirely revised, yet it seems as though some of the work done on the endocrine glands, especially on the adrenals, could have been incorporated into this phase of physiology.

RELIGION AND HEALTH.

Religion and Health. By JAMES J. WALSH, M. D., Ph. D., Sc. D., etc., Medical Director of Fordham University School of Sociology; Professor of Physiological Psychology, Cathedral College Lecturer on Psychology and Sociology, Marywood College, Scranton, Pa., Mt. St. Mary's, Plainfield, N. J. Boston: Little, Brown & Co., 1920. Pp. 341.

A cheery young lieutenant who spent his leave during the war with a sad relative, said, "I suppose it's being religious makes aunt so beastly miserable." He was only voicing a thought which comes to many who are chilled and puzzled by the behavior of the religious. A young man who was accidentally locked up in a refrigerating room, when asked how he felt, said, "Just as I did when I went to a social tea at a church." Such discourteous youngsters would do well to listen to Dr. Walsh, as he gives an absolutely fair hearing to the assertions of religion and health. What one man has done, man can do. Disease, plus religion, can see a man mentally and morally triumphant. Disease, lacking religion, sees the pitiable sight of a slow deterioration in body and also in soul.

That which should have been Chapter One has wandered away to the end of the book. This treats of a morbid condition in which ill health is mistaken for spiritual declension and gloom settles down because a person is too lazy to take a walk or a blue pill. To the question at the beginning of the book, Can we still believe? Dr. Walsh brings a long array of eminent scientists to prove that the divorce between science and religion is three quarters imagination. The calming effects of prayer in disease and health are more powerful than is realized. An old French invocation to prayer begins: "Come, let us gather ourselves together," which exactly expresses that calm concentration of thought likely to make the practice beneficial. Fasting and abstinence, holidays and holydays are shown to have sound medical backing for their reasonable usage, though the author believes in a more extensive abstinence from excessive rest, regarding it as a mischievous source of selfishness and laziness. The old eight hour plan is his.

We sin always when we think too much
Of what we think and are. Albeit our thoughts
Be verily as bitter as self-sacrifice.
If we sleep on rocks or roses, sleeping past the hour
of noon
We're lazy.

A sharp distinction is drawn between recreation and dissipation, and he deplors those who have no mental recreation, but must seek it all outside in shows and vaudeville and dances. The pleasures of sense, unbridled by religion, are never held fully in check by mere commonsense motives. He deprecates the modern idea of sex teaching in schools and public places. Young folk have not been terrified by the knowledge of the hideous possible consequences of impurity. The temptation comes with hurtling force against those who have not been grounded in faith. You cannot neutralize sex temptations by the provision of knowledge alone.

The increase in suicide is traced to the decrease of attention to religion and the absence of religious training in youth. The suicides have no courage to

face the small trials which lead to it. Lessening of the reverence for human life and a lessening of the awfulness of murder have also increased homicide.

The author quotes from his own experience with patients to show how true religion may dominate pain and continuous suffering. Of cancer alone scarcely less than a hundred thousand persons will die of it during the next twelve months in this country alone; over a million and a half throughout the world. Where no religion is this must only mean just so much pain to be borne without any good reason as far as they can see. He gives so many instances of work heroically done in spite of suffering that it almost seems as if those enduring it were called to "active service" instead of ingloriously abiding in barracks.

The book will deter many from suffering the will of God, when, in reality, they are yielding to their own inclination in not resisting disease. Fewer persons will put "Thy Will Be Done" on tombstones, because they will realize, after listening to Dr. Walsh, that the Lord prefers living, healthy persons to diers, and, having realized, will brace themselves to eradicate all that is unseemly in their religion and health.

THE LIGHT HEART.

The Light Heart. By MAURICE HEWLETT. New York: Henry Holt & Co., 1920. Pp. xii-188.

Maurice Hewlett knows how to write of men and things as they are. He gives flashing pictures from human life and its settings, or better still he has the grace that lets such pictures speak for themselves. There were men of old times whose lives as they moved and spoke were much like the abrupt setting in which they lived. Hewlett has searched their records, the tales of Iceland and the forbidding country about it. He reads, as no one who comes close to their literature can fail to do, the direct honesty, clearcut action, and the play of heart gripping love or the impairing subtlety of treachery which passed over their lives. Though "the starkness of their Sagas shocks" this writer of modern times he is skillful in his sympathy in portraying the high relief and the softer shadows of these people. They are far away in time as they are remote through their difference in climate and the forbidding circumstances which this brings with it. No time or space separates them from us in elements of character, in the varying interplay of the elements which distinguishes each individual so clearly in these northern tales. There is here in *The Light Heart* a man who is a friend of man, devoted to an ideal attachment even unto death. Thormod carries a light heart toward the necessities of everyday toil or everyday responsibilities. "He had the poet's way of thinking rather than of doing, that knack of working out the ways of a deed so fully in the mind that when the time comes to do it, it seems already done, and done with: wherefore you simply leave it undone." He was equally indecisive in his affairs with women, and, therefore, took such affairs lightly and left them off without further concern, or only that of the feeblest. He could turn and look back upon himself in a similar impersonal fashion.

His devotion to his friend, Thorgar, had something of the same objectivity. He felt that he loved him for what he saw him to be and dared not risk surprising him lest he should find him sometime something different. But there was a steadfastness, a seriousness, in his love for this friend, and then for the hero that follows that means his life for them. There are these two tales of the power of one man's love which Hewlett has woven into one continued story. Thorgar is slain and Thormod, half heathen as he was in the dawn of a Christian Iceland, consecrates himself to a sweeping vengeance in the spirit of the sworn friendship they had compacted. This done, carried out with cold deliberateness and unstaying violence in the narrow settlements of Greenland, Thormod returns to a newly found friend, King Olaf. At their first meeting at King Olaf's court, in the slaughter of the king's losing battle, Thormod's love is swift, intuitively sensitive, straight to its mark. It renders simple uncringing homage, and in the end can be satisfied only to be with the king also in death.

The book has not such inspiriting force as some of Hewlett's earlier reproductions of Icelandic literature. But neither has Thormod the vigor of character which marks the Icelandic's restraint and ferocious unrestraint. There is a roundabout elaborateness in the execution of Thormod's deeds, and in the general light aloofness of his character. A light heart, yet a widely human one, and it centres itself on the type of love which is his. Hewlett found Thormod the man, not Thormod's deeds, the theme of the two tales woven here. Through him modern literature is enriched by one more representative human soul.

THE AMERICAN RED CROSS IN ITALY.

The Story of the American Red Cross in Italy. By CHARLES M. BAKEWELL. New York: The Macmillan Company, 1920. Pp. viii-253.

The Armistice had been signed. The tricolor had been planted on the Brenner in the north and the Julian Alps in the east. All Italian lands had been redeemed, but new burdens had to be carried, for the prosperous little towns along the Piave were heaps of ruins. Along the Brenta, up through the Val Sugana and the Val Lagurina, desolation, desolation. Army banners were furled, the fight was not now against alien foes, but against starvation, despair, disease, and thousands of ill clad, hungry released prisoners.

The one unfurled banner bore an emblem of defeat. "The Kingliest Kings are crowned with thorns," the royal arms had been stretched on a cross, yet, for four long years they had valiantly headed a fight unarmed, but victoriously, against slaughter and hellish pain, rapine and desolation.

The story of the American Red Cross, read when the Armistice is two years old, read in the relative quiet of a restless peace thrills with its brimming cup of misery its triumph when tears of blood marred strong men's faces, when hatred and despair were just able to nerve shaking hands for one more effort.

When the first call came for help, the American Relief Clearing House had emptied its warehouse

and treasury. It turned its offices over to the Emergency Commission, and the Clearing House became the agent of the Red Cross in the Roman district, being given at once 100,000 lire for purchase of supplies for refugees. One afternoon news was received that 12,000 refugees would pass through the Portonaccio Station, the first train arriving at six. Within an hour the Red Cross had the baggage car on the northbound Florence express loaded with supplies, and it arrived before the first refugee train. The Permanent Commission of the Red Cross, under Colonel Perkins, arrived in Rome in December, 1917.

There were only thirty-two workers at first; at the end of the war it numbered 949 not including the enrollment of Italians, approximately one thousand more.

The book is not written in praise of America. It is a modest record penned for those interested, but it is wonderfully lucid, keeping a clear track right through the war, never wearying with statistics and accounts, but giving stern facts and glances humorous and tender, of helpers and helped. One little piece of postwar work was the returning to America (according to promise) of Italian American citizens who went over to serve. In November, 1919, nearly four thousand, mostly with families, were gathered in Naples, waiting to embark. The Red Cross came forward with funds to provide extra clerks for checking the passports and relieving the wants of those necessarily detained in Naples.

The Red Cross Army of every nation sets out this year on a peace time campaign against the Devil and all his works, and the Devil is a fine military tactician. Perhaps the words of a young Italian learning English may aptly close this brief review: "Hurry for Uncle Sam: Hurry for Wilson: Hurry for Italy and our King."

New Publications Received.

[We publish full lists of books received, but we acknowledge no obligation to review them all. Nevertheless, so far as space permits, we review those in which we think our readers are likely to be interested.]

THE DARK MOTHER. By WALDO FRANK. New York: Bonj & Liveright, 1920. Pp. 376.

MAN'S UNCONSCIOUS PASSION. By WILFRED LAY, Ph. D. New York: Dodd, Mead & Co., 1920. Pp. 246.

THE CRESCENT MOON. By F. BRETT YOUNG. New York: E. P. Dutton & Co., Third Edition, 1920. Pp. 284.

THE HOUSE OF LYNCH. By LEONARD MERRICK. With an Introduction by G. K. CHESTERTON. New York: E. P. Dutton & Co. 1924.

RESURRECTION. By LEO TOLSTOY. Translated by ARCHIBALD J. WOLFE. In Two Volumes. New York: International Book-Publishing Company, 1920. Pp. vol. i, ix-337; vol. ii, 398.

TASCHENBUCH DER KNOCHEN-UND GELENKTUBERKULOSE (Chirurgische Tuberkulose) mit einem Anhang: Die Tuberkulose des Ohres, des Auges und der Haut. Ein Leitfaden für den praktischen Arzt. Von Dr. H. SCHWERMANN, Facharzt für Tuberkulose, Oberarzt am Sanatorium Schwarzwaldheim Schömberg-Neuenbürg. Mit 10 Abbildungen im Text. Leipzig: Verlag von Curt Kabitzsch, 1920. Seiten 150.

Practical Therapeutics and Preventive Medicine

A Compendium of Treatment and Prophylaxis, Original and Adapted

Intravenous Hydrogen Peroxide in Influenzal Pneumonia.—T. H. Oliver and D. V. Murphy (*Lancet*, February 21, 1920) report an exceedingly severe epidemic of influenza among the Indian troops in Busrah where the mortality in the toxic bronchopneumonia cases was eighty per cent. So hopeless were all of the accepted methods of treatment that they felt justified in trying intravenous hydrogen peroxide to combat in a measure the anoxemia and theoretically to attack the toxemia by means of the nascent oxygen liberated. Two ounces of ozone in eight ounces of water were injected into the veins during the course of fifteen minutes, with stops of half a minute in every four. The danger of gas embolism was appreciated, hence the long duration of the infusion. Also the infusion was watched very closely at the cannula and when a large bubble was seen the rate of infusion was greatly reduced. The method was used on twenty-five patients, all of whom were *in extremis*. Thirteen recovered and twelve died. Of these twelve, nine showed no visible change either for the better or the worse, while three improved temporarily. One patient only died within five hours of the infusion, in a rigor. Of the thirteen recoveries, ten patients were delirious at the time of the infusion and three were comatose. In these patients the average respiration before was 46, and twenty-four hours after infusion it was 31.5. The average pulse was 118 before and 98 twenty-four hours later. The average temperature was from 101-103 and in all save one instance the injection was followed by a rigor, after which—except in two cases—the temperature fell to normal. The afebrile period lasted eighteen to thirty-six hours when the temperature rose to 99-101 and fell by lysis in four to seven days.

Certain Points in the Diagnosis and Treatment of Pulmonary Tuberculosis.—Lawrason Brown (*American Journal of the Medical Sciences*, September, 1920) asserts that not every patient in whom a diagnosis of pulmonary tuberculosis can be made needs vigorous treatment. It was an attempt to discover a simple method that any practitioner could use in his office that led to the study of active and inactive cases, but no simple method was found. He believes that in considering the need for treatment, symptoms vastly outweigh physical findings in the majority of cases. Tubercle bacilli can occur in a perfectly quiescent case, where it is only necessary for the patient to lead a quiet life, but when the bacilli are found in a patient who has recently begun to show symptoms, vigorous treatment is demanded. Râles can persist for years in arrested cases. The x ray helps greatly in revealing changes that occur from time to time, but an increase of x ray shadows may occur months before the last plate has been taken, and at that time the disease may have been arrested. Any patient with unexplained pleurisy with effusion needs treatment for pulmonary tuberculosis, unless a parenchymat-

ous lesion in the lungs can be definitely excluded, and even then he inclines to the side of caution, for a slight deposit may be lost in the cloudiness that obscures that part of the plate. An inexplicable hemoptysis should be similarly treated. Suspected pulmonary tuberculosis he treats by rapidly increasing the patient's exercise to the unlimited stage, and after about three months, if all has gone well, return him to his work. Dr. Brown believes that after a careful study the patient can be taken into confidence and told the possibilities frankly.

Glucose as an Adjunct Measure in the Treatment of Pneumonia.—Henry J. John (*American Journal of the Medical Sciences*, October, 1920) comes to the following conclusions: 1. The administration of glucose is without danger provided any reasonable care is used. In the twelve hundred administrations not a single accident occurred. The patient is made comfortable and sleep is provided for him. Through this the whole organism is strengthened for the prolonged fight against the infection. 3. The temperature is lowered. 4. Nutrition is provided for the overtaxed heart muscle without having to go through the ordinary digestive processes, storage in the liver as glycogen and reconversion into glucose again before it can be burned by the tissues. One hundred to three hundred calories are thus supplied to the body in each dose. 5. A considerable amount of fluid is provided for the circulation. This, together with the preceding, slows the heart, thus producing artificial rest. 6. The elimination through kidneys and skin is increased. 7. Practically all the medication can be supplied in the glucose, thus a much more accurate dosage can be depended on. 8. The antipneumococcic serum type I or the anti-streptococcic serum, the antitetanic serum, can be administered in this glucose medium. This is far superior to saline, for glucose will do much more than saline, thus being a much more rational medium to use as a diluent for any intravenous medication. 9. The use of glucose is strictly a physiological measure and is to be used as such.

Therapeutic Tracheal Fistula in Laryngeal Tuberculosis.—G. Rosenthal (*Paris médical*, April 17, 1920), in cases in which the initial examination of the larynx already reveals large ulcerations, loss of epiglottic tissue, and grape seed points of edema on the arytenoids, already threatening closure of the larynx, performs tracheotomy in order to rest the larynx. Injection of oil containing gomenol and guaiacol or iodoform three times daily through the cannula is at once instituted. Large amounts are given, either with the syringe—twenty mils— or by the author's "drop" procedure—twenty to fifty mils. Two or three syringefuls of a one in 200 solution of French novocaine are introduced beforehand to anesthetize the parts. As soon as rest has led to some regression of the laryngeal lesions, the necessary surgical measures are carried

out by direct laryngoscopy to destroy completely the local tuberculous process. The ordinary cannula is then replaced by the author's cannula for therapeutic tracheal fistula, which is shaped like the adult's cannula but has the calibre of that used for tracheotomy in a child. The oily injections are continued through this small cannula, and also through the third one, subsequently used, which measures only three millimetres in external diameter. Later, if improvement continues, a two millimetre cannula is substituted, and the injections are given by the natural route, i. e., by way of the mouth. In cases not so advanced as to demand ordinary tracheotomy, though too far advanced for the ultraviolet rays and chemical or galvanic cauterization, a small tracheal fistula cannula is first inserted, and larger cannulas later inserted if necessary, before resorting to the actual, mutilating tracheotomy. The needle used to prepare the way for the small cannula is curved and measures six to seven tenths of a millimetre in diameter. It is introduced through the cricothyroid space, but fails to injure the posterior tracheal wall, as do the straight needles rather recently recommended. The two or three millimetre cannula, coupled with the pulmonary "drop" instillations, may suffice to arrest the expectoration. Later, if required, the larger tube may be used, though without causing closure of the upper respiratory route. By this general method the need for ordinary tracheotomy is restricted to the most severe cases.

Action of Rare Earth Salts of the Cerium Group in Experimental Tuberculosis.—Albert Frouin (*Bulletin de l'Académie de médecine*, June 15, 1920) injected sulphates of lanthanum, neodymium, praseodymium, and samarium intraperitoneally in fifty animals, beginning seven days after inoculation with tubercle bacilli and repeated twice weekly and later once weekly. In guineapigs 0.2 mil of a one per cent. solution of the salts was the amount injected. These animals lived an average of sixty-three days longer than the ten controls not receiving salt injections. In a second series of thirty guineapigs those receiving the salts lived an average of forty-five days longer than the ten controls. Rabbits were inoculated in the marginal ear vein with a suspension of bovine bacilli, and six hours later ten of them were given 0.5 mil of the one per cent. solution of salts intravenously; 0.25 mil was administered twice weekly thereafter. Three rabbits died before the two controls, but the other seven lived three to five months longer than the controls. In many of the guineapigs there was found in addition to extensive tuberculous lesions, an adhesive peritonitis uniting all the abdominal viscera and the abdominal wall with sheets of connective tissue. The omentum appeared as a fibrous cord. In other animals, with less extensive adhesions, a more or less pronounced fibrosis of the lymphnodes, omentum, and the liver was observed. This connective tissue reaction is looked upon as a defensive process similar to that met with in old, latent tuberculous foci which are being recovered from. A connective tissue in the lungs was similarly met with in rabbits that had lived four or more months after tubercle inoculation in the blood stream.

Heat Hyperpyrexia.—W. H. Willcox (*Lancet*, March 20, 1920) discusses his observations on this condition as it existed among the troops in Mesopotamia. Regarding etiology, the chief factors were a temperature of over 110° F. in the shade, lasting over several days with a stagnation of the air. No age is peculiarly susceptible to the condition but the mortality is higher in men over forty. Predisposing causes are exertion during the heat of the day and any infectious disease which normally raises the temperature of the patient. The types of illness into which the cases were classified are: 1, Mild heat exhaustion; 2, gastric type where the patient had a flushed face, was restless and irritable with nausea and occasionally vomiting and where the temperature was only slightly elevated; 3, gastrointestinal type with sudden onset and collapse, nausea, vomiting and diarrhea, and often with cramps in the legs and abdomen; and 4, heat hyperpyrexia with sudden rise in temperature and loss of consciousness and finally death after convulsions. The onset and course varied greatly and all sorts of peculiar symptoms were noted. Among the more constant findings were a marked cardiac dilatation with a systolic murmur lasting several weeks, an excess of indican in the urine, and a very frequent loss of the knee jerks in the more severe cases. Acetone and diacetic were found in the urine in only a few cases. The treatment of the gastric types consisted in removal of the patient to a cool atmosphere, bicarbonate of soda in full doses by mouth, and free purgation. Heat hyperpyrexia demands treatment with sprays of ice cold water, fans, and quinine hydrochloride intravenously or intramuscularly if there is the slightest suspicion of malaria. Convulsions are treated by venesection morphine or chloroform inhalations.

Influenza as an Etiological Factor in Nephritis.—W. W. D. Thomson and H. F. Macauley (*Lancet*, February 28, 1920) report four cases of nephritis in the children of one family, manifesting itself about three weeks after an attack of influenza in each instance. The condition was characterized by an edema and albuminuria of varying severity, the presence of epithelial and blood casts with erythrocytes and leucocytes in the urine, and by a favorable course with recovery. The literature on the subject is extensively summarized and the following conclusions are drawn: 1. Nephritis is a more common complication of influenza than is generally supposed. 2. The virus may affect the kidneys in various ways: a, producing a transient albuminuria; b, causing an acute nephritis during the course of the disease; c, resulting in an acute nephritis during the course of convalescence; d, lighting up a latent nephritis. 3. Nephritis may follow even a mild attack of influenza. 4. The nephritis may be such a slight and transient affair and the symptoms of the influenza so pronounced that the diagnosis will not be made unless a careful routine examination of the urine is done. 5. Probably the frequency and severity of the complication varies in different epidemics and in different localities. 6. The examiners of applicants for life insurance may expect to find a higher proportion of albuminuria than in normal times.

Radium Treatment of X Ray Epithelioma.—P. Degrais and A. Bellot (*Presse médicale*, June 5, 1920) report three cases in which epithelioma or obstinate ulcerations due to professional x ray exposures were successfully cured with radium. Such results will enable those called upon to treat cases of this type to dispense with amputation of the affected extremity in the future. In one of the cases reported by the authors three excision operations had already been performed and been followed by recurrence. The ulcers soon healed under radium, and the accompanying severe pain was wholly relieved. Hyperkeratosis due to the x rays likewise yielded to radium, used in the same manner as for the treatment of warts.

A Study of the Relative Toxic Effects Produced by Regional Radiation.—W. Denis and Charles L. Martin (*American Journal of the Medical Sciences*, October, 1920) thus summarize their paper: 1. A definite massive dose of x rays administered to the body of a rabbit produces a severe systemic reaction and death only when some portion of the intestinal tract lies within the irradiated area. 2. It is possible to produce a definite acidosis (lowering of the alkaline reserve) in rabbits by administering a heavy dose of x rays over the abdomen. Such animals give no evidence of suffering from a röntgen ray nephritis. 3. The results suggest the hypothesis that acidosis may be a factor in treatment sickness following abdominal irradiation.

Treatment of Penetrating Injuries of the Eyeball.—H. H. Roth (*International Journal of Surgery*, September, 1920) gives the following conclusions for the conservative treatment of penetrating injuries of the eyeball: 1. Radiographic examinations should be made in every case of ocular injury from any penetrating substance, especially where lowered visual acuity is the result of the accident. 2. The use of the conjunctival flap in penetrating injuries of the cornea and sclera is our greatest aid in preventing infection and prolapse of the internal structures of the eye. 3. Hexamethylenetetramine is a remedy to be used in all injuries involving the opening of the eyeball in order to prevent and combat infection, and it can be given freely and over an extended period of time, and in only a few cases does it produce renal symptoms.

The Bone Flap in Cranial Surgery.—Harvey C. Masland (*Annals of Surgery*, October, 1920) gives the following summary of the operation he uses for cutting the bone flap in cranial surgery: The preliminary openings, usually but two, are small. The relations of the power and of the construction of the trephine to the skull opening are so adjusted that the trephine must jam before penetrating the dura. If the preliminary saw cut through the outer table is used the guard is immediately adjustable to the depth desired. The inside guard is of a shape to secure easy separation of the dura, and there is fine tactile sense of its efficiency in this respect. There is no burning of the bone and so the vitality of the exposed osteoblasts is preserved. There is bone support for the replaced bone flap. If a greater provision for internal pressure is desired the bone flap can be variously sectioned in vital fragments to gain the desired end.

X Ray Treatment of Universal Psoriasis.—John Remer and W. D. Witherbee (*Medical Record*, August 28, 1920) report approximately one hundred cases successfully treated in the past year by this method. They are convinced that it is the simplest and most satisfactory method of treating this disease. The x ray exposures are preferably given three times a week, allowing a day between each two exposures. For the first treatment, the head and arms are exposed, in the second treatment the trunk and buttocks; in the third, the legs and thighs. The treatment is concluded in from four to eight weeks, depending on the severity of the case.

Preoperative Treatment of Diabetic Patients.—Max Kahn (*Surgery, Gynecology and Obstetrics*, October, 1920) gives the following rules for preoperative treatment of diabetes: 1. Keep the bowels open, preferably by enemata, in order to avoid diarrhoea and the consequent drainage of alkaline salts from the body. 2. Administer fluids in liberal amounts—a glass of liquid every hour or hour and a half. 3. Increase the tolerance for carbohydrates. 4. Avoid substances that induce the formation of the acids—such as fats, and sometimes proteins. 5. Administer substances which favor the combustion of the ketones, as for example, oatmeal, levulose, alcohol, etc. 6. Do not prescribe alkalies.

Advantages of Extension in Diseased Joints.—W. A. Lane (*Lancet*, March 22, 1920) records his conversion to the use of traction instead of fixation in the treatment of diseased articular surfaces. The reason why the method is so useful is that traction permits of so little friction between the surfaces that only a mild transient inflammation is set up when the joint is moved instead of the severe inflammation which results from the bruising of surfaces which are not held apart by traction. Then too such a procedure tends to furnish the joint with a more free blood supply than is otherwise the case and the muscles are allowed to function normally.

Combined Intramuscular and Subcutaneous Antitoxin Administration in Diphtheria.—P. F. Armand-Delille (*Bulletins et mémoires de la Société médicale des hôpitaux de Paris*, March 18, 1920) comments on the rapidity of absorption of antitoxin when it is administered intramuscularly, the use of this route constituting a definite step forward in diphtheria treatment. Since, however, serum thus given is rapidly eliminated, late symptoms such as paralyzes developing where this method is used alone, it should be supplemented next day by another dose given subcutaneously in order to keep up the effect. The author's present routine procedure in cases of average severity in children three to ten years of age is to give thirty to forty mils of serum intramuscularly at once, and on the next day forty mils subcutaneously. This dose may be increased in the event of toxic or malignant angina with extensive and extending membranes. If, on the third day, there is still a membrane, leading to the suspicion that toxin is still being formed owing to insufficient neutralization by the earlier injection, a third subcutaneous injection of thirty to sixty mils is given. In croup the speed of action of the intramuscular dose is plainly manifest, but the added subcutaneous dose should nevertheless be given.

Miscellany from Home and Foreign Journals

Clinical Diagnosis of Diphtheria.—H. Drinkwater (*Lancet*, May 29, 1920) reaffirms the necessity of early diagnosis in diphtheria and gives several clear directions for the accurate clinical diagnosis of the condition with points of differentiation from follicular tonsillitis and Vincent's angina. He divides the fauces into six areas, three on either side, the tonsillar, the uvular and the palatal areas. Every area may show some deposit and in any area there may be one or more patches. In diphtheria the deposit in any one area is always single though there may be several patches on the fauces. The same is true in Vincent's angina. In follicular tonsillitis there are several patches on the tonsils and the same is found in influenza. The characteristics of the diphtheritic patch are three. 1. It is raised above the level of the mucous membrane. 2. The edges are sharply defined all around. 3. The color varies greatly from glistening white to bluish or yellowish with patches of black or red. Vincent's angina is the most difficult to differentiate from diphtheria and in some cases it is impossible to make the differentiation without microscopic and cultural methods. But there are several characteristics which when present serve to make the diagnosis. When the fauces show a sharply defined vertically directed ulcer in which the membrane extends scarcely beyond the edges of the ulcer the diagnosis is clinically Vincent's. Also when the lower edge of the membrane is thinned out and the border is ill defined, a diagnosis of Vincent's should be made. In follicular tonsillitis and influenza the multiple patches in the various areas rule out the diagnosis of diphtheria.

Abscess of the Liver.—A. L. Candler (*Lancet*, February 21, 1920) discusses his experience with liver abscess in the British general hospitals of Mesopotamia. *Entamoeba histolytica* was the cause of the condition but in the series of three cases of hepatitis and thirteen of abscess, a history of diarrhea was obtainable in only three instances. Of the two fatal cases the bowel at postmortem showed only one small healing ulcer in the ascending colon in one instance and no abnormality at all in the other. Also in the stools of twelve of the series amebæ were found in only three. Hence the conclusion is made that probably in the amebic dysentery cases so slight in bowel involvement that the diagnosis is impossible, hepatic abscess is much more likely to develop than in the clear cut cases which are diagnosed early and the patients given a thorough course of treatment. Liver abscess does not give a clear cut clinical picture as there are wide variations in temperature, pulse, respiration and leucocytosis, though all are often moderately raised. Tenderness or tumor can usually be made out when the process is on the anterior surface below the costal margin. In the usual subdiaphragmatic location, however, the signs are less characteristic. Enlarged liver, raised upper border of dullness, bulging of diaphragm as shown by x ray, and raised arch of dullness under the axilla must suggest the

condition strongly. The diagnosis, however, is made by obtaining pus through a needle, if possible, or by laparotomy, if necessary. Treatment consists in opening and draining the wound, irrigating it with a solution of ten grains of quinine to the ounce and keeping both the wound and the cavity sterile by careful dressing. Withdrawal of the drainage tubes at the earliest possible moment lessens the likelihood of infecting the wound and so hastens the healing process. Hypodermic injections of one grain of emetine hydrochloride daily for ten days must be given as general treatment and, after a rest, repeated if necessary.

The Thymus as an Endocrine Organ.—A. P. Dustin (*Prèsse médicale*, June 5, 1920) asserts that the hitherto accredited theory that the small thymic cells are true lymphocytes and the Hassall bodies epithelial derivatives with an endocrine function can no longer be considered valid. The only really functioning cell is the small thymic cell, which resembles a lymphocyte but is actually derived by a strictly special process from the primordial epithelium of the thymus. The main function of the organ is division of these small cells by karyokinesis and disappearance of the cells by pyknosis, nuclein derivatives being set free in the system. This liberation of nuclein material by the thymus is strongly influenced, if not initiated, by the thyroid gland. The thymus thus acts as a regulator and disseminator of nucleins and their derivatives in the organism. Important applications of these facts may be made in morbid conditions of the thymus, lymphoid formations, tumors, and in the biochemical disturbances of nucleinic metabolism. The organ does not operate, as would a gland, through a secretion, but by fixation of substances of the nucleoproteid group in the condition of actual formed elements or cells.

Clinical Diagnosis of Typhus Fever.—J. Rieux (*Paris médical*, June 5, 1920) summarizes the earlier clinical manifestations of typhus fever as follows: Any patient who, after being taken ill rather suddenly—i. e., who can tell on what day he became ill—without any definite localization of the disease, shows a progressively rising and later constant febrile temperature, marked headache with unpleasant dreams, severe prostration, a pulse rate of 100 to 120 a minute, always proportionate to the temperature, and injection of the conjunctivæ, without any abdominal or pulmonary symptoms, should be looked upon as a typhus suspect. The suspicion is confirmed when the typhus eruption appears, about the fourth or fifth day. The differentiation from typhoid fever rests mainly upon the mode of onset, the lack of agreement between the pulse and temperature in typhoid fever, the presence of intestinal and pulmonary symptoms in the latter affection, and the presence of conjunctival injection in typhus. Extraneous factors of diagnostic import include the epidemicity of the disease, which is a cold weather affection and occurs in massive but dragging epidemics, similar to epi-

demics of measles or mumps. Transmission of the disease by lice is also an established fact of possible diagnostic significance, though some physicians, orderlies, and especially nurses contracting the disease have asserted that they did not harbor any of these parasites. The Weil-Felix reaction is an accepted laboratory test, but is not available until the end of the first week. Negative results of blood cultures and examinations for malarial organisms and the spirillum of Obermeier are thus of greater significance early in the disease.

A Study of the Blood after Splenectomy, with Special Reference to the Leucocytes.—Milton W. Hall (*American Journal of the Medical Sciences*, July, 1920) thus summarizes the results of his observations: The removal of the spleen resulted in a considerable increase in the total leucocyte count which persisted with much irregularity for over three months. In the early period all types of white cells were increased in nearly the same proportion, although a slight increase of endothelial cells was noted at the expense of the lymphocytes. In the intermediate period both total and differential count showed such marked variation as to render averages valueless, but the total count usually was high. In the final period a comparative equilibrium was reached, with a moderate increase in the total count, due entirely to lymphocytes and endothelial cells, while the granular leucocytes showed strictly normal figures. The endothelial cells were constantly increased both relatively and absolutely. The observations in the Arneth index suggest that the increase in the count is at least in part due to the removal of some factor restricting the production of white cells. No eosinophilia appeared during the course of the work.

Effects of Occupation and Race on the Health of Recruits.—G. R. Hall (*Lancet*, June 5, 1920) compiles statistics made available by the wholesale examinations of British recruits. An examination of 2,500 men suffering from heart disease revealed the fact that only forty per cent. suffered from valvular disease of the heart, while in the rest illness was due to want of tone or to other minor, and nearly all curable, conditions. Apparently there were two cardiac cases among the dark recruits to one among the light. In 8,000 men, the feet were defective in 23.8 per cent. of cases, flatfoot being the usual fault. The teeth were bad, in a state to affect health, in 42.5 per cent. of the 8,000; 14.6 per cent. also showed defects of the genitalia but varicocele was the chief defect, comprising eighty per cent. of the cases. Of 20,141 recruits, 6.2 per cent. were referred to the ophthalmic surgeon, and 2.5 per cent. of these men were rejected. As to racial effects on the health of the individuals, it was found that among the Russian Jews there was a definitely higher incidence of various diseases and defects than among the British men in all cases except in valvular disease of the heart where the incidence was distinctly higher among the British. It was also found that the young Jews who had been brought up in England were approximately as healthy as the British youths, indicating that the Russian Jew is not racially defective but that he has suffered from his environment.

Delayed Symptoms in Fracture of Vertebral Bodies.—Robert H. Baker (*Surgery, Gynecology and Obstetrics*, October, 1920) in a discussion of Kümmel's disease presents the following conclusions: 1. Compression fracture of the spinal bodies without cord symptoms is frequently undiagnosed, or incorrectly diagnosed at the time of injury. 2. A negative finding by the x ray at the period of initial injury is not proof positive against fracture. 3. Symptoms referable to the fracture may not occur for some time after injury. 4. At this later period the signs and x ray findings are all in keeping with a diagnosis of compression fracture of the spinal bodies. 5. The exact sequence in the pathology leading to such a diagnosis is not understood. 6. The prognosis will depend on the time of diagnosis and the institution of proper treatment. 7. The treatment is that of compression fracture of the spine.

Involvement of the Auricle and Conduction Pathways of the Heart Following Influenza.—Walter W. Hamburger (*American Journal of the Medical Sciences*, October, 1920) reports six cases of postinfluenzal myocardial involvement, in which the auricle and conduction pathways of the heart were particularly affected. From a study of the literature, together with clinical and electrocardiographic studies, he offers the following grouping of postinfluenzal cardiac complications. 1. Fatal cases showing acute parenchymatous degeneration and vacuolization of the myocardium. 2. Nonfatal acute cases showing involvement of auricle and conduction system during height of infection, with complete restoration to normal cardiac mechanism with subsidence of infection. Duration two to six weeks. 3. Nonfatal chronic cases with arrhythmia and involvement of the auricle persisting and causing partial invalidism long after subsidence of acute infection. Duration twelve to seventeen months—plus. He suggests that acute respiratory infections single out early the auricle and conduction pathways of the heart.

Vital Capacity Constants in the Study of Pulmonary Tuberculosis.—G. Dreyer and L. S. T. Burrell (*Lancet*, June 5, 1920) report the results of their studies on the vital capacity in normal individuals and in persons suffering from active or quiescent pulmonary tuberculosis. The formulæ with the methods of measurement are given in detail together with brief abstracts of the reports on two hundred cases. The authors feel justified in drawing the following conclusions: 1. There is a definite decrease in the vital capacity of the tuberculous patient, taking into account the nature of his employment and his general physical condition. 2. The vital capacity of the individual increases with the clinical improvement and decreases with advance of the disease, thus giving a numerical index as to the progress of the case. 3. The determination of the vital capacity of the case furnishes a useful means of classification of the extent and severity of the condition. 4. The measurement furnishes an aid to diagnosis in doubtful cases for if it is normal there is no tuberculosis present. 5. The measurement also furnishes an index to the efficacy of any method of treatment.

Proceedings of National and Local Societies

BRITISH NATIONAL ASSOCIATION FOR THE PREVENTION OF TUBERCULOSIS.

*Annual Conference Held in Liverpool, England,
October 7, 8, and 9, 1920.*

The President, SIR ARTHUR STANLEY, in the Chair.

(Concluded from page 832.)

Importance of Early Treatment.—Dr. HALLIDAY SUTHERLAND, of London, dwelt upon the great need for timely treatment. The reason why results were so bad was that patients arrived in a too far advanced stage of the disease. On one occasion he was asked by a doctor to take in a favorable case. Not knowing the doctor, he consented. When the cab arrived at the institution the man in it was dead. They could not expect a miracle in anything subject to natural forces. If the machinery they now had was used properly the problem would be solved in a generation. He strongly deprecated the lumping together of all cases, slight and advanced.

Tuberculosis and Poverty.—BAILLIE JAMES STEWART, of Glasgow, said that poverty, with its attendant disabilities, bad housing and food, was the chief cause of tuberculosis, and asserted that until poverty was abolished these conferences would go on.

Practical Difficulties in Connection with Carrying Out Tuberculosis Schemes.—Dr. J. G. ADAMI, F. R. S., formerly professor of pathology in McGill University, Montreal, now vice-chancellor of the University of Liverpool, delivered a forceful address in which he pointed out that the tuberculosis problem was not altogether or even primarily a medical one unless it was considered as possible that some specific medicinal cure, that would be promptly effective, could be discovered. If such a drug could be obtained, one that would destroy the bacillus, he doubted whether it could be introduced into the body in sufficient concentration. Could all cases of tuberculosis be isolated and kept isolated, in ten years' time tuberculosis would be rendered as rare in Great Britain as was leprosy. This idea was not feasible, however; no Chancellor of the Exchequer would advance the funds requisite, nor, unless a periodical physical examination of the entire population was inaugurated, could a considerable proportion of these cases be detected. What was possible, however, in positive cases, was to segregate the patients in large numbers. The greater the proportion of those isolated, the more rapid the reduction in the incidence of the disease. The four essentials were recognition, notification, isolation, and treatment. A combination of voluntary and official support was essential and would be most economically brought about by the establishment of local tuberculosis dispensaries. Professor Adami went on to describe the working at the Royal Institution, Montreal, of the class treatment introduced by Dr. Joseph Pratt, of Boston, Mass., and declared that this method of treatment gave far better results than the sanatorium treatment at a

lower cost for each patient. He urged a modification of the system, together with the establishment of camps and night camps for open air treatment in the parks and gardens of cities and towns, as being the course along which the best and most economical results could be obtained.

Dr. W. H. DICKINSON, of Newcastle-on-Tyne, said recovery among the poor was nearly always retarded by financial embarrassment. This should, as far as possible, be remedied by local and State assistance.

Reforms Needed in Sanatorium Management.—Dr. CHARLES MINOR, of Asheville, N. C., said that what was needed was reform in the management of public sanatoriums for the working classes. The whole staff from the medical superintendent down should be of the right kind, who would treat the patients as human beings having souls as well as bodies. No good results could be obtained by mixing cases. When managed aright, tuberculosis was not the hopeless disease it was supposed to be. However, Dr. Minor advocated the mixing of the sexes. If the assembly were all women it became catty, and if all men it became rude, and they had to be brought together in order to get a civilized family. The cantankerous people should be put together in one ward. He advocated cheerfulness.

Importance of an Accurate Diagnosis.—Dr. B. J. I. GLOVER, of Liverpool, referred to the importance of making an accurate diagnosis on the part of the tuberculosis officer, and to the fact that certain cases of chronic bronchitis were sometimes wrongly labeled as tuberculous and sent into sanatoriums, thus wasting valuable beds.

Milk and Tuberculosis.—The last session of the conference was devoted to a discussion of the milk question. Sir Robert Philip, of Edinburgh, was in the chair.

Dr. A. W. MACFADDEN, of the Ministry of Health, opened the discussion and said, in part, that the figures indicated the present exceedingly low consumption of milk in industrial districts and the wastage in milking herds from tuberculosis. He laid stress on the importance of milk to the community, especially as a means for supplying accessory food factors. Tuberculosis in cattle made the business of milk production an unprofitable one to the farmer. When the new legislation had come into full operation two per cent. of their stock might be expected to come annually for slaughter under the provisions of the tuberculosis order. From the consumers' point of view he noted that in Dr. Stanley Griffith's recent report to the Medical Research Council twenty per cent. of the cases of human tuberculosis examined by him were found to be of bovine origin. He referred also to the research being carried out at the present time at the Reading Agricultural College to determine the most economical means of producing and distributing wholesome milk. Under the new legislation, part of which is still before Parliament, county councils will, for the first time, be brought into

touch with the machinery of production. Local authorities will be empowered to appoint a sufficient number of veterinary surgeons to carry out the inspection of dairy cattle in their districts. It is anticipated and hoped that this scheme of inspection will result in bringing to light the cases of tuberculosis in cattle, which will then be slaughtered and compensation paid according to the provisions of the tuberculosis order. The system of granting certificates to farmers who produced milk of a certain quality had resulted in the production of some tubercle free dairy stock and was a valuable experiment.

Professor J. M. BEATTIE, of Liverpool, stated that proprietary milk preparations for the feeding of children were not practical substitutes for fresh milk, and that the sterilization and pasteurization of milk were not a guarantee against tubercle infection. Professor Beattie dealt with three main methods of preventing infection by means of milk. Samples of dried milk had not shown tubercle bacilli, but experience had demonstrated the fact that the process of suspension was often imperfectly carried out in the home, so that the child got sometimes little besides water, and often a fluid that was contaminated in manufacture. Professor Delépine had found living bacilli in milk dried over cylinders heated to 138° C.-140° C. Pasteurization also killed tubercle bacilli in the great bulk of cases when properly carried out, but the commercial methods used in Great Britain were very ineffective. His experience, however, in examining samples from the Liverpool Infant Welfare Centre, showed that if properly carried out the method of sterilizing milk by heating it was effective. The milk, however, must be heated above 70° C., at which temperature the milk proteins underwent some change. The results of sterilization at lower temperatures by electricity had been unsatisfactory. The rational method of procedure was to control milk at its source of supply and he suggested systematic inspection of dairy herds, and examination of composite samples of milk from these herds, with special samples from animals suspected of tuberculosis, together with the isolation, on special isolation farms, of any suspicious animal.

Sir ROBERT JONES, of Liverpool, said that in any children's hospital the cases of surgical tuberculosis might be divided into three groups: 1, tuberculosis, 2, poliomyelitis, 3, rickets. Half of the cripples, among whom he practically spent his life, were tuberculous. Furthermore, two thirds of the infection in these tuberculous children was bovine in character. In nearly every instance the infection could be traced back directly to the cow. If such cows were not slaughtered they should be branded so that they could not pass from a controlled to an uncontrolled area to infect a new series of children.

Dr. PAUL A. LEWIS, of the Henry Phipps Institute, Philadelphia, explained how the American system of grading had arisen through the supply of milk to large concerns, who often had to transport it 500 miles to the cities. He said that this system had been the largest single factor in the education of the farmer, who was naturally anxious to secure the higher prices paid for higher grades

of milk. In the large towns where only grade A milk could be sold there had been a marked diminution of gland tuberculosis. This diminution had not occurred in country districts where the less satisfactory milk was still obtainable.

Dr. DINGWALL FORDYCE, of Edinburgh, said that although it might seem ridiculous to say so, the medical profession was not as well educated as it should be in the elements of child nurture. It would be better for the nation if there were small healthy families rather than large ones in which many of the children died. Dr. Fordyce recommended that all milk sold in Great Britain today should be boiled. Babies could be fed successfully on boiled milk if vitamins were supplied additionally through fruit or vegetable juices.

Professor STENHOUSE WILLIAMS, of Reading, made the most striking speech of the discussion and recounted the difficulties which had confronted the dairy trade, the members of which had always been most anxious to adopt the best measures for the purification of the milk supply. It had been very difficult to procure money or facts to support research. In order to insure a decent milk supply there must be the right man in the cow house. No inspector would rise early enough to control the milking conditions. The milker must, therefore, be educated and given a good wage. At least two per cent. of cows, which to outward appearance were in good health, were giving tuberculous milk. Such milk was sent out from four farms out of fourteen. Not only did these cows affect milk directly, but their dung remained infected for twelve months if kept in a dark place and so might contaminate other milk. Nothing less than the tuberculin test would eliminate these cows from the herds. The farmer asked how he was to replenish his stock if the tuberculous cattle were destroyed. They had presented a scheme four years ago for raising nontuberculous cows at Reading to replace cows so eliminated, but money had not been forthcoming. Another practical difficulty was the absence of any standard tuberculin or any standard method of using it. He condemned vigorously the propaganda which would excuse the consumption of tuberculous milk on the ground that it immunized children. The dose of tubercle bacilli was unknown, and it was not possible to say that the bacilli which entered the child's body did not remain latent and reappeared after a lapse of years as human bacilli.

Dr. J. RUDD LEESON, of Middlesex County Council, made the most iconoclastic speech of the meeting, endeavoring to upset all traditional views as to the nutritive properties of milk. He followed in the footsteps of Dr. Harry Campbell, but out-heroded Herod, denying any virtues in milk as a food. Rather he regarded it as a menace to the health of a country, saying that he would prefer to see a barrel of gunpowder in a house than a glass of milk. He declared that people had no business to drink milk. It was quite unnatural, as was shown by the fact that when a child's teeth came the mother's milk ceased and that applied to all mammalia. He looked upon the drinking of milk as one of the curses of civilization.

Dr. WILLIAM ALLEN DALEY pointed out that the determination of the presence of bacilli in milk by inoculation tests took too long, and advocated research to discover a more rapid method.

Resolutions on Tuberculosis Prevention.—The following resolutions were moved by Sir ROBERT JONES and seconded by Dr. HYSLOP THOMSON:

That this conference viewed with satisfaction the growing interest that was being shown throughout the country in relation to the prevention of tuberculosis. It reaffirmed its belief that the methods which were being adopted were justified by the results obtained, and would urge their still more vigorous prosecution. In particular it would urge the Government to consider the immediate institution of a more definite system of medical inspection in the case of certain industries where tuberculosis was especially rife. It would also urge that the Tuberculosis Order, 1914, be brought into operation with as little delay as possible. The conference further resolved that these resolutions be sent to the council of the National Association for the Prevention of Tuberculosis with a view to their transmission to the Prime Minister, the Minister of Health, and the Minister of Agriculture.

A discussion then took place in the course of which Dr. E. I. McDONALD, tuberculosis officer, County Carlow, Ireland, made an insistent plea for more adequate remuneration for the general practitioner, who at present was given the vital and difficult task of discovering early cases without reward. The resolutions were then put to the meeting and carried unanimously.

The Liverpool branch of the Church of England Temperance Society gave a breakfast on October 8th to the members attending the conference. Dr. HAIË, who presided, said that alcoholism was a national question, and though we might not feel it wrong to drink alcoholic beverages ourselves, we must look upon the whole problem with a social conscience.

Alcoholism and Tuberculosis.—Dr. I. N. KELYNACK read a paper on this subject, in which he dealt first with the direct action of alcohol, quoting the late Sir William Osler in support of the contention that the resistance of the body to infection was lowered by its use. But the chief way by which the alcoholic exposed himself to infection from tubercle bacilli was through the indirect effects of addiction upon personal hygiene and upon social and domestic conduct. Those who were improperly fed and clothed as a result of poverty through drink fell an easy prey. Much contagion was contracted at the public bar. Dr. Kelynack read a symposium of opinions in agreement with his own, contributed by Sir Robert Philip, Sir George Sims Woodhead, Sir Thomas Oliver, Sir Henry Gauvain, Professor Hope, Professor E. L. Collis, Dr. Nathan Raw, and Dr. C. T. McAlister. He concluded by urging additional research on alcohol and tuberculosis by the profession and for a school campaign of temperance education along the lines recommended in the new syllabus of the board of education. Agents of insurance bodies, in his opinion, should give health instruction in England as they did in America.

The keynote of the meeting with regard to the

tuberculosis problem, as with the problem of all disease at the present time, was that prevention is better than cure, and in order effectually to prevent there must be earnest and intelligent cooperation between the medical profession and the community.

Too great reliance had been placed upon sanatorium treatment, and grave defects in the system had made themselves evident which to a considerable extent minimized its value. It was now obvious that in order to stamp out tuberculosis in the first instance, early diagnosis was essential. The disease could be successfully treated in the early stages but was not amenable to successful treatment when infection had gained a firm foothold. Consequently the rational mode of dealing with tuberculosis was by the exercise of preventive methods. Of course, such methods were notoriously difficult to bring into play. Early diagnosis was immensely difficult—it seemed almost impossible—and the milk question was another hard nut to crack. But these problems must be faced and solved if success was to be complete. Furthermore, it was necessary, if the spread of the disease was to be controlled, that those who were in the stage of the disease which made them a menace to their neighbors and the community must be segregated. These were the two important problems to be solved in the campaign against tuberculosis: early diagnosis and appropriate treatment, and the segregation of the sufferer when he had become a danger to the public.

At the outbreak of war progress had been made in the treatment, preventive and otherwise, of tuberculosis, but war conditions naturally rendered all efforts of no avail, and during the war the disease had made great headway. In Great Britain, at the present time, the whole matter was being reconsidered and the treatment established on a somewhat different basis. It was recognized that the main hope of eradicating the disease, or even of greatly diminishing its incidence and prevalence, lay in prevention reinforced by the segregation of those in an advanced stage of the malady. To this end, therefore, there was needed education of the public, for without education cooperation would not come, and without cooperation an early diagnosis could not be made and proper treatment instituted before it was too late. With respect to many details involved in the tuberculosis question, America was considerably ahead of Great Britain.

Nutrition Clinics and Tuberculosis.—William R. P. Emerson (*Boston Medical and Surgical Journal*, September 16, 1920) says that the problem of tuberculosis is for the most part the problem of nutrition. If children can be made well in a sanatorium, they get health; but if they can be cured in their own homes, they get health, with health education and character. Nutrition work, which covers a new and hitherto neglected field in medical work, must be carried on with proper authority. It cannot fit in as an adjunct to other programs, but other programs must be adjusted to fit the problem of nutrition, which is the fundamental problem of tuberculosis.

THE PARATHYROID AND CONVULSIVE STATES.*

General Considerations.

BY SMITH ELY JELLIFFE, M. D.,
New York.

I shall attempt to present certain general conceptions which have helped me in my efforts to analyze some of the problems which in general we speak of as the epilepsies. In this attempt to bring some formulations before you I may be considered somewhat tedious in so far as I shall deal with some elementary considerations which I deem essential to pave the way to certain aspects of the situation.

Such elementary considerations involve the general hypotheses of the science of energetics. For the purposes of our discussion I shall ask you to assume that the human being is not an isolated bit of living matter, a shut in system acting by itself and independent of its environment. It is no such thing. It, like all other living organisms, is a highly complicated, greatly involved and ingeniously intricate system or systems of mechanisms, whose chief and only functions are the capture, the transformation, and the release of energy. This energy, as you well know, comes from cosmic sources, and although the human being has not yet evolved to such a point that it can utilize all of the surrounding energy it does manipulate enormous quantities of the energy that impinges upon it and for the most part manipulates it for the well being of that individual and for the continuance of living beings, the race.

Further elementary considerations force me to remind you of some of the remarkable anatomical structures by which the capture, the transformation, and the release of this energy are made possible. Anatomically and neurologically speaking, the term receptors is used to describe those mechanisms which gather the energy in from innumerable cosmic sources. This capture of energy by the receptors has been in progress many million years and is performed automatically, unconsciously, unceasingly for the most part, and the functions have become structuralized into organs, which are still undergoing slow evolution, unrecognizable as changing even by the best means at hand for morphological observation. Solely for the purpose of illustration I shall remind you of only a few of the receptor mechanisms which have built up complex structures in this

effort to obtain energy from the universe. The weight of the earth, its relation to other masses in the universe and the effects upon all bodies in the environment we speak of as gravity. The muscular system, particularly that part of it known as the anisotropic disc system in so-called voluntary muscle, is one of the bits of structure which has been evolved in response to this constantly acting gravity energy system. The chief receptors, so far as morphology has penetrated these structures, lie within the muscles and tendons and constitute parts of an extremely complicated apparatus, which correlates the controls from many sources of our command over spatial relations through muscular action. We are not now interested in this control part of the machine, the transformers, but are speaking of the energy source side. Thus the globe is constantly working on our body and supplying it with energy stimuli.

Again let us turn to light stimuli. Light not only acts upon the optic receptors of the eye, but it is acting on the layer of pigment which in the Malpighian layer is found throughout the entire body. Here is a constant energy supply that must be handled by the body machinery. Whereas we must confess to an almost abysmal ignorance concerning these mechanisms, Cajal's recent work on the nervous structures of the skin, McCord's observations on the action of pineal substance upon melanophores permit us to conjecture some tentative working hypotheses concerning the pineal as a part of this particular functional group.

Food is, from my point of view, a comparatively insignificant source of the energy that the human being captures and transforms. It is all important, however, in supplying the chemical elements which are essential in the transforming machinery.

As some of you know, from a special point of view, I have maintained that the most important of the energy sources that the human being handles is the energy that is transformed or brought over into the human mechanism through the dynamics of the symbol. It would take us too far afield to discuss the hypotheses which science is working with concerning these mechanisms.

So, then, conceive of these receptors, connectors and effectors capturing, transforming, and releasing enormous amounts of energy. In the evolution of this process, as you know from your anatomical considerations, a highly complicated and closely integrated series of nerve structure arcs has been

*Revised notes of paper given at the National Association for the Study of Epilepsy, June 14, 1920.

devised. These arcs are broken here and there, by anatomical structures which have received the name of the synapses, in order to permit a greater facility of distribution of the energy being transformed for various vital processes. Here again I must depreciate the definiteness of our knowledge concerning the great complexity of the synapse. Morphologically we know almost nothing about them; physiologically we know a little more. We know just a little concerning the electrophysical resistance to the passage of energy at the synapse. Some of this I have summarized from my own observations and the literature of the laboratory, particularly as it has been partially revealed in working on the problem of tetany (1). Now it is particularly to some of the work that is carried on at the synapse that I wish to call attention; so far as convulsive phenomena combined with a series of other phenomena are concerned, which gathered together constitute the nucleus of the epilepsy problem, I feel that any light thrown upon the machinery at the synaptic junction level is of value in the solution of parts of the epilepsy problem, even though such value may be restricted, because no interpretation of so complicated a group of phenomena as the epileptic phenomena can ever be completely explained at a physicochemical level. If I may outline a very concrete analogy, I may speak of this synaptic junction somewhat in the light of a hair trigger in a gun. Whereas oiling the hair trigger may induce a more rapid explosion of the contents of the gun, the directing of the gun, here, there, or somewhere else, namely at the target, has little or nothing to do with the hair trigger. That is, the epileptic phenomena *en gross* can only be explained as the gun *in toto* with the man behind the gun. The ultimate comprehension of the epileptic phenomena will only receive its adequate setting when the investigation of the unconscious of the individual who is behind the gun is integrated with the other parts of the machinery. But so far as the present analogy is concerned an analysis of the mechanisms of the hair trigger may be of certain limited service. For it is certain that the electrical resistance at the synaptic junctions, peripheral, spinal, medullary, cerebellar, midbrain to cortex, and back again to the muscle and plate effectors, control the energy discharges and distributions, and aid in the integration of the machine, in its work of proper and adequate supply of energy for metabolic and projicient purposes. This electrical resistance serves at least a double service. It functions for time, and thus attempts to control the flow of energy from one neuron to another within orderly time relations. Concerning this timing function we have some definite information, *loc. cit.* It also functions for quantitative capacities, and through the elaborate network of synaptic contacts permits a balancing in dynamic distribution along physiological limits.

Both of these functions are perturbed in the groups of convulsive disorders, spasmophilia, tics, choreas, and other disturbances, as well as many of the convulsive phenomena of the epilepsies. The problem of localization of the perturbed synaptic junctions cannot be entered into just at this moment.

Now the functional integrity of the synapse, among a host of other relations, is intimately bound up in the problem of the integrity of the bivalent cations of the body, of which calcium and magnesium are the most frequently found in the chemical fundamentals of the human machine. Calcium plays an important rôle, we know perfectly well, as we more or less intensely study the phenomena of tetany, and it is by reason of this aspect of the subject that I have hazarded these general remarks. As you know, tetany is almost always associated with deficient parathyroid function. Such parathyroid modifications may originate from innumerable etiological factors. Whether we can have specific parathyroid malfunctioning independent of other endocrine activities I shall not attempt to state. In defective parathyroid states the necessary calcium integration factors seem to be most seriously interfered with. The hypothesis would state that these glands regulate the proper distribution of the calcium for its numerous functions, one of which is the specific activity of regulating the synaptic junction function; there seems to be little doubt that it is so involved. So, then, coming around to the physicochemical point of view, all convulsive phenomena may be scrutinized to advantage from the viewpoint of possible "hair triggeriness," that is, a diminution of resistance to the passage of electrical stimuli with perverted synaptic junction function, primarily brought about through parathyroid dysfunction.

This only takes us to a very general statement. Which synapses in the chains are chiefly involved? Are they those of the incoming arcs, or those of the outgoing ones? Is it a problem of faulty capture and short cut distributions in a faulty manner, or are the difficulties to be sought on the effector sides of the mechanism? These questions cannot yet be answered. Paton and his coworkers have attempted an analysis of the tetany situation along these lines, in which, however, they have omitted several synapses in their discussion, having made the functioning neural arcs too simple. But it was not my mission to solve the epilepsy problem. I wished only to discuss one defect of a general nature, which, if found in any human machine, made it more difficult for that machine to distribute its energy properly under stress or strain. Clearing up a general underlying mechanical defect of the distributing apparatus, might permit the machine to function better even with a faulty biological teleology, which a study of the unconscious might reveal as present. Certainly a very poor gunner, who might not be certain concerning his quarry—a forester or a deer—would have a serious handicap if the trigger of his gun were so touchy as to go off with the slightest pressure, maybe of his finger, maybe of a swishing branch of a shrub, or a sudden jolt from uncertain footing. With security in that part of the machine his chances might be better for his goals. Thus the work at the synapse may throw some important light on the problem to which this society has devoted itself.

Just one word more then from a possible therapeutic point of view, which has been partially experimented with by myself and more or less ex-

tensively reported on by Bolten, and a number of investigators who have found that by parathyroid therapy in certain types of individuals where there was a certain definite causal relationship between parathyroid disease and the possibility of controlling certain factors in the convulsive phenomena, very excellent results have been obtained.

My opinions are still in a formative state, but the results which I have obtained from investigation and the reports obtained by reading the literature indicate that some help in controlling certain of the factors which I have outlined may come from a carefully considered parathyroid therapy. Just to feed parathyroid to every epileptic and expect him to get well is as silly as to give every man in New York a brick and expect to get a Woolworth building. Behind the type of cases of possible action there should be present the specific features of the "hair trigger" synaptic activity. Careful study of the patient for all of the tetany reactions is needed, then one may have some foundation. Therapeutics is so empirical at best, however, that even a shotgun use of the parathyroid may bag a bird when one least expects it. Interestingly enough, it has seemed that parathyroid given by rectum in its crude state is its most effective form. Given in other ways, by the gastrointestinal canal, it undergoes destructive digestive changes; even hypodermic use seems to alter its composition, but taken by way of the rectum it would appear that no such deterioration takes place, and some very surprising and striking results have been obtained, not in the cure of an epileptic specially, but in the help of this one particular factor which I have tried to emphasize in this rather condensed communication.

MORE ADEQUATE PROVISION FOR EPILEPTICS.*

BY WILLIAM T. SHANAHAN, M.D.,

Sonyea, N. Y.,

Medical Superintendent, Craig Colony.

One may ask what is now being done in America to meet the needs of the many thousand epileptics not under any particular care or supervision? Are the established institutions serving their respective communities to the greatest degree possible? While many of the epileptics referred to would probably never be required to come under direct institutional care, nevertheless the question arises, Should extension work be arranged either as clinic days at Craig Colony or at a distance where epileptics unable to consult a physician might come for examination and advice? In a recent communication from one of long experience in the care and treat-

ment of epileptics, the present situation in New York State regarding the care of these people was well summed up in saying the provision was lamentably inadequate.

The general subject of care and treatment of epileptics in special colonies or villages, as well as in the outside world, has been so well covered in the literature of the past thirty years or more that there can be nothing better expected at this time than to call attention to certain phases of the problem already minutely described, stress their importance and strive to make them effective to a broader extent than has been thus far accomplished. We can but aim to bring about a more general application of the principles advocated by Letchworth, Peterson, Spratling, Clark and others.

From the twenty-sixth annual report of the State Board of Charities of the State of New York, 1892, page 373, I would quote: "The colony idea is essential, as is shown by the express language of the law as well as its spirit, and by the needs and nature of the proper care and treatment of epileptics in community life. This colony design includes not only the separation of the patients into detached buildings, but the arrangement of the cottages upon irregular lines and at different distances, in accordance with the situations of the various building sites, adapted to the selfsupport of the inmates through natural advantages for economy of administration, and for the successful prosecution of trades, industries and agricultural labors."

The writer of the foregoing apparently expected the epileptics to be received would be of good mentality, whereas upward of sixty per cent. of those received at Craig Colony, since its first patient was admitted in January, 1896, have been markedly impaired mentally.

Established in 1894, the Craig Colony with a moderate amount of funds for new construction, made available annually, should have had before this capacity for at least two thousand patients, with every ordinary facility for affording them humane, scientific and economical care and treatment. The slowing up in development of Craig Colony long antedated the World War. As a fact, during the past decade, practically no appropriations were made for additional dormitory cottages or for other coordinated structures required to permit of developing the Colony along the general lines so well laid down nearly twenty-five years ago. The few cottages built have been provided to replace old Shaker structures no longer suitable for patients.

A portion of Section 1, of Chapter 331, of Laws of 1907, being an act authorizing the selection of a site for what is now Letchworth Village, reads as follows: "Section 1. Selection of lands.—For the purpose of acquiring a site for the Eastern New York State Custodial Asylum which it is proposed to establish for the care of epileptics and other feeble-minded persons needing custodial care."

The commission appointed to select the site mentioned in its report that figures obtained showed conclusively that there was a large number of dependent epileptic and feeble-minded persons for whose proper care, treatment and education the state had made no provision. In comment upon this, I desire

*Read at the annual meeting of National Association for Study of Epilepsy, New York, June 3, 1920.

to call your attention to the fact that up to the present, thirteen years later, the state has made no further provision for the epileptics referred to in this report, as subsequently the law governing Letchworth Village was modified or at least its interpretation changed so that only the feeble-minded are received. The intention of establishing a separate institution to which only the most defective class could be sent was not a good policy.

The population of New York State is such that to care for its epileptics as they should be cared for, the state must needs establish districts as it did long since for the insane, and is now preparing to do for the feeble-minded. If this were accomplished and the sites fixed on, there should be a sufficient area in which to locate groups for the housing of all types of epileptics within that radius. The annual census of the dependent epileptics in the state as required by the State Board of Charities does not bring forth satisfactory information to approximate the total number who might demand or desire care in a colony. Many counties either report no epileptics or very, very few in comparison with their population.

The rounding out of the Craig Colony by the erection of various buildings listed in the original plan, is plainly indicated so that the scientific and therapeutic ends for which the institution was established may be progressively furthered. A minimum of markedly defective, primarily custodial cases should be ultimately provided for at the colony. If the project, already referred to, of districting the state is eventually accomplished, those patients offering some possibility of improvement or an arrest of symptoms should be given preference in the list of applicants seeking admission. This, however, cannot be done until the colony is provided with the necessary places in which to accommodate more applicants of this type and the means of treating them in an up to date, scientific manner.

In the fifty-third annual report of the New York State Board of Charities for the year 1919, the following is submitted, referring to Craig Colony: "But as it is estimated that the ratio of epileptics in the general population is one to five hundred, one institution having a capacity of one thousand four hundred inmates, situated in the extreme western part of the state, is not sufficient provision for a population of ten million or more persons. It is impossible to care adequately and properly for the needs of the state at Sonyea, where there is constant overcrowding and where a long waiting list is constantly maintained. The great distance from New York City is an additional hardship to the patients who are separated from friends and relatives for long periods of time. There should be in the vicinity of the metropolis an institution for this type of sufferers, and in addition there should be provided throughout the state clinical and dispensary facilities whereby discharged patients and potential epileptics may receive aftercare and expert advice in the treatment of their disorder."

The Hospital Development Commission in New York State in its report submitted to the Legislature under date of February 18, 1918, stated: "We are not prepared to say that another institu-

tion for feeble-minded should be authorized. The institution at Letchworth Village was originally intended for epileptics. Today this original purpose has been lost sight of, and perhaps properly so. The Craig Colony for Epileptics is another phase of the same problem. This institution has patients who are both insane and feeble-minded. A great many epileptics ultimately become insane. It is a question whether hospitals for the insane should care for insane epileptics or whether institutions for epileptics should care for that class, or whether the Craig Colony should be regarded as a charitable institution, or should come under the control of an existing commission or some commission should be formed in the future. The question arises in connection with this entire situation as to what is mental normality and what is defectiveness. Can any sharp line be drawn between the two? The ability to make a proper social adaptation in one station of life may be much greater than that required in another circle, and so on."

In practically every other state, except New York, the institutions for the care of the insane, feeble-minded and epileptic are all placed under the same commission or board.

On February 1, 1920, there were a little over a thousand epileptics residing in the various state hospitals for the insane in New York State: Binghamton 73; Brooklyn 34; Buffalo 77; Central Islip 128; Gowanda 29; Hudson River 117; Kings Park 128; Manhattan 162; Middletown 65; Ogdensburg 61; Rochester 42; Utica 49, and Willard 90; giving a total of 1,055. Of this number, a considerable proportion might be cared for in an institution such as the Craig Colony if proper buildings were available. With the removal of the majority of the epileptics from the hospitals for the insane, there would then be made available many beds for the ordinary insane.

At the present time, the only states providing separate institutions solely for the care of epileptics are the following: Ohio, New York, Massachusetts, Kansas, New Jersey, Indiana, Texas, Michigan, Iowa and Ontario, Canada. Pennsylvania and Missouri have private institutions for epileptics. Of the remaining states, the majority either care for epileptics in separate cottages or wards in institutions for the insane or the ordinary mentally defective. Three states, Illinois, Connecticut and Virginia, originally established separate institutions to be devoted solely to the care of epileptics, but have since changed the type of institutions so as to care for both epileptics and feeble-minded in the same institution. In most of those states having separate institutions, because of the present unsettled state of affairs, it is not expected to increase their capacity materially in the near future. In Ohio there has been some agitation for the starting of another hospital for epileptics, as well as in New York. In Ohio, during the past year, there has been an increased capacity by 250, and by next year it is expected that there will be a similar additional increase in capacity. In Michigan the capacity was increased by 215 during last year. Indiana has buildings nearing completion to permit of adding to its capacity for a considerable number, but owing to such a

great increase in the cost of construction, appropriations will not nearly permit of erecting buildings of the size originally planned for. Indiana desires to erect a structure where any physician in the state can send an epileptic for observation, diagnosis and suggestions as to treatment, similar arrangement for which should be available in all states, so that such individual could be received for a short period without any steps for commitment being made necessary. New Jersey is seeking to secure a considerable appropriation so as to enlarge its village for epileptics. At the Craig Colony additional structures have been built to increase the capacity by two hundred, but cannot be made available until provision is made for housing nurses and attendants, when they can be secured.

I may be pardoned perhaps if I review some of the ideals to be sought after when establishing a colony. The site should be reasonably near a city or large town, and contain tracts available for the erection of buildings without necessitating a great amount of landscape effort.

The first patients to be admitted should be those epileptics mentally and physically capable, barring an occasional seizure, of working regularly and requiring the least supervision. If at the onset patients are admitted irrespective of their physical or mental disability, or of both, it will be difficult with such a handicap to develop the institution properly during the early days of its existence when every bit of energy that can be secured should be utilized for constructive purposes. The colony will grow toward completion more satisfactorily if this one idea is borne in mind. Many of those sent to a colony should be kept there indefinitely, both for their own good and for that of the public.

One of the greatest problems institutions have to contend with is the providing of proper care and supervision for those of its inmates who are markedly defective mentally. These will not ordinarily improve materially as a result of colony treatment. The average epileptic does, however, after a residence of several months show more or less improvement, in regard both to his epilepsy and to his general health, some having a complete cessation of seizures.

The educational work of an institution for epileptics is exceedingly important. It should be developed along such lines as not only to care for all of the younger patients whose mental state permits of educational effort being applied but should be extended so as to care for some of the patients of a more advanced chronological age, who because of restricted environment during their earlier years were deprived of educational advantages. Education with the epileptic is of peculiar value as it must be considered not only from the ordinary viewpoint of assisting in the mental development of the individual but also for its therapeutic value. The pathetic side, especially, of the epileptic school child should appeal to all. He is capable of study, yet deprived of school opportunities because of his disorder. This is often sufficient to prevent any relief being afforded him, as it brings discouragement and perhaps results in an exaggeration of his symptoms. Craig Colony is arranging to have its educational

department affiliated with a neighboring State Normal School. Under such an extension plan the pupils will receive desired standards of instruction and the Normal School can train many of its student teachers in methods practical in nature to be made use of in special classes in schools throughout the state and really give better understanding of normal children.

William Pryor Letchworth mentions the importance of extended classification in institutions for epileptics, e. g., sex, adults from children, different grades of mentality, etc. All of those having experience in state institutions will agree that the thoroughness with which this classification can be carried out has a great bearing on the degree of success attainable in care and treatment, especially of those of better mentality. As classification is of fundamental importance in approaching the ideal of individual treatment, too much stress cannot be laid on the desirability of having small buildings, the details of the interior construction of which make for not only easier and safer but more beneficial care for epileptics. Large buildings in a colony are entirely contrary to the first principle of colony organization. The smaller the cottages and the nearer they approach a home, the greater the success in classifying and the more nearly the structure affords contentment for its residents.

There should be available in a colony, cottages for patients who become temporarily confused. From time to time patients who under ordinary circumstances are of such a status mentally as to permit of their residing with the more intelligent patients, become temporarily mentally unbalanced and require at such times close supervision and special treatment. Special facilities should be provided for their humane care during the existence of such periods in the way of simply arranged one story structures with proper outfit for hydrotherapy, special diet kitchen and other essentials.

As to the ultimate size of a colony there has been much discussion along both theoretical and practical lines. "One fundamental error in founding many institutions is in making them too small." This statement made by Dr. William P. Spratling many years ago still holds true. A moderate sized colony or village can have available many important features that cost prohibits to the institution which is too small. The epileptic population in the district will naturally regulate to a great extent the ultimate size of the institution. Ordinarily, the institution having capacity for from five hundred to a thousand patients can have a reasonable variety of occupational and recreational activities for therapeutics, can maintain various industries of a value toward lessening the net cost of maintenance, and can provide facilities for satisfactory classification and scientific care and treatment, under the guidance of an executive who can have a close personal and intimate familiarity with the operation of the colony and an acquaintance with its inmates. In an institution with two or three times this population, the superintendent must perforce have a less direct relation to the various phases of institutional activities. As to the economical administration, there is probably nothing gained after an institution

passes a capacity of perhaps a thousand inmates. Another point made by Mr. Letchworth many years ago and which I believe should be borne in mind when new institutions are established is to give the institution a title without inserting in the same the word epileptic. The Craig Colony has this year secured the enactment of legislation restoring its original title, Craig Colony.

The occupations offered the colonists should be most varied. There is no good reason why the epileptic whose mentality is not too low should not, under proper direction, pursue any ordinary avocation barring one which would place him in situations dangerous to him because of his seizures. Work is especially valuable as a means of treatment, as carefully regulated occupations often seem to lessen the number of seizures and prevent mental deterioration. The type of employment should, if possible, prove interesting and in many cases must be of a character different from that pursued previous to admission to the colony.

The most valuable form of labor, both from the viewpoint of treatment and from that of monetary return to the colony, is perhaps out of door work in the garden and on the farm, with their diversified interests, including forestry, breeding and raising of live stock, and other occupations. After that in importance comes the work in shops, household, laundry, and sewing rooms. If sufficient suitable land and equipment are available, there is no good reason why all vegetables and milk required and a considerable portion of meat, eggs, fruit, and other articles of diet cannot be raised on the colony premises. A considerable proportion of repairs and minor improvements can be done, largely by patient labor, and many articles, such as mats, rugs, brushes, brooms, willow baskets and furniture, mattresses, clothing, stockings, caps, hats, and other utensils can be made by the colonists. The making of soap, printing and binding, caning chairs and other activities can easily be carried on. As the institution grows, the industrial work can be progressively developed. Local conditions may permit special industries, for instance, brick and tile making, forestry, butter and cheese making.

The earning capacity of the epileptic, as a class, has been overestimated by many of the general public, and even by some more familiar with their special care. The very word defective should imply that one must not expect a community of defectives to be selfsupporting. Of the total number of epileptics in the average state colony, about fifty per cent. are capable of doing labor of some kind and from ten to fifteen per cent. can perform considerable work when not incapacitated in consequence of seizures. Various games and sports, both indoor and out, should be provided.

Conscientious heads of departments, sympathetic in nature, should be appointed so that it will always be evident that the diversions are therapeutic measures primarily, and for entertainment secondarily, and that industrial departments are for monetary return less than for therapeutic value.

A state institution must perforce expect to provide the common necessities of life without the luxuries which a private, well endowed institution

would be in a position to furnish its inmates. In judging a state institution's standards, this fact must always be foremost in the mind of the examiner. Proper housing, food, clothing, medical and nursing care, sensible hygienic methods as to bathing, recreation, and other activities, with all reasonable opportunities for relatives and friends to visit patients and assignment so far as means permit of compatible patients in each cottage, are demands which should be met. The proper care of inmates should not, however, be based solely on economy. The best care in the proper sense is most economical.

While the *per capita* cost of maintenance must receive careful consideration, nevertheless we must bear in mind that there is a certain irreducible minimal plane which we must keep above if the epileptic is to receive the consistently regulated care and treatment required by one of his makeup. Some nonessentials may be ignored, efforts toward research and investigation may be deferred and hygienic and dietary standards may be modified but cannot be abolished, unless we seek to disregard entirely the purposes for which the special institutions have been established.

The social aspects of epilepsy have in recent years been recognized to a greater extent by the general public than formerly. The difficulty experienced in ordinary homes in giving care to an epileptic relative is such that urgent relief is often demanded. Not only may the epileptic in the family cause much worry to the other members, but such special attention is required by him that another member must remain in the home, who could otherwise add to the family income. Except in families with means, an epileptic having frequent seizures or showing mental change cannot be kept at home indefinitely, but must be placed in an institution when such is available. In the specially arranged institution he is allowed all the liberty which broad consideration of his condition would warrant. He is afforded a more comfortable existence than can ordinarily be obtained outside, removed from an environment where many irritating and annoying stresses are active and placed where, so far as facilities permit, all the upsetting factors are obviated.

The true epileptic, as has been mentioned, has an abnormal makeup, and while he may be fortunate enough to have his convulsions and other seizure phenomena in abeyance, his mannerisms, his reactions to various influences in ordinary environment, can only be changed in part and not entirely removed. His is a receptive state which differs from the nonepileptic, so that disturbing influences acting upon him may bring to light or cause a recurrence of attacks which had been thought to be permanently removed.

Individualization is mandatory for success in treatment. Relief, so far as possible from disturbance from environment, must be secured to make socialization possible, with little or no lowering of the intellectual level. Music, artistic pursuits, re-education, must be made use of for epileptics with sufficient mentality. Mental and physical recreation and rest in proper proportion for the abnormal physical and mental endowment which exists are

required. Entertainments and amusements are primarily part of treatment. All work and no play makes for mental dullness. Recreation, properly arranged, promotes a cheerful atmosphere everywhere, but especially so in an isolated community like a colony. Employees to be retained in the service must also have means of recreation afforded them. If those having to do with the making of appropriations had to live, day in and day out, in an institution for the care of defectives, an always depressing situation, they might be more considerate of requests for funds for establishing means of diversion and recreation as well as for expedience in advancing the general purposes for which the institution was established. One potent reason why we meet with such apathy from those who could help the situation is that they forget the individual in considering the mass.

The average epileptic in a colony can be allowed entire liberty about the premises and various privileges consistent with the mental status of the individual. Serious quarrels or infractions of rules are not more frequent than in an ordinary village of the same population.

The village idea, with varied but harmonious types of architecture, should always be foremost in the development of a colony so that the stamp of the institution may be as much in the background as possible. Preceding the inauguration of the colony development, complete plans as to its ultimate size, arrangements of groups, and other details should be carefully formulated, but these plans should not be so fixed that the benefits of experience cannot be applied as the colony passes through its different stages of growth.

Difficulties encountered by hospitals in obtaining funds for development are common, but often there are special troubles besetting state institutions, owing to lack of sufficient first hand information by the appropriating bodies of actual requirements and the purposes of the particular institution. Plans for progressive development may be delayed for many, many years because of lack of adequate funds.

It has been demonstrated upon investigation made in various parts of the country that a considerable proportion of adult epileptics of better mentality would be able to live fairly well as wage earners, and could accomplish vastly more than the majority of people think possible, if the general public would appreciate the fact that many of them are incapacitated but for brief periods and would make allowance for these interruptions in their conscious life. It has been well said that many of them are obliged to accept work which is not congenial and often far below their capacity and that the length of their service depends more upon infrequency of seizures than it does upon their efficiency or the character of their occupation. Too often the unfortunate epileptic of better mentality is relegated to unskilled labor, even in which capacity he is buffeted about from place to place when his seizures occur. If employers and fellow employees could be made to look upon him in a different manner, be a little patient and sympathetic, one might say human, the problem of adequate provision for many epileptics would be reasonably well solved. There is no doubt

whatever that the epileptic of better mentality who has to maintain himself and often others, has his condition made worse by constantly worrying over the difficulty of obtaining and retaining a position.

For this class, a more numerous one than is ordinarily thought, there is an almost unlimited opportunity of service by those interested in their afflicted fellowmen. Outpatient clinics maintained by special institutions for consultation can accomplish much for them. Every human individual should have the privilege of living under the best possible conditions. It is not only a duty but an obligation of the normal, healthy group to afford reasonable opportunities and assistance to the handicapped to bring this to pass in our great nation.

A salary commensurate with qualifications demanded and suitable living accommodations for members of the resident medical staff should be provided with separate cottages, permitting married officers to live an ordinary family life, tending to attract men of a professional type, interested and inclined to pursue institutional activities as a life specialty. Adequate compensation and proper living accommodations must also be had to insure a nursing and teaching force, equipped to carry out the therapeutics of remedial cases as outlined and directed by the medical staff.

A public institution cannot, with justice, be criticized adversely when it is beyond its power because of inadequate salaries, as well as insufficient living accommodations to attract nurses and attendants who are sympathetic, intelligent and altruistic and with sufficient inherent ability and self-control to meet the stress of institutional employment. Under these circumstances we cannot expect to obtain even an ordinary class of employees. The care of patients, let alone the treatment, cannot be carried out in the manner sought for unless there are available in sufficient numbers nurses and attendants possessing these qualities.

Every institution for epileptics, after it is well established, should have as part of its organization a training school for nurses and attendants. Such a school has many advantages and can do much to elevate the general standard of care of the patients in the institution. In the last analysis the end results and work of an institution for epileptics, the same as for other mentally or physically ill, rests upon a foundation more or less firm, depending upon the quality of its nursing force as it is the members of this particular organization who come in intimate contact with the patients at the colony. Every legitimate means should be exerted to attract to the service of the institution the most efficient individuals to compose its nursing force. While the majority of the graduates of the training school for nurses leave the institution in which they are trained, nevertheless, during the course of training the institution has the benefit of their work.

An institution has to contend with the proposition of preventing, so far as possible, patients leaving without permission. In the open colony system, there is a maximum of liberty for the majority of the patients and occasionally one takes advantage of the privilege extended and departs. Minimal custodial care is the ideal to be sought for in aiming

to effect a satisfactory improvement in the health of the colonist. Not infrequently relatives and friends of the patients are at fault, as they, by their manner or attitude, incite the particular patient to run away. Newly admitted patients at times fail to adapt themselves to their unaccustomed environment. Suffering from nostalgia, they become discontented or dissatisfied because of not finding conditions as represented by relatives or friends who make false or misleading statements to them so as to induce them to come to the institution. With epileptics subject as they are to loss of consciousness and occasionally a wandering impulse, a few leave because of such irresponsible condition, which is temporary in nature.

It is my opinion that all institutions for epileptics should operate under a law which would provide that all of those applicants who are mentally incompetent should be duly committed by law through a proper court, and that those applicants who are of normal mentality should be received as voluntary patients, it being provided that upon short written notice they may leave the institution. It is not an uncommon experience to find many physicians, social workers and poor law officers who cannot recognize the fact that some epileptics are quite normal mentally; they seem to feel that all are in every respect different from ordinary individuals. Every effort should be made to obtain applicants who are normal mentally, or who approach that status. Not only is the outlook for the epileptic of normal mentality quite good if put under proper care at an early period of his disorder, but the care of such a patient is much easier and more pleasant, and adds materially to the encouragement of those working in institutions. This is a feature which should be given consideration as time goes on. Since Craig Colony was first opened for patients, over five thousand have been received, of which number ten per cent. have graded mentally as approximately normal; fifteen per cent. have been found to have undergone a more or less marked mental deterioration from what was apparently originally an average normal mental condition; seventy-five per cent. of the entire number have been primarily mentally defective, exhibiting different grades of feeble-mindedness.

Broad viewpoints of the treatment of the epileptics must embrace not only the question of intrainstitutional but also extrainstitutional care, depending on the various circumstances of the individual epileptic. Every legitimate means of publicity should be employed in communities towards encouraging epileptics and those interested in them to place this class under early proper guidance in an effort to effect such change in their mode of life as may be indicated. Common sense principles should prevail in giving advice as to the general treatment of epilepsy and related conditions. Success can only be obtained from individual treatment founded upon the critical analysis of the epileptic himself. A prescription of sedatives and a few words pertaining to diet and hygiene will accomplish little.

The possibility of social advantages in the way of extension work by institutions for epileptics and following up discharged patients is not given suffi-

cient recognition. All institutions for epileptics should have a sufficiently expansive organization to permit of care being extended along these lines, such work ultimately proving of material value to the various communities thus served. Craig Colony was a pioneer in requesting funds for field workers, but unfortunately, its requests have not thus far borne fruit. In an effort to diffuse information not only by word of mouth but by action, in regard to prophylaxis, social adaptation, support of institution and other important matters so far as epileptics are concerned, too much stress cannot be laid on the necessity for applicants of better mentality being truthfully told the purpose for which they are sent to the state colony. They should not be deceived by pretending they are to be placed in a summer hotel, taken on a pleasure trip, assigned to new employment, or some other falsehood. The failure to properly acquaint the applicant with the reason why he or she should enter the institution naturally causes loss of confidence in relatives and friends and gives rise to suspicion, not only of those persons but also the institution itself, and is a potential source of difficulty in bringing about a readjustment to the new living conditions and the cooperation so essential on the part of the patient is either halfheartedly given or lacking to such a degree as to amount to an antagonistic attitude. I remember reading sometime since a comment by Dr. Copp that, "No institution can accept the fact that it is only a place to live in. It is more than a custodial function. You cannot say 'There is nothing to be done' because the patient is not going to get well."

It has been stated by investigators that about ten per cent. of epileptics seek institutional care because of present conditions. Our efforts should be exerted toward affording care and relief when such is possible to many now uncared for. It should, however, be borne in mind that the majority of epileptics so-called do not require institutional care, nor is it demanded by the community as for the insane whom people fear.

When a benevolent public and well disposed legislators can once forget the existing erroneous idea of epilepsy and look on it as an illness which is likely to attack their nearest and dearest of any age, and at any time, we hope in our own state at least, when the financial crisis passes and things assume a more normal aspect, they will awake and wonder and reproach themselves for their neglect toward this class of patients, making amends by supplying the places so sadly needed.

When the condition of the respective states warrants, I would urge an energetic campaign to provide colony care or proper supervision for a much larger number of the great group of epileptics with little mental defect in whom there is promise of improvement and who are now unable for one reason or another to obtain the continued advice they so much need. All agencies interested must cooperate if success is to be had. New York should further develop Craig Colony and ultimately establish another colony near Greater New York.

A COMPARATIVE STUDY OF THE PHENOMENA OF EPILEPSY.*

With the Actions of Normal Man.

BY CHESTER A. MARSH, M. D.,

New Castle, Ind.,

Assistant Physician, Indiana Village for Epileptics.

The spirit of the day is one of intense eagerness to build anew. The medical profession has taken part in the world's militant conflict which brought about the destruction of institutions that had ceased to insure progress and growth. But as order and purpose must always govern mankind, we now look for the signs of new laws and principles, growing out of the ruins of war, which shall make for a higher state of civilization. This is what is taking place throughout the world today and what is true of the social organism as a whole we must expect of its parts. The stimulus for this new growth in medicine is felt when we review the progress made in this field during the war. We point with pride to important advances made, under army influences, in surgical measures, and to new discoveries in immunology; to increased efficiency in methods of diagnosis and to standardization in röntgenological technic. Truly a new foundation has been laid out of the materials of destruction for a greater development in the science of medicine.

But this vast medical force, having been released from the paternalistic control of the army by demobilization, now faces, upon its own resources, the problems of readjustment. Although there is a general hope and confidence for better things, not a few men view with alarm our present status. Such a position can be held only by men who lack proper perspective. In our own particular field—the study of the phenomena of epilepsy—we find example of this narrowness of vision in those who cry that nothing but conflicting views are presented concerning the cause and treatment of epilepsy; that nothing but a confusion of ideas exists in what is said or done to help the epileptic. Such men are wont to say that alcohol as a causative factor in epilepsy is overrated and that all who suffer from epilepsy do not show a taint in their family history. They believe that the psychogenic theory of the cause of epilepsy is a bursting bubble and that feeble facts marshalled against the pituitary gland have greatly increased the consumption of pituitary extract. They feel that surgical measures of whatever kind performed on the epileptic are ill advised and indiscriminate, whether it be on the colon to alleviate intestinal stasis or on the skull to relieve intracranial pressure; and that eye strain as a cause of epilepsy cannot be held as important until some institution can prove conclusively that there is such a thing as an epileptic eye. They are able to offer only unfavorable criticism as a reward to the workers of the past.

Knowing then that in past experience is found the elements of truth upon which progress is made, we cannot wholly disregard any particular line of investigation that has been made in the study of epilepsy. Though we realize, perhaps, that we can

utilize but little of the information thus obtained, we are compelled to examine in detail material that often seems irrelevant. Our reason for wanting to know something of the family history, something of the health or sickness of brothers and sisters, of father and mother and other close relatives, then becomes apparent. We see why it is important to know something of their mental calibre, of their temperament as to industriousness, of family traits, of tendencies to nervousness—in sickness or in health—of insanity, feeble-mindedness or epilepsy, peculiarities as to eccentricities, mannerisms, geniuses or cranks, of immorality, sexual or criminalistic tendencies, of chronic disease, including syphilis, tuberculosis, cancer, alcoholism or drug addiction. All of these are important as well as any other condition of disorder the family may manifest.

In the personal history of the patient, also, we spare no effort in our examination of details. Factors bearing on the prenatal history of the patient are not without importance in the disorder of epilepsy. We want to know in particular something of the general condition of the father and mother at the time of conception of the patient—were they healthy—were they intoxicated—what was their mental state at the time—was the child desired or was it an accidental conception—was there an attempt at the time or afterward to interrupt the pregnancy? It is important to know how many induced abortions and how many which were without intervention; the condition of the mother's health, both mental and physical, during the pregnancy; whether or not at this time she was sick or received an injury.

In the postnatal history we should know something of the health of the patient at birth and during the nursing period; something of his mental and physical characteristics up to the school age, and in particular his temperament; as to whether or not he had crying spells, fits of anger, or a tendency toward whims, and whether or not he had broad interests in play. In his school history we should know whether or not he was normal, slow or precocious in his studies. Whether or not he took well with playmates and possessed lots of friends; were broad interests developed, and the nature of them.

When we take up the immediate complaint of the patient, it is interesting to know the patient's and family's assigned cause of the disorder; the character of seizures and the duration of the affliction; the disposition of the patient previous to the onset of the affliction and before and after seizures.

The physical examination should be thorough and complete; any physical defect on inspection, palpation, percussion and auscultation, should be noted. This should include complete laboratory tests of the urine and blood, with x ray findings of the head, chest and alimentary tract. This of course includes a complete neurological examination, localizing as far as possible the seat and type of lesion discovered. In doing this, all reflexes should be tested, including the pupillary, abdominal, knee, and others; sensation, tactile and deep muscle sense; station, cerebellar by the Romberg; tremors of the eyes, mouth, face and fingers; speech by test phrases.

The mental examination should be as complete

*Read before the National Association for the Study of Epilepsy at the New York Academy of Medicine, June 3, 1920.

as we can make it. In this, the mental age of the patient should be determined, as by the Simon-Binet test, for example. His emotional life should be viewed as manifested at different periods in his life, showing particular and general interests in surrounding affairs, noting especially his temperament under conditions of stress and under favorable circumstances, with special emphasis of any manifestations of a lack or poverty of emotional interests. It is particularly important to note how the patient sleeps, if well and how long, whether or not it is shallow, restless, or with a tendency to dream and the nature of the dreams. The mental examination should include an observation of the patient's powers of perception, noting illusions, hallucinations and delusions, either admitted, elicited or indicated; his powers of consciousness, whether clear or befogged; of attention, whether normal or distractable; of memory, whether it is good for recent as well as remote events; of orientation as to time, place and person; his train of thought, whether it shows retardation or a flight of ideas; his power of judgment, rational or delusional; if the latter, whether of persecution, fears, selfaccusation or of grandiose ideas; his judgment as to the value of things; and his general conduct at play or at work, at home or in an institution, without restraint or under close guard.

In a general way this is the nature of a proper examination of our patient. The rehashing of these points no doubt has been tiresome. It has not been my purpose, however, to put myself in a position to say what method should constitute a proper examination. My purpose is rather to emphasize the importance of a careful examination of the patient. Through such an examination, we are able to discover not only any process of disease or mental disorder which our patient may have, but we come into possession of knowledge which helps us to understand more fully the factors at work which produce a convulsion and tend to its repetition. We are able to pick up those elements of truths from these various sources of investigation once supposed to explain the phenomena of epilepsy and putting them together we are able not only to see their particular application, but we are able to draw conclusions from them which throw a better light on our problem.

In the past we were wont to look upon epilepsy as an entity in itself, just as we now view syphilis, typhoid or cancer. From such a viewpoint, the bacteriologist hoped to find a germ as the causative agent. But no infectious organism is found which produces the disorder. From a similar position the pathologist with untiring toil labored to discover some gross lesion which would account for the condition. But no pathological condition is known that is common to all so afflicted. In a similar manner the clinician has failed to establish such theories as endocrinological disturbance, acidosis or increased intracranial pressure. The psychiatrist, by a classification of abnormal mental symptoms as seen in the epileptic, points to a generalized instability of the cortical centres and to an inherited nervous tendency. A more recent classification presents a very careful study of the mental symptoms of the

epileptic, from which a conclusion is drawn that there is an epileptic type, a person with a peculiar but definite mental makeup, which, when present, constitutes a potential epileptic character that goes the epileptic way when a certain type of stress is encountered. Unfavorable criticism is not to be passed upon any of these theories for it is work of a constructive nature which guides us in the care and treatment of our patient.

We cannot, however, in our study of the phenomena of epilepsy, view it from any particular angle alone. We must strike a deeper level than that where mental symptoms are classified or where epilepsy, spoken of in the plural as the epilepsies, is classified according to known or unknown symptoms. We must do more than classify. Our problem leads us to a point of broader perspective where processes of physical and mental disease may be observed in their proper relation in the disorder. We must see that both physical disease and abnormal mental processes produce activity of a particular character and that the whole phenomena of a partial or entire loss of consciousness, with or without convulsions, can be explained only in terms of action of a definite type.

Bodily activity of all kinds is dependent upon mental states of which we may or may not at the time be aware. These mental states are purposeful in their operation for they act as the motive force behind our actions. When they find expression in a normal manner, they tend to secure for us our general good fortune. Should they find expression in an abnormal manner, however, and be habitually exercised in this way they may lead to the possessor's destruction.

The phenomena of epilepsy is an example of an habitual abnormal expression of mental activity. The epileptic, when he meets unsurmountable difficulties, is beset with mental states over which he has no control. Everything which emphasizes the futility of his efforts serves all the more to increase his emotional drive until the higher brain centres, which have to do with the directing and the consciousness of efforts, are exhausted from overwork because of this extreme nervous tension. This exhaustion means a cessation of function until a period of rest intervenes. So the patient suffers, according to the degree of fatigue or exhaustion which exists, a partial or complete loss of consciousness. This is not deep enough to involve the motor centres, so the emotion goes on to expression in muscular activity partially or wholly unguided and undirected, which we know as a convulsive seizure. When this becomes the patient's habitual channel of outlet for strong emotional states, we denote the condition as epilepsy.

The factors which tend to produce these strong mental states, while numerous and varied, are cryptogenic in their nature. By a classification of the mental symptoms as seen in the epileptic, some workers have thought that they could account for the disorder on the basis of an instability of the cortical centres of the brain. From a similar reasoning we have heard of the term psychogenic epilepsy. Such a conception is confusing and misleading, for mental states, as such, which cause us to act, come

only as things attract or excite us and they come from without and not from within the brain itself.

The manner in which we react to these things which draw our attention is dependent largely upon our general attitude toward things about us. A normal man has always cultivated broad interests in the things of life so that when he is confronted with an experience of an unpleasant nature, he is able to escape it by entertaining more pleasant thoughts, that are ever striving for recognition in his mind. Such conflicting thoughts tend to weaken strong emotional states. The epileptic, however, is not of this temperament. He gradually drifts into a life of restriction through an intensive application of his energy to particular instead of broad interests.

The tendency of the epileptic toward a poverty of interests in life is one largely of circumstances over which he has but little control. Such persons, it is true, are often endowed with family traits of nervousness, manifested usually in overindustriousness; yet misfortunes of some kind in which there are blighted hopes can usually be found which lead them into a life of restricted pursuits. Sickness, sin and poverty have been said to be three of the greatest scourges of society, which lead to untold misery and suffering. They work hand in hand, often as a vicious circle, reducing the possibilities of pleasurable activities of every individual touched by them. These conditions, as manifested in the epileptic, do not point so much, then, to an individual endowed primarily with inherited mental stigmata as they do to the handicap society places before him as he seeks good fortune.

The following case histories are presented to show the processes at work which produce thwarted ambitions, narrowing of life interests and an epileptic reaction as a result of strong emotional states of mind:

Case I.—751—Patient O. A. S.—Male, aged forty-one, divorced, admitted December 19, 1919. First epileptic attack at age of thirty-two. Infrequent at first, but later occurring about once a month, at which time he had three or four severe spells. Patient gave a history of several convulsions at the age of two years, when he suffered much from colic and indigestion. The patient's family history was negative for chronic or mental disease of any kind. Physical examination of the patient was negative except for partial atrophy of both testicles which followed as a complication of mumps at the age of fourteen. Mentally the patient seemed normal, except that he was of a nervous and restless disposition. He was very industrious and headstrong at times. While he was ever ready to carry on a general conversation, it was impossible to get him to talk of his own life.

The following information was obtained from his sister, who visited him at the institution: She related that as a boy he was exemplary in his habits and not different from his associates. At the age of twenty he was married to a beautiful girl, a woman ideal in character and disposition. They lived prosperously and happily on a farm in Indiana for eight years, but no children were born to them. At the end of this time, upon the solicitation of his wife,

who wished to live near her brother, they moved to Oregon. Shortly after a year had passed the patient suddenly appeared at his mother's home in Indiana. He was found walking back and forth in the back yard of her home. Upon being asked what he was doing back home, he remarked that he had stayed away from his mother as long as possible. His mother and sister, noting that his visit was rather an extended one, persuaded him to have his wife return. After six months she came back. Five months later she gave birth to a baby boy. Nothing was said to either the wife or patient and no trouble arose between them. Shortly afterward, they returned to Oregon. A year later the patient suffered his first epileptic attack.

Having given me this information, the sister warned me not to mention this to her brother, saying that he became raving mad when the subject was mentioned. Thinking that the patient would be benefited by an explanation of the factors at work in his disorder, her admonition was disregarded. Almost at the first word, the patient was aware of the nature of my interview. He became violent in his manner of speech, censuring me in vigorous terms for bringing up unpleasant memories which he so earnestly attempted to keep from his mind. After his anger was spent, an attempt was made to have him understand that he could not expect to bear his troubles alone in silence and that with a better insight into the workings of his mind, he probably could be helped to avoid his silent brooding which had much to do with his seizures. He sat in silence, but before many words were said, he fell unconscious in a convulsion. The syndrome of physical disease and permanent disability, marriage and thwarted ambition because of this disability, the invasion of his home, the sin of his wife and all that went with it, and finally the bearing of his unpleasant experience without visible complaint until the break came, is interesting material for speculation.

Case II.—525—E. S., male, aged forty-eight, married; admitted October 16, 1916. Seizures, grand mal in type; patient often irritable before a period of seizures, which come at about three weeks' intervals or oftener, and disturbed a few days following. During disturbed spells he had illusions of things crawling about him; "wants to settle the thing; put over the deal in first class order." At such times he had a tendency toward violence and destructiveness.

The family history was negative. Patient had three healthy, grown children. The personal history showed that the patient had always been healthy except for scrofula at six years of age, which was said to have been very severe. Patient showed no present signs or symptoms of this condition. Physical examination on entrance to the institution negative. The patient was a robust man with no apparent physical defects. Blood and spinal fluid repeatedly negative. Mental examination during the intervals between seizures showed that the patient had no marked mental deterioration. He was very industrious and capable. He was able to direct other patients in their work, but was prone to use force when his leadership was questioned.

Careful inquiry regarding the patient's past history brought out these interesting facts. As a boy, his school days were limited. Most of his time was spent in his father's mill, where he did more than a man's work. He never had a vacation, never had time off, but, as he himself said, "always had his head to the grindstone." His married life, although happy, stimulated him to increased efforts, more especially when it became necessary to provide for his children. He became a man of means, yet he never gained the wealth he desired for his family. In late years he became farmer, merchant and automobile salesman, so eager was he to accumulate money. He has often said that he never could stand to fail in selling an automobile. In fact, he stated that he never gave up until a deal was made.

While at the institution his main desire was to get back home to his family. When it was explained that he must get his mind off this subject if he ever expected to get home, he agreed to try to do so. He succeeded for a time in keeping unpleasant thoughts away by employing his mind in work at hand. He went over two months without a seizure, when one Sunday evening he suffered an attack. The next morning he admitted that he had been thinking* about his family, but stoutly maintained that he had not let his thoughts get to the point of unpleasantness or worry. He explained that he had been sitting on a bench in the yard watching the road. As each automobile approached he would say to himself: "That's my wife and children coming for me." When they passed by, however, he urgently maintained that he did not worry about it, but watched for the next machine in order to repeat the same process. He was quite surprised when he was told that the whole experience was an unpleasant one; that, to be a pleasant one, the machine would have to turn in, bringing his wife and children; that to watch each car with a desire in his mind was building up hope after hope, with the greatest suspense which is always unpleasant until the desire is satisfied. The patient was never able to stop worrying about his family. With a broad smile on his face he was ever ready to say, "Doctor, I believe that we ought to be able to get together in an agreement whereby I can get home for a while at least." He died recently in an epileptic seizure.

We might go on indefinitely reciting, from case histories, the influences at work in the disorder of epilepsy which limit the patient's field of pleasurable activity, for they are infinite in number. Each case manifests them in its own peculiar manner. But, aside from mental complexes, the stigmata of disease plays a strong part in this way. Syphilis probably is one of the greatest. Between twenty-five and thirty per cent. of our patients show a positive blood Wassermann, all of which, except a very small proportion, is congenital in type. The body as a living organism resents such infringement upon its welfare and when consciousness is impaired, a convulsion is one of the forms of resentment.

It is difficult to say just to what extent the toxins of syphilis and other diseases, or exogenous and endogenous toxins of whatever source, affect the

conscious centres of the brain. The greatest apparent damage results, however, from permanent disablement, which is an end result of processes of disease. The hemiplegic patient, for example, is prevented from entering into normal pleasurable activity because of his affliction. If he is energetic, he becomes the victim of thwarted ambitions. He comes not only to a full realization of his physical and mental handicap resulting from the inroads of disease, but he is made to feel that he is different from normal people and consequently is no longer able to associate with them on an equal footing. His life from this time becomes one of isolation in spite of his efforts to prevent it. If he persists in his attempts to take part in the activities of those about him, he becomes an object of ridicule and abuse. Denied desired pleasurable pursuits and being handicapped because of a restriction of outside interests, the patient tends, when obstacles on every hand confront him, to become explosive in character. In the face of unsurmountable difficulties, which serve only to increase strong emotional states of mind, the epileptic reaction comes as a complete breakdown to physical and mental effort.

Examining the disorder of epilepsy from this point of view, we come into possession of definite principles applicable in the care and treatment of our patient. These principles have long been understood by those experienced in handling the epileptic, but the general practitioner and surgeon have often been the victims of advice of doubtful value. When in this light we come into a full realization of the meaning of the phenomena of epilepsy, we see in our patient a person who may be afflicted, not different from any other person, with a surgical or diseased condition. Disease processes are then combatted, not with the hope of curing epilepsy, but because the patient is sick. Surgical procedure is instituted when the patient has a surgical condition and not to stop epileptic attacks.

We treat the patient, and not a disorder. Our patients, for example, may have syphilis, which has much to do, as we have seen, as a causative agent in the production of seizures, yet we do not hope to cure epilepsy by arresting syphilitic processes. We may, by treatment, produce a negative blood and spinal-fluid. We may also place a patient in such an environment that he may be helped to avoid strong emotional states of mind and therefore have his seizures temporarily or permanently controlled. Perhaps even then our prognosis can be no greater than is offered in other processes of disease. The army ruling held that malaria is never cured, but only arrested. Syphilis, once thought to be completely driven from the human body by salvarsan and mercury, is now thought to be arrested only and not cured. Epilepsy no doubt will be considered in this way. Our hopes then in controlling the disorder will be similar to those in diseases of all kinds. Understanding the phenomena, we shall expect only to arrest and not cure the disorder. The future problem will engage our efforts in the prevention of epilepsy just as the supreme purpose of the medical profession is to prevent disease.

In conclusion, then, it may be said that constructive thought is fostered today in every human interest. The ideas set forth in this brief space are intended only in this spirit and the views presented make no assertion to any sort of completeness. They aim at stimulating thought and challenging discussion, for it is only by exposing our own and correcting each other's errors that thought is advanced. Likewise, originality is not claimed in all that is said here, for we build only upon the materials of past experience. Perhaps when all is known about the phenomena here considered, some one will come forth with a review of the literature, giving everyone due credit for the part which they have played in the work. At the present, as we gather from all the sources possible, the beginnings of knowledge on the subject, we can but strive to see it in its proper relation. In this light, epilepsy is considered here as an abnormal muscular expression of strong mental states. It is a particular type of reaction which occurs when purposeful efforts of mind and body come to defeat. It is seen in an individual who, possessing a poverty of interests in his environment, cannot, as the normal man does, escape strong emotional feeling by entertaining conflicting thoughts which weaken strong mental states.

MENTALITY IN EPILEPSY.*

BY WALTER H. KIDDER, M. D.,
Oswego, N. Y.

However clear, however familiar to even the casual observer, are the grosser symptoms of those manifestations which we call epilepsy, the causes, the pathology, and even the more detailed symptomatology, are so vague and so shrouded in mystery that he who ever writes upon the subject must needs be either very brave or, perhaps, sometimes only foolish. However, even in this day of specialization, epileptics are, in the main, observed and cared for by general practitioners, and it may not be inapt for one who represents in some degree the unspecialized mind to bring before you briefly observations of a few simple things which help the less skilled in the study and care of the epileptic.

Looking back over the writings of the past three or four generations we find a fairly clear, if wholly arbitrary, distinction made between nervous disease and mental disease. Even though the present day neurologist has allowed the psychiatrist to purloin some of his neurasthenics, and the psychiatrist has been forced to accept epileptics, provided, of course, their epilepsy was with psychoses, the nervous and the mental classifications remain apart, as separate and distinct.

To the casual observer the nervous symptoms of epilepsy have been so manifest that it is not strange that writers have uniformly classed this disorder with the nervous diseases. Without regard to its technical accuracy, this classification has given to the student and to the general observer the tendency to pay more particular attention to the somatic and

nervous manifestations than to the less apparent, if none the less definite, mental picture. From the earliest days there has been recognition of the grosser effects of this disease on the mind. In ancient times it was called the sacred disease, "Because it affects the Mind, the most noble and sacred Part of a rational Creature" (1). To this terminology Hippocrates took exception, and of those who called it the sacred disease he said, "Such persons, then, using the divinity as a pretext and screen of their own inability to afford any assistance, have given out that the disease is sacred, adding suitable reasons for this opinion, they have instituted a mode of treatment which is safe for themselves, namely, by applying purifications and incantations, and enforcing abstinence from baths and many articles of food which are unwholesome to men in diseases. . . . All these they enjoin with references to its divinity, as if possessed of more knowledge, and announcing before other pretents, so that if the person should recover, theirs would be the honor and credit; and if he should die, they would have a certain defense, as if the gods, and not they, were to blame." (2). In the fifth century Cælius Aurelianus wrote a masterful description of the physical characteristics of epilepsy, and added, "The Mind is anxious and uneasy, prone to anger on the slightest occasions, . . . forgetful of circumstances almost immediately before transacted, and ready to be clouded and overcast with the impressions of gloom and melancholy" (3). Nearly two centuries ago an English writer opened a dissertation on epilepsy with this sentence: "Among the several Calamities to which human Nature is subjected, none is more justly formidable, than that universal and involuntary concussion, and violent Agitation, of the external Parts, which is accompanied with a Suspension both of the external and internal Senses, and which we commonly call an Epilepsy; for, during the Shocks of this terrible Misfortune, the body is not only variously distorted and deform'd, but also the Mind, as it were, unhing'd, and deprived of its genuine Powers" (4). So, wherever we turn in literature, descriptions of the epileptic contain references to the effect of the disease upon the mind.

As an important factor in the causation of the epileptic attack mental influence received early attention. After advising that patients suffering from epileptic convulsions "abstain from food one day in four," Celsus, writing in the first century, says: "Intense thoughtfulness, or fatigue of mind, is also to be guarded against . . . for application of mind is not safe for those who are subject to this disorder." In the second century Galen made similar comment, citing the case of a schoolmaster; and an old but more recent writer said: "But, above all things, every occasion of terror, dread, or anger, is to be carefully avoided; because these have a strong tendency to bring on the paroxysms" (5). In all of these early comments the question of mental influence receives little attention except in relation to the individual convulsion, though many writers, from Cælius Aurelianus down, including Esquirol, Jules Falret and Trousseau, came hopefully near to drawing a picture of the basic epileptic

*Read before the National Association for the Study of Epilepsy, New York, June 3, 1920.

mentality. In 1861 Jules Falret wrote: "The intellectual disorders observed in epileptics may be divided into three principal categories: First, those which, manifesting themselves in the intervals between the attacks, are independent of these, and constitute the habitual mental state of epileptics; second, those which occur temporarily before, during or after the attack, and may be considered as epiphenomena of the attack itself; third, and last, intellectual disorders, more or less prolonged, which coming on in paroxysms, either directly connected with the convulsive or vertiginous phenomena, or occurring independently of these, specially deserve the name of epileptic insanity." Again, when we compare the basic epileptic mentality with that of simple developmental inferiority, this writer helps us in the establishment of a differentiation, mentioning particularly the high degree of capability to which the epileptic mind will at times rise, as shown by well known historical characters.

Perhaps it was only suggestions of history which led Dr. Ireland in his series of charming psychological biographies to dwell upon the epileptic mentality as attributed to Cæsar, Mahomet, Napoleon, and others. Some of us, however, prefer to believe that his long association with the developmentally subnormal and the epileptic had bred in him consciousness of the existence of a distinct type of mentality in the epileptic, and that his recognition in these historical characters of an often diminished repressive function and a moral obliquity to consequences furnished a basis to his diagnoses.

Two years ago, Dr. L. Pierce Clark said: ". . . Given a certain potential constitution plus a special type of stress applied to it, we gain a certain psychological effect which we have called the epileptic reaction. . . . The epileptic constitution has long been recognized as the enduring mental stigma of essential epilepsy itself. Only recently have studies disclosed that the main tenets of such a character are present years before the nervous disorder of epilepsy is shown in fits. . . . A disintegration of habits and character, known as deterioration, occurs more easily in one thus handicapped by a defective endowment. Therefore, mental or behavior deterioration often precedes actual epileptic seizures for a considerable time. . . . Any effective plan of treatment must essentially take strict and early account of the makeup of epileptics, before all else" (7).

That epilepsy, or for that matter any other disorder which profoundly affects the neurological, the psychological and the sociological life of the individual, usually induces pronounced mental involution, is recognized. It has been remarked that "Epilepsy and feeble-mindedness show a great similarity in their hereditary reactions and both appear to be due to a defect of the germ plasm, that is, they are both recessives" (8). In the true case of feeble-mindedness we expect change to be limited to a single direction, regression. On the other hand, we meet epileptics whose mentality shows what we may regard as the psychic epileptic characteristic, and we find, under wise direction and treatment, these patients showing improvement in mental condition and adaptability. In other words, in the

epileptic mind we find two more or less distinct types of subnormality. The one is relatively obvious, occurring particularly in the epileptic of long standing, a resultant condition fraught with hopelessness. The other is more vague, representing a basic state which may long antedate the appearance of the grosser symptoms, or may even exist throughout life without the accompaniment of convulsions or other somatic disturbances, and which is not necessarily progressive.

Of epilepsy we are told that it is "worth while to consider the attack as due to a faulty distribution of energy which may be brought about in many ways and through divers mechanisms" (9). However we regard the ailment, whether as a disease, a symptom, complex, or what not, we must recognize one fact: Its symptoms are strikingly definite. Physically, few diseases exhibit a clearer or more constant line of symptoms. To some of us the mental picture seems no less determinate. The deductions of logic do not lead us to expect definite results from various and indefinite causes. However much we may be impressed by the variousness of influences which may promote the development of epilepsy, he who asserts that the disease is not an entity will do well to guard his declaration with qualifications. If we have a basic mental condition essential to the development of epilepsy, whatever influence tends to better that condition must in great measure help in combating the general epileptic state.

Some of us have come to the idea of basing our prognoses on the mental state, and to gauge progress by mental change. In children we even go so far as to base our estimate in part on the psychology of the child's adult associates and mentors. We impress upon the child and upon the parents the necessity of developing the cheerful viewpoint, of avoiding displays of temper, the sulks and the general spirit of contrariness. To the parents of the child and to the adult or near adult epileptic we give a matter of fact explanation of the seriousness of the disease, and we tell them that a patient entering upon a course of treatment is like the acolyte who seeks entrance to a monkish order. Trials and tribulations and selfdenials will be his, and they must be met with fortitude and with cheerfulness. To each epileptic we give a life purpose, the purpose of overcoming his disease. Without effort to eliminate individual mental conflicts, the effort is made to develop a poise which makes conflicts unlikely.

It is interesting to note that in an epileptic whose acute attacks are fairly well controlled by a given dose of bromide or other sedative drug, consistent mental therapy permits equally good results with a much reduced dose of medicine. Moreover, when so administered the use of bromides is not accompanied by increased mental dulling, but oftentimes by a distinct gain in mental acuity. In prognosis it is much safer to base predictions upon this mental change than upon the exact numbers or character of the fits. Though the administration of the bromides to these patients has been strongly criticized, few now deny their usefulness. Let me predict that the time will be when the place of mental

therapy in the treatment of such patients will be as firmly established.

EPILEPSY TREATED WITH LUMINAL.*

Preliminary Report of Twenty-two Cases.

BY HARVEY M. WATKINS, M. D.,

Palmer, Mass.,

Assistant Physician, Monson State Hospital.

The treatment of epilepsy has always been most unsatisfactory. Each year we see new drugs and new combinations being introduced as curealls for the relief of convulsions and as each of them is gradually discarded we again turn to the bromides, meanwhile continuing to look for something better, more satisfactory and with less bad effects. Before the war a new product, luminal, appeared on the market. This was used at the Monson State Hospital during part of 1913 and 1914 after which it could not be obtained. Since then it has again appeared and various assertions have been made for its use, particularly in epilepsy.

CLASS OF DRUG AND DOSE.

Luminal, known chemically as phenylethylmalonylurea, belongs to the same class of drugs as veronal, trional and barbital—the so-called ethylated compounds. It was first made in Germany but recently has been made in this country. It is made in two forms, tablet and powder. In epilepsy the dose varies from three quarters to one and a half grains twice daily in tablet form although the powder form, luminal sodium, may be used subcutaneously, five to ten grains in freshly prepared solution. The assertions made for luminal vary. According to the manufacturers it possesses a pronounced sedative and antispasmodic action in epilepsy even in small doses and according to a prominent authority, acts virtually as a specific in some cases. Bad effects are practically absent when given in customary doses.

Dercum (1) reports that in epilepsy even when most confirmed, the drug exercises a remarkable control over the seizures. "The latter were usually promptly inhibited altogether." Also that the drug seemed to exercise more control over the group of so-called essential epilepsies. "Indeed in some instances the drug acted virtually as a specific."

My own rather brief observation with luminal covers a period of three months, February, March and April of 1920. During this time I have administered the drug to twenty-two patients, no other medicine being used except an occasional laxative.

Seven of my patients were of the idiopathic type, five were patients in whom the petit mal seizures predominated, two were status patients and the remaining eight patients were those in whom there was an equal distribution of grand mal and petit mal seizures. The method of administration has been one and a half grains in tablet form twice daily, night and morning.

Among the first symptoms noted following its use was the constant and almost universal complaint of sleepiness and drowsiness. These later developed into various symptoms resembling those of bromism—dizziness, depression, mental apathy, confusion, memory defects, hallucinations and delusions—practically all of the bad effects of bromides were observed with the exception of the rash. At the end of two weeks the drug was reduced one half in seven patients who showed the more marked symptoms of bromism, but the symptoms persisted, although with less severity. In two cases it was necessary to withdraw the drug entirely at the end of one month on account of the development of severe mental symptoms.

The most marked effect of the drug was noted in the decrease in the number of convulsions. This effect was noticeable the second and third days following its administration. There was a decrease in the number of convulsions in every case with the exception of two in which there was an increase. The seizures were greatly reduced even in the two cases in which the drug was entirely withdrawn after a month.

The number of convulsions during the three months while taking luminal was—first month 199, second month 143, third month 141, a total of 483 and an average per month of 161 or 7.31 per patient per month. For three months previous to luminal administration there was a monthly average of 532 convulsions or 24.18 per patient per month. These figures are based on three month periods and indicate a reduction of seventy per cent. in the number of convulsions while taking the drug. The monthly average for one year previous to luminal administration was 476 as compared to 161 convulsions while taking luminal, showing a reduction in number of sixty-six per cent. in all classes, which seems to be the more accurate percentage of reduction.

The lessening in the number of convulsions was most marked in the idiopathic cases, the percentage varying from twenty-two to one hundred per cent. There was also marked reduction in the petit mal cases except in one instance in which there was a very high increase of 330 per cent. In one other case there was an increase of 108 per cent. in about an equal distribution of grand mal and petit mal seizures. In the two status cases there were no attacks of status during the three months, but the patients did have an occasional grand mal convulsion.

The smaller doses seemed to have practically the same effect on the control of seizures as the larger. There was no appreciable change observed by me in the weights of the patients, little or no change in blood pressure, temperature or respiration. The mentality did not seem to improve under its use as in only one case was there improvement mentally.

*Read before the National Association for the Study of Epilepsy. New York Academy of Medicine, June 3, 1920.

UNTOWARD EFFECTS.

The manufacturers assert that under the use of customary doses bad effects are practically absent. Dercum states that he observed at no time the slightest deleterious or untoward effects on the mental life of the patient—"nothing indeed save the cessation of the attacks." Farnell (2) reported two cases in which there were toxic effects, both patients showing speech disturbances, slurring, scanning and parasphasic. Ataxia was marked in both cases. In one there was tendency to drop foot and the knee reflexes were absent. The dose employed was from five to ten grains.

Symptoms of bromism were present in the majority of my patients, but in only two would I consider the effect toxic. One patient began to show untoward symptoms from the first, had periods of crying and confusion which later developed into delusions of persecution. Finally she threatened bodily harm to anyone who came near her and it was necessary to watch her closely. The luminal was reduced one half without any change in her mental condition and at the end of a month was discontinued entirely.

In the other patient there were hallucinations, both auditory and visual, later crawling on the floor, climbing the doors and windows, appeared unsteady in gait, would disrobe frequently and remain in a nude condition unless constantly watched. The drug was discontinued after a month as she became more confused. She was in this mental state eighteen days out of the thirty during its administration. After having five seizures she became more rational.

The first patient had no convulsions during luminal administration and the second patient showed a decided decrease in the number of convulsions. I believe I would have had a higher percentage of toxic effects had the drug not been reduced in seven cases. Its effect should be watched carefully as its administration is not unattended with untoward symptoms.

WITHDRAWAL SYMPTOMS.

Immediately following the withdrawal of luminal there was a large increase in the number of convulsions in practically every case. As is true in all drugs that have a tendency to control convulsions, once the drug is discontinued the number of seizures rapidly increases. Seventeen of the twenty-two patients had convulsions within the first ten days, three of them being in bed for one week. The two status patients had severe attacks of status within fifteen days. There was an average of 32.64 convulsions per patient per month following its withdrawal as compared to 24.18 previous to taking the drug and 7.31 convulsions per patient while taking luminal, showing that the epileptic habit returns seemingly with increased vigor following its withdrawal. No other withdrawal symptoms were noted as the use of the drug appeared to be unattended by pleasant or euphoric sensations.

CONCLUSIONS.

Cures are not to be expected. It is at best a palliative remedy. It is not virtually a specific.

It reduces the total number of convulsions in all classes sixty-six per cent. although a small proportion

of patients have an increased number of convulsions during its use. It has practically no effect upon some patients, and about ten per cent. show untoward symptoms from its use.

It has all the bad effects of bromides with the exception of the rash.

The drug must be used over a long period of time and continually, as once its administration is discontinued the epileptic habit returns with increased severity.

Undoubtedly luminal serves a field in the therapeutics of epilepsy. It is worth a trial in every case but to determine its relative value it will be necessary to use it in a great number of cases and over a long period of time.

PRACTICAL EXPERIENCE IN THE
TRAINING TREATMENT OF
EPILEPTICS.*

BY T. E. UNIKER,
Stamford, Conn.

This paper contains data taken from notes obtained in a careful study of a series of cases of essential epilepsy, ranging in age from ten to fifty years and covering a period of ten years' duration. During this period of observation, the general plan as regards physical treatment, changed but little. At first the attention was centred upon the possibility of some physical defect being responsible for the attack. Extensive x ray examinations were made of the head, the stomach and intestinal tract. The blood and spinal fluid in each case were carefully examined and a daily analysis of urine made until all signs of intestinal putrefaction had disappeared. Special attention was given to the correction of poor digestion, constipation and faulty circulation and a proper diet administered at all times, but as the physical defects were relieved and the attacks continued, more attention was paid to assisting the patients to adjust and adapt themselves to the simple environment the club life offered, for the patients were housed in a simple homelike residence in the country which we called The Club. It had been evident from the beginning that all the patients, without exception, showed periodic states of annoyance, irritation and lethargies in various degrees of severity according to their character makeup, and it was further noted that such states always terminated in a climax of one or more attacks.

All patients gave a history of sedative treatment before coming under observation and all showed a general tendency to sluggish circulation and low blood pressure. They were constipated and had mucocolitis in various stages. All the sedatives were stopped soon after the beginning of treatment.

*Read before the National Association for the study of Epilepsy, New York Academy of Medicine, June 3, 1920. The case material used in this paper was obtained while assisting Dr. L. Pierce Clark in his private service.

Colon irrigations were given at frequent intervals until the colitis disappeared. A daily routine was prescribed for each patient that involved more or less physical activity, such as walking, gardening, tennis, baseball and shop work. Under this careful training all the patients soon began to take on a healthy appearance. Their skin became clear, the expression bright, they were more alert and the muscles were firm. The constipation and colitis were corrected; the poor digestion returned to normal; the sluggish circulation improved and to all appearances these patients were as perfect physically as medical science could make them, but nevertheless their attacks continued with the same degree of force and frequency. It was noted, however, that as they gained in physical strength, their attacks did not seem to produce as much fatigue, and they recovered more quickly.

The one dominating factor that remained unchanged was the attitude of the patients toward their environment. This was characterized by a rather passive, indifferent state as regards routine work. If they did display a normal reaction to their environment, it was short lived and what they accomplished was but little compared to the time and energy expended. They performed their daily tasks in a mechanical sort of way and had to be constantly directed, or it was necessary to make suggestions that would remind them of their responsibility. Little or no spontaneous action on their part was observed unless the task promised some personal reward. They were not consistent in their work but had fits and starts of action and it was noticeable that they found it difficult to concentrate well for any length of time without becoming mentally fatigued and showing distraction. Above all, they were extremely sensitive. Some personal discomfort, however trivial, caused great anxiety, while a greater disaster to a fellow club member caused no effect and was promptly forgotten. The patients seemed always to be wishing they could do something that was beyond their mental and physical fitness and were extremely selfcentred. They had few interests outside that which immediately concerned themselves or their family. Regardless of age, they showed an abnormal infantile attachment to parents. They were slow both mentally and physically; stood stress of any sort poorly and rarely if ever appeared genuinely happy. They appeared to be constantly at war with their environment and were forever finding it difficult to adjust and adapt themselves to any change, no matter how simple. What seemed quite pleasing one day might be annoying and irritating the next. Their rapid change of mood went hand in hand with their ability to adjust to the social demands their very existence imposed upon them. They got along poorly with each other and were constantly pointing out defects the others had, but failed to note or recognize that they possessed the same traits themselves. They would have quiet spells where they displayed a strong desire to retreat from the club group and would go to their rooms, busy themselves with looking over their personal belongings and lapse into day dream states. The content of the dreamy states always revealed a personal wish that the

patient seemed unable to gratify or to find anything that would compensate.

All of the characteristic traits mentioned above continued as the patient retreated from his environment. This retreat varied in length according to the individual's ability to stand the mental stress that such a condition involved and then the cycle terminated in a climax of convulsive attacks.

Following the attacks there was a short period of mild lethargy and then the patient began life anew, with a clean slate. The environment, that previous to the attacks seemed so annoying and irritating, now was no longer troublesome. It existed just as it did before the attacks. The patient came in contact with it, but the attack had evidently compensated in some way for the time being and left him apparently contented under conditions that were previously unbearable to him.

In nearly every case the attack acted as a sort of protective mechanism by creating an amnesia for all the annoying and irritating factors present previous to its occurrence. Conditions and events that the patient could not make adjustments to were erased from his memory, sometimes forever, never to be recalled, while in other cases a recalling of painful events immediately brought on another seizure. This protective mechanism enabled the patient to exist with a fair degree of comfort for a time, until the effort to adjust and adapt himself to his environment once more automatically caused the retreat. The symptoms continued until the attack came to his rescue.

Further details concerning the constitutional makeup of the epileptic as I had opportunity to observe it during this study, while I lived constantly in daily contact with the patients, are unnecessary. Dr. L. Pierce Clark has frequently given the facts to the medical profession. They prove the existence of this characteristic makeup so conclusively that there is no room for doubt that it exists and is present long before the first seizure. It is needless for me to say that I found all the patients under my care battling with reality from day to day just as they were able to adjust and adapt; being governed entirely by the degree of constitutional makeup they possessed.

The periodical seizure reactions always relieved the stress of meeting responsibilities the club life presented and shut out the painful conflicts. It then became obvious that the problem was one of reeducation. Once it had been proved that everything possible had been done to correct physical factors, and no relief from the attacks occurred, it was assumed that the patient being unable to meet reality, retreated away from it and that the attack was the climax that brought relief from a state that was unbearable. It was at this point of the study that a plan of reeducation and tactful training was inaugurated with the hope, that by frequent explanatory interviews, at a level of the patient's ability to grasp, he would gradually gain an insight into his defects and learn to adjust and adapt accordingly, thereby preventing the necessity of the retreat which always resulted in attacks. With this view in mind, a careful study was made of each patient's reactions to his environment. His character behavior, charted

daily, showed that when his interests were spontaneous and he was actively engaged with his tasks, he had little difficulty, but as soon as he began to day dream and display states of irritation and annoyance, it was always a sign that sooner or later an attack would follow, unless something could be done to assist him to meet the issues that were evidently the cause of the retreat.

The following plan was then put into operation. Just as soon as the patient began to display day dream states, or became unduly annoyed or irritated, he was taken to a quiet room and told that we would try to find out what the difficulty was and correct it. He was given to understand that this was just a friendly chat and great care was always taken to show a kind and sympathetic attitude in getting him to consent to this plan. He was never given the impression that he was expected to do as was requested but shown that there was some one who was genuinely interested in him and who wished to assist him.

It was soon learned that while each case under observation presented a supersensitive makeup, this sensitiveness had to be measured in order to permit the worker to know just how to approach the patient and get him to reveal willingly the nature of the conflict that was gradually causing him to drift away from reality. An actual indictment is too painful. Most of the patients even resented being told that they were day dreaming, and would frown and set up such a defense that nothing could be gained. Therefore, in beginning the treatment the talks were always referred to a group setting rather than to the individual himself. The very realization of his defects is too painful to the epileptic, so care must be taken to gain the patient's full and willing cooperation during the training treatment. Once the patient relaxes sufficiently to realize his shortcomings, the teaching is then more acceptable to him, but it will be found that the lesson must be gone over many times before he will actually begin to put it into operation of his own accord. The epileptic is quick to note character defects in others but fails to apply this ability where he is personally concerned, hence the necessity of tactfully bringing to his notice, character traits that require correction.

The following episodes are good examples of the types of conflicts displayed by the epileptic and the method used in obtaining the mental content of the dream states is equally applicable to the states of lethargy, annoyance and irritation. It is not asserted that in every case, where the cause of the retreat is learned, and means are produced for its correction, that the attack is prevented, but it was observed that this approach never failed to relieve the acuteness of the conditions noted and put the patient in a mental attitude that enabled him to become productive once more. As the training continued, it was further noted that the patients became changed individuals. Their interests in the club affairs awakened, their memory improved and their attacks began to decrease in force and frequency. They took on new responsibilities just as they showed ability to do so and best of all became aware that it was this insight into their defects that was enabling them to exist in a happier state than ever

before. Patients who displayed a marked and active automatism following their attacks soon showed that this symptom was getting milder and milder until little or no activity was noted after the seizure. Encouraged by the good results, the training treatment was continued and enlarged upon and in every instance the patients showed their pleasure at finding some means that would enable them to meet the conflicting trials that reality presented to their peculiar makeup.

CASE I.—This patient was fifty years old and had had epilepsy for the greater part of his life. His attacks were petit mal in type but varied in degrees of severity according to his conflicts. He had been expecting a visit from his wife for several days. She had written him the exact date and train she would arrive on. He made elaborate preparations for this event and appeared childishly happy. They had lunch together in a little hotel in the village after which they returned to the club. The patient's wife reported that when she met him he was all smiles and apparently happy and in the best of spirits and that this good feeling continued throughout most of the meal but as they prepared to return to the club she noticed that he was beginning to have one of his quiet spells. He appeared depressed and when his wife asked him what was wrong he would not tell, saying everything was all right. He became pouty and disagreed with his wife in everything she suggested. If she wanted to go for a walk, he found fault and wanted to remain at home. This attitude kept up all afternoon until his wife left. For a time the symptoms noted continued but not with the same force. He was taken aside in the evening for a therapeutic talk which occurred as follows: Nurse:—"I'm sure you must have had a very pleasant time today, was everything quite all right?" The patient was silent for a time, assuming a thoughtful attitude and then said: "Well it was and it wasn't—I seemed to be happy to meet my wife and for a time while we were having lunch together everything seemed quite all right, but then I began to feel depressed—things didn't go right." Nurse:—"Was there anything wrong with the dinner or the service, did you feel you wanted anything, wished for anything?" The patient was again silent for a long period, then began to smile boyishly and after several unsuccessful attempts finally resumed:—"Yes—there was something wrong—now that I think of it—but that could not have caused me to feel so mean—could it? You see I have had a cold for several days—I had written my wife about it—and she delayed her visit to me on this account—did not want me to give her the cold I guess—but it was almost gone today, I thought, and I wanted to kiss her—but I said to myself that I could not kiss her because I might give her my cold—I just couldn't help feeling put out to think she was right there and I couldn't kiss her—and it made me mad, I guess—"

Here at last was revealed the underlying cause of the dissatisfied state. A wish for personal gratification that the patient could not gain, plus his inability to even express his thoughts so that there was nothing to do but repress his emotions. If the epileptic could give vent to his feelings in the

form of verbal expression, he would not be compelled to suffer in silence. This training treatment enables the epileptic to acquire gradually the ability to express himself and in consequence there is a marked change in his behavior reactions.

As soon as the conflict was revealed in this case, the patient was given the following advice: "Now John, when this desire to kiss your wife came to you and you realized that having a cold there was a possibility of transferring it to her, you should have spoken up and told her about it and at the same time kissed her hand. In this way you would not have had to repress the desire so sharply, there would have been an understanding between you and there would have been no necessity of finding fault with your wife all on account of not being able to kiss her." This was imparted to the patient in the most kindly tone, not really as a corrective measure, but rather as brotherly or fatherly advice. Then after the talk was over he was asked to give his view of the matter, and it was surprising to note the changed attitude. He was no longer pouty, annoyed or irritated, but gave a free account of his feelings during the day and said that now he realized that if he could have had everything as he wished it, there would not have been any necessity of acting as he did. He retired to his room and wrote a letter to his wife explaining the situation to her and asked her to excuse him for his actions and told her he was going to be more thoughtful in the future.

This patient was extremely sensitive and the approach necessary to get his confidence, had to be done in this kindly manner. First, no mention that he had appeared annoyed or irritated during this visit, had to be kept in mind. The talk was brought about in such a way that it was made easy for him to reveal the conflict. To have asked him why he had appeared annoyed and irritated with his wife would have caused him to set up a defense that would have prevented any cooperation. This is a most important point and one that has to be kept constantly in mind when training such patients. When this patient came under observation he was so sensitive that he took exception to almost every suggestion. He had to receive prompt attention to all his demands or he became violently annoyed. This annoyance lasted for hours and nearly always terminated in an attack but after training treatment had been in force for a year, it was noticeable that he was beginning to put into operation the methods that the teaching offered and in consequence of this insight, the annoyance slowly disappeared and the attacks dropped from six and eight a week to three and four a month. It was further noted that in the beginning of treatment the automatism following seizures was prolonged and of a destructive type, but as he gained in insight and actually kept within his limits, this activity following the attacks soon passed away and the attack itself lasted but half a minute or so. This patient for a long time insisted that his bowels and stomach played a great part in these attacks. He didn't know just how, but said he had always been told that constipation caused attacks. As he gained in insight he slowly gave up the idea, and he said: "It looks as if I would have to change my whole character."

CASE II.—Young man, aged twenty-five years, who had had epilepsy since he was eighteen. He displayed all the characteristic signs of the constitutional makeup. From earliest infancy he was a stubborn, difficult child and had frequent tantrums all through childhood. While he learned easily he never did things that were original or clever and never went into anything deeply. If he had an idea and was balked in it he never argued or teased, but at once threw himself on the floor and went into a tantrum. As he grew older the tantrums were no longer present but were replaced by attacks. For days previous to an attack he slowly began to retreat from activity with the group and could be seen sitting alone apparently in deep thought. He would find fault with the different members of the group. Finally things would get so unbearable he would say: "If I am going to have an attack I wish I would have it and get this feeling over with."

This patient had been taking bromide at the rate of 120 grains a day over a long period when he first came under observation. Even then he was having three attacks of grand mal a month together with three or four of petit mal weekly. The bromide was slowly withdrawn and his attacks increased to two attacks of grand mal a week with one of petit mal daily. The training treatment began just as soon as he was in perfect physical condition. He was gradually shown how his attitude toward his environment was not just normal; that it appeared to be rather childish at times and not at all what one would expect for a young man of his age. Of course the whole approach had to be very tactfully applied so as not to make it too painful for him.

At first he was inclined to think he was doing quite right but soon began to see the logic of it all and then carefully tried to follow out the training treatment. He learned exactly how to control his physical activities, his diet, and to apply the daily teaching in such a way that brought about the best results. His grand mal attacks decreased from the number mentioned to one every six or eight weeks and the attacks of petit mal occurred at intervals of four or five days. His interests increased. He took up a course in agriculture and became more spontaneous in all his activities. At first his only topic of conversation was his parents and other relatives. He carried their letters about in his pocket and used them to produce talk with the club members and strangers whom he met. He was not happy unless he received a letter a day from his parents and wrote one to them but as his interests increased and he became more active in the club life, he soon began to regulate the letter writing to once a week and take up other topics of conversation besides his relatives. This character change all came hand in hand with his insight into his defects and a realization of the conflicts that resulted from them. This patient gave the following view of his difficulty: "If my parents would understand me—they treat me like a child—will never let me do anything so, how can I learn?—I never was let do anything and was always kept down and grew up in a sort of a fear that no matter what I did it was sure to be wrong—and then I got into the habit of always let-

ting others decide for me—it was easier I guess—but I can see now that it was wrong—and I want to learn how to get over this trouble.”

He lost his intensive childish attachment for his parents and became more active in the group settings. Just as he gained insight into his defects and acted accordingly, he became more proficient and had less difficulty with his environment, in consequence of which he had fewer attacks.

CASE III.—Another patient, a youthful epileptic, showed a marked antagonism toward his mother and other members of the family. He insisted that they did not understand him, and by their very attitude, created stressful states that caused him to break. In other words, they held him to too high a standard and expected too much of him. This patient presented a classical constitutional makeup. He was taught in the same careful manner and assisted from day to day to put into operation the lessons given, for he was possessed of a poor machine and simply couldn't do what he realized was right. As he learned and saw the great advantage to be gained by this proper approach, he wrote frequent letters imploring his mother and other members of the family to learn this method of approach and assist him. It is just as essential that the parents have this insight as it is for the patients. With this in mind, the parents and people with whom the patients expected to live after they concluded treatment, were given frequent talks in which they were taught just how the work was carried on. One patient remarked: “If I could get the folks at home to create the same kind of environment as I have here, I know I could go home and do my work there and get well, but things seem different at home; the folks don't understand and I'm always getting into trouble. I can't do things the way they want me to. I have my own way and if I'm let work along the lines that are easiest for me I can accomplish more and am happier.”

From the notes cited in this paper it will be seen that the patients studied showed an inability to adjust and adapt themselves to their environment, which in turn seemed to cause them to retreat from reality. They stood mental and physical stress poorly and lacked the ability to give expression in any way, appearing to suffer in silence until the fit relieved them. The stress of life was too great, yet they were constantly irritated and annoyed because they could not accomplish their desires, regardless of the fact that they were aware of the poor machine that nature had given them. The training treatment that brought such good results in the cases cited was characterized by a gentleness of approach that inspired the patient to reveal the conflict in time so that something could be done to prevent the great damage caused by repression. In this way the patient realized that the difficulty was within and not with reality. He released an affect and had an opportunity to get square with things. He was rendered more receptive, realized that at least some one was interested who understood him, and, in consequence of this good feeling, he was more willing to accept the corrective advice offered. In every case so treated, I have had the

patients tell me that they derived instant relief from the acute annoyance and irritation, and the depression that seemed to cloud their minds passed away and made the outlook brighter, which in turn enabled them to resume their routine work. They became changed persons as they gradually learned to know themselves; they became more proficient and assumed charge of their affairs and directed their actions with good judgment.

The epileptic requires more rest than most people. He can never be hurried. If this training treatment enables such patients to recognize the necessity of this and by carefully following out such teachings. Their attacks are reduced, they become happier and more contented, and it would seem that this form of approach was well worth serious consideration.

I might conclude by saying that at no time is it ever advisable to keep from the patient the true nature of his disease. From the very beginning, just as soon as a positive diagnosis has been made, efforts should be centred on imparting to the patient in the most acceptable form, a thorough knowledge of his disease and the methods by which he is to secure an arrest or cure. By showing him the personal gain to be had from carefully adhering to the rules governing his particular case, he will have this as an incentive, giving hope when reality tends to block his progress.

The cessation of attacks is by no means an indication that the patient is cured. It is also necessary that the patient be able to assume charge of his or her own affairs and, above all, to have a true insight into the nature and conditions that brought about his disease. He must be able of his own accord to direct his actions so as to avoid the stresses that cause him trouble. A changed mental attitude toward himself and his environment must take place before any real successful results can be expected. The training treatment seems the best method of reeducating the epileptic, but it requires great patience and much time to accomplish even a little, but if the fight is carried on tactfully the results are always gratifying and never fail, once the patient begins to act of his own accord.

THE CLUB.

INJECTIONS OF CEREBROSPINAL FLUID IN CEREBROSPINAL FEVER.

BY NAVROJI A. COOPER, M. D.,
Bombay, India.

Honorary Physician, B. D. P. P. G. Hospital.

An interesting case of a young boy of fourteen years of age suffering from a severe form of cerebrospinal fever was admitted into the B. D. Petit Parsee General Hospital on April 7, 1920. As the case was unique of its kind in the matter of bringing about the patient's complete recovery from the malady as well as all its concomitant adverse symptoms, nervous, sensory, and muscular, under the injections of the patient's own cerebrospinal fluid, my colleague, Dr. R. Rao, who saw the patient, desired me to report it fully for the information of the profession at large.

The affection started with swellings and pains in the joints, of a shifting character (even the smaller joints of the fingers being involved), accompanied by fever and occasional vomiting. He was treated by a local practitioner for about a month by anti-rheumatic drugs. These had no effect and the condition went from bad to worse. Bronchopneumonia supervened and the patient was delirious at times. In this condition the patient was brought to the hospital and placed under the care of one of my colleagues. The temperature went up from 102° F. to 105°, with an increase in respiration. The pulse was feeble and rapid. He continued to be very excited and was delirious at times. All the larger joints showed a condition of arthritis. There was a bronchopneumonia in the right lung and the general condition was very low.

The following findings were shown from day to day. April 8, 1920, slight leucocytosis, nothing abnormal in the urine. April 10th, the Widal test was negative. On April 11th, a throat swab showed nothing important bacteriologically. On April 13th, the condition seemed serious. The patient improved somewhat under stimulants and oxygen inhalation towards evening but the mental symptoms were more marked. On April 15th, signs of meningeal irritation were noticed. There was a marked retraction of the neck, and rigidity of the limbs. Kernig's sign and ankle clonus were present as well as a bronchopneumonia in both lungs. The general condition was extremely unfavorable. There was a loss of control of the bladder and rectum. A lumbar puncture was made on the 16th, and about one and one half ounces of fluid removed, which was turbid with an abundance of albumin and a negative Fehling reaction. No tubercle bacilli or other microorganisms found. There was a relative increase of polymorphonuclear cells. The culture was sterile. Lumbar puncture was again made on the 18th. The fluid was slightly turbid. There were a few diplococci present resembling pneumococci but they showed no capsule. The culture was negative. On the 19th, a lumbar puncture was again made and fifteen c. c. of fluid removed. On the 20th the patient seemed to be a bit brighter but the general condition was very low, with a rapid, feeble pulse. Smear from a throat swab showed a fair number of squamous epithelial cells, a fair number of pus cells, a few staphylococci, streptococci and diplococci and bacilli. There were no tubercle bacilli. A lumbar puncture was again made on the 21st. The fluid was turbid, the culture was negative. On the 24th the patient seemed to be a little better after the last lumbar puncture. As my colleague had to leave Bombay on the 27th for some time, the patient was transferred to me for further treatment. From the 7th to the 27th the patient had had nineteen injections of camphor in oil, three of pituitrin, four of digitalin, and five of strychnine (before meningeal symptoms were discovered) and four lumbar punctures together with stimulants by mouth such as musk, ammonia, digitalis, brandy, and oxygen inhalations. On the 27th I noted the condition of the patient to be as follows:

The patient was unconscious, lying with his head rigidly retracted with staring eyes and dilated pupils, which did not react to light or accommodation.

There was no nystagmus or strabismus, a marked rigidity of the muscles of the neck, abdomen, and back was manifest and all the limbs were strongly flexed. There was absolutely no control of bladder or rectum. Kernig's, Babinski's, and ankle clonus were present. There were tremors of the limbs and body (more of the upper half) with bronchopneumonia of both lungs and a rapid feeble pulse. The patient would shriek at times and utter low moans frequently.

The patient was put on a simple diaphoretic mixture with aromatic spirits of ammonia as the only stimulant. Urotropin and guaiacol carbonate, five grains of each, were given twice a day and an injection of mixed influenza vaccine consisting of pneumonia, streptococci, influenza bacilli and staphylococci was given every day.

On May 8th the signs of bronchopneumonia were not so extensive, and though the temperature was slightly affected under vaccine therapy, the meningeal symptoms remained the same. On the 9th all medication was stopped. On the 11th the patient was restless all the night, shrieking loudly all the time. Hyoscine injections and bromides were given but had no effect. At 3 a. m. cold sponging was resorted to as the entire body of the patient was trembling. On the 12th a lumbar puncture was made and ten c. c. of fluid was withdrawn. It was sterile. Chemicals reactions could not be taken as the amount of fluid was too small. Of this fluid three quarters c. c. was injected subcutaneously and it was repeated every day till the 17th. Gradually the temperature fell and meningeal symptoms abated with every injection until the 18th, when the temperature dropped to 97° F. The patient appeared brighter with a marked improvement in his general condition. The pupils were still dilated but reacted to light. On the 22nd the condition was better. He kept his eyes closed. The pupils were not so widely dilated. Stiffness of the neck was less marked. On the 24th the patient put out his tongue on being asked to do so for the first time. Intelligence was improving every day and at times he answered questions in monosyllables. On the 26th the patient spoke a short sentence for the first time. Memory seemed to have failed. He knew nothing about his illness. The stiffness of the neck was not so marked. He lay with his upper extremities and left leg extended. On June 6th the tremor was still present, though not continuous. On the 8th the tremors disappeared. There was very little rigidity of the limbs. The pupils were gradually contracting but the patient could not read clearly and lucidly. It took time for the patient to recognize letters and he made mistakes in deciphering what he had learned before. His memory had failed to a great extent though he could give his own name and the names of his father and one sister, he had forgotten the names of his six brothers, one sister, and his mother. He was given daily lessons and was made to read papers and school books. On the 10th he was able to speak and read without difficulty and understand what he read. The rigidity of all the muscles excepting those of the right leg disappeared. He still passed urine in bed. On the 16th he was better in all respects, and asked for the urine bottle when he wished to pass urine. On the 20th he spoke

intelligently and was able to read without difficulty and sat up in bed without any help. On the 26th of July he left the hospital in perfect health without the slightest defect.

CONCLUSIONS.

1. The case was very serious and of a severe form of cerebrospinal meningitis from the very beginning.
2. The disease simulated rheumatism in the beginning. Neither the salicylates nor other medication had any effect on the course of the disease. If anything, the condition went from bad to worse.
3. There was a distinctly good effect from the mixed influenza vaccine in the bronchopneumonic condition, but not on meningeal symptoms.
4. After the administration of the vaccine and urotropin the cerebrospinal fluid was found sterile and clear.
5. It is certain that both the vaccine and urotropin had no effect on his meningeal symptoms and fever.
6. The fever and meningeal symptoms abated gradually every day under injection of the cerebrospinal fluid.
7. His complete recovery was due to the injections of his own toxins contained in the cerebrospinal fluid without which the patient could not have made an advance toward such an uninterrupted and perfect recovery.

CUMBALLA HALL.

VENESECTION: A LOST ART.*

BY DAVID W. KRAMER, M. D.,
Philadelphia,

Demonstrator of Clinical Medicine, Jefferson Medical College; Assistant Visiting Physician, Jewish Hospital and Philadelphia General Hospital.

HISTORY OF VENESECTION.

Venesection or blood letting is a measure that has been employed almost universally and has been traced back to about 2500 B. C. (1), its unwritten history probably being of far greater antiquity. Hippocrates (460-370 B. C.) bled extensively and wrote a treatise upon the subject. Galen also let blood in many cases; he is quoted as the first to specify the proper quantities to be withdrawn under various conditions, recommending from a half pint to a pint and a half in the average case.

Through centuries of ancient and medieval history frequent references are made to venesection, and there is no doubt that the practice was often abused. In the fifteenth and sixteenth centuries (2), Pierre Brissot stands out as a reformer. There was much controversy over the site of bleeding, the Arabic teaching being that blood should be drawn at a distance from the lesion, whereas the more strict followers of Hippocrates preferred to open a vein near the lesion and on the same side of the body.

Sydenham (1624-1689) revised the application of blood letting, and used it extensively but with discretion; usually he began treatment by opening a vein, but seldom took more than eight or ten ounces at a time. Hahnemann and the homeopathic school (1779-1843) founded their indictment of orthodox medical practice largely upon the indiscriminate bleeding in favor with the German physicians of their day. In the early part of the nineteenth cen-

ture, venesection was still in vogue, with a tendency toward its abuse. Louis, in 1835, advised against its promiscuous employment and especially insisted that it was of little worth in pneumonia. In the latter part of the nineteenth century, blood letting had become restricted to conditions clearly indicating its employment. Of late it seems to be used only on rare occasions. If we were to question interns in nearly all hospitals as to the number of venesections performed during a six months' period of their service in medical wards, their replies would indicate that it is almost a forgotten measure. Yet, when we come to consider the number of conditions in which it gives relief without danger, especially in certain phases of common diseases, we find that definite indications for its application are by no means so rare.

INDICATIONS FOR BLOOD LETTING.

Blood may be taken by opening a vein, by inserting a cannula into a vein, or by means of wet cups or leeches. Each method has conditions of election, but, generally speaking, venesection is the most prompt and certain. It is a relatively simple measure, and is easily carried out, both at home and in the hospital. No doubt it may be a somewhat gruesome affair when performed at the house with little or no assistance, but it is feasible even then. Its indications are, in general, of two classes—a, palliative, where its employment materially adds to the patient's comfort for the time being; and b, restorative, when it may, in addition, prolong life or even determine recovery.

Textbooks (3) furnish us with lists of conditions in which venesection may be of use. I need not emphasize apoplexy, Osler's or Vaquez's disease, pulmonary edema, eclampsia, or other conditions in which blood letting is more or less recognized as part of the routine treatment. Nor shall I dwell on all the others; but for present purposes shall limit myself to some five, in which it may be safely done with marked benefit but is too often omitted. These are—pneumonia, influenza, and other acute intoxications, cardiac affections, uremia, and vascular hypertension.

It is understood, of course, that I refer only to certain phases of certain cases. Venesection is not to be ordered promiscuously in any class or set of cases. Only when clearly indicated will it reward us with definite and helpful results.

BENEFITS TO BE DERIVED FROM VENESECTION.

The amount of blood in an animal is said by most authorities to be about one thirteenth of the body weight. Haldane and Smith (4) give one twentieth of the body weight as the figure in man.

In venesection, as in hemorrhage, there is loss in vascular content both in fluid and in cells (5). The diminution in volume manifests itself at once; that in the corpuscular elements may not reach its greatest point for several days, evidently depending upon the manner in which blood replacement takes place. The volume is probably restored in a few hours by rapid absorption of fluid from the tissues; thus the blood becomes greatly diluted, as manifested by the reduction in hemoglobin. This is a natural sequence of events. Lee (6) makes use of the hemoglobin estimation as a guide to blood volume, and this has

*Cases studied in Dr. S. Solis-Cohen's service at the Jewish Hospital.

its prognostic value. A patient presenting a relatively low hemoglobin—say sixty to eighty per cent.—at the end of twenty-four hours or more after hemorrhage is in much better condition than one who presents a hemoglobin ratio of a hundred per cent. In the former case the vessels have been refilled. In the latter case there has been no influx of fluid.

Bearing these facts in mind, we may discuss the benefits of venesection. These may be enumerated as follows:

1. *Relief of an overdistended right auricle*, a fact noted in animal experimentation, and which plays an important rôle in therapeutics.

2. *Diminution in blood volume*; this is only temporary.

3. *Diminution in blood viscosity*, as a result of replacing the diminished volume by the fluids of the tissues.

4. *Reduction, or sometimes elevation, of blood pressure*. This demands fuller discussion elsewhere.

5. *Diminution of toxemias*. This is to be observed not only in uremia but markedly in certain acute infections, particularly that baffling group which we have been in the habit of calling gripe or influenza. I shall speak first of these toxic infections in the discussion of conditions in which venesection is useful.

INDICATIONS FOR BLOOD LETTING.

Infectious toxemia.—This type of infection comes on with an apparent suddenness, perhaps after a precedent coryza or sore throat, and manifests itself as an overwhelming intoxication, with prostration, intense headache, and cyanosis. It seems to have a predilection for attacking the heart muscle almost from its very onset, as evidenced by the feeble heart sounds and the weak, rapid pulse, commonly of a low pressure. S. Solis-Cohen, in his clinical conferences with classes at Jefferson Medical College, has pointed out that cases in which hemoptysis or profuse epistaxis occurs early, have, as a rule, a favorable prognosis; terming this "Nature's hint to the physician."

Venesection is accordingly indicated when the pulse rate increases, the systolic pressure diminishes, cyanosis becomes more intense, and evidences of pulmonary congestion appear, together with an increase in cardiac dullness to the right—in short, when, with progress of the toxemia, the heart is about to give way. Blood letting, with the removal of eight to ten ounces, exerts an obvious beneficial influence upon the course of the infection, and this may prove to be the turning point toward recovery. If for any reason venesection is impracticable, wet cups or leeches may be applied instead.

The benefits observed may be attributed, in part, no doubt, to the relief of the overburdened right heart; but I do not believe that this factor alone is to be credited with the resulting rise of blood pressure, disappearance of cyanosis and improvement in heart sounds. The removal of so much blood, overladen with toxic products or bacteria, possibly both, plus the resulting factor, viz: the draining off of tissue fluids, evidently has something

to do in bringing about the happy change of condition.

Is it not possible that when the fluid is drained off from the tissues, more or less of the toxins which have been harassing the tissue cells are removed and normal function is encouraged to reestablish itself? In the few cases that I have observed, this influence seems to be quite evident and asserts itself quickly, say within twenty-four hours. Patients who had the appearance of being washed out, who were rapidly going down hill, and in whom the prognosis seemed grave, appeared to pass through a peculiar period, analogous to the crisis, after which period they not only looked stronger and more comfortable, but voluntarily told us that they felt so.

This may be illustrated in the following case, which ordinarily would be diagnosed influenza, but which I think belongs to the group of streptococcus infections. It may be noted, in passing, that the danger in influenza is virtually always from some concurrent infection; in the recent epidemics, apparently streptococic.

STREPTOCOCCIC TOXEMIA.

CASE I.—Mrs. B. G., aged sixty years Admitted June 13, 1920, with the history of a so-called cold in the head, soreness of throat, intense headache, palpitation. Had been suffering with heart trouble during the past twenty years. Examination revealed an angry looking and injected throat; cyanosis of lips and finger tips. Heart showed auricular fibrillation and partial heart block; congestion of lungs. White blood cells, 8500; blood pressure, systolic 90, diastolic 50. The patient's condition became progressively worse despite the usual medicinal treatment.

June 16th, 6 p. m. Patient was very restless, stuporous, did not recognize her children. Temperature 102.3° F.; pulse 120; respiration 30. White blood cells, 10,000; blood pressure, systolic 108, diastolic 58. 8 p. m., venesection; ten ounces of blood taken. 10 p. m., the patient seemed brighter, with the stupor subsiding. June 17th, the appearance was brighter, respirations less labored, blood pressure 105-62. June 19th, temperature normal, pulse 70, respiration 28, blood pressure 110-65. In this case venesection was performed despite a relatively low blood pressure. The patient made an uneventful recovery, except for a pleuritic pain, which disappeared within two days.

PNEUMONIA.

I shall not discuss the advisability of bleeding early in pneumonia. Personally, I have not resorted to it. Years ago it was a routine measure, but despite the fact that some still teach it to be indicated when dealing with full blooded, plethoric individuals with high tension, I doubt whether it is now applied in even a small proportion of cases.

It is my intention, on the other hand, to emphasize as strongly as possible the good results of venesection in certain stages presented during the course of a pneumonia, especially when there are signs of impending danger from a dilating right heart. This, as is commonly recognized, may be manifested by feeble pulse, with increase in rate, more or less

marked cyanosis, signs of increasing pulmonary congestion, and extension of cardiac dullness to the right. A gradual or, less commonly, a sudden drop of the diastolic pressure may be added to the list of ominous happenings. When this clinical picture is present, we must realize that we are dealing with a profound toxemia and an overworked, tired and softened myocardium, which is trying to continue functioning but is slipping and failing. We may likewise realize that pneumonia kills not through consolidation of the lungs, but by depressing the heart and vessels both directly and through the autonomic nervous system.

Prevalent treatment in the form of medication is directed chiefly to stimulating and encouraging the heart to keep up its good work, with the hope that the infection will run its limited course before the heart collapses and the patient dies. With this in mind, why not materially aid the heart instead of merely encouraging it? Words of cheer in the form of stimulation will give us results—that is true enough—but venesection will enable the heart to respond more promptly and probably save a certain percentage of patients who would otherwise perish. Pneumonia, truly, is a battle for life from its very beginning, and every patient has a chance so long as the heart beats and so long as the lungs functionate. Therefore, we should stand by and fight for and with the patient regardless of how dark the outlook. It may require a little courage to decide upon venesection when conditions are so poor, but we may give the sick man the benefit of the doubt. Nor have I permitted a low blood pressure to deter me from this course of treatment. Nothing is more startling to the inexperienced than the manner in which the pulse steadies and the pressure rises after bleeding, in cases of the kind described. In the instance which I am about to cite, the systolic pressure never reached higher than 120, and the diastolic pressure dropped steadily from fifty to ten. At this point venesection was performed, removing ten to twelve ounces of blood. In my judgment, this enabled the man to make his successful fight for life.

MASSIVE BRONCHOPNEUMONIA.

CASE II.—H. D.; twenty-two years; mechanic. Admitted May 21, 1920, with a history of shortness of breath and pain in the left side following a chill, the preceding day, May 20th. There had been before this a cold in the head and chest lasting three or four days. Examination revealed an extensive bronchopneumonia approaching the lobar type on account of the large area involved. Temperature, 102; pulse, 120; respiration, 34. Lips and finger tips were cyanosed and there was some tenderness over the liver—a symptom that I have noticed in others suffering from this type of infection. Leucocyte count, 7,000; blood pressure on admission, systolic 105, diastolic 30.

May 27th, patient's condition very low. Temperature, 102.4° F; pulse, 116; respiration, 50.

The man complained of tearing like pains in the right side of chest, when coughing. He presented a picture of prostration and exhaustion. The systolic pressure remained at 120, due to stimulation, as the patient was being treated according to the definite plan (7). The diastolic pressure, however, dropped

to ten; *this was the time selected for venesection.* Ten to twelve ounces of blood were removed from a superficial vein. The patient's condition remained, at first, unchanged except for *an improvement in diastolic pressure, which rose to forty.* The following day, May 28th, the patient was more comfortable; blood pressure, 120-20; pulse subsiding, drop in temperature. May 29th, a definite change in patient's condition. Although examination revealed persistent consolidation in the right base, there was marked general improvement; the temperature was normal; the pulse ranged between eighty and ninety, and blood pressure was more stable, systolic, 118; diastolic, 45. June 11th, patient showed delayed resolution. Gradual recovery ensued, and the man was discharged well, June 20th, a month after admission.

Permit me now to cite another case of pneumonia where venesection was successful in giving needed relief. The patient was seen in consultation with Dr. Joseph Aspel, to whom I am indebted for the report.

CASE III.—Lobar pneumonia, with dilating right heart and tendency to pulmonary edema. B. R., aged forty-seven years; illness began June 8th, with chill and fever. Examination revealed poor heart sounds, some râles at bases especially on left; mild delirium. Temperature 102.2° F., pulse 124, respiration 40; blood pressure, systolic 98, diastolic 58; respirations moist and labored; treated by definite plan. June 11th. The condition was worse; patient delirious; distinct cyanosis about lips and finger tips; heart sounds more feeble. June 14th. Condition grave; patient very toxic; abdomen distended; cyanosis; moist breathing; pulmonary congestion marked; pulse more rapid; 9 p. m., temperature 103, pulse 140, respiration 40; 10 p. m., venesection was performed; sixteen ounces of blood removed from superficial vein; midnight, temperature 102, pulse 118, respiration 36; pulse good. June 15th. Rested more comfortably, seemed brighter; respirations not so moist. From this day patient made a gradual but uneventful recovery.

CARDIAC CONDITIONS.

Cardiac dyspnea.—When dyspnea in cardiac affections becomes so acute as to make the patient decidedly uncomfortable, even while resting in bed, the advisability of venesection should be seriously considered.

CASE IV.—The clinical picture indicating its employment may be illustrated by this case which presented a mitral regurgitant lesion and an enlarged heart, with all the evidences of decompensation. While making rounds, my attention was called to this man, who, with a blue face, was having extreme difficulty in breathing, moaning and groaning with his respirations. The eyes were staring; the dyspnea was so intense that speech was impossible; the hands were cold and the pulse almost gone. This patient seemed moribund and I had little hope that anything could be done. He responded somewhat to camphorated oil, but did not improve sufficiently to change the prognosis. Venesection was done as a last resort. The loss of sixteen ounces of blood produced an immediate change for the better. The cyanosis lessened, the dyspnea soon became less

urgent and the man was able to speak. His heart now responded more readily to medicinal stimulation and in a few days showed decided improvement.

Another cardiac case in which dyspnea was the main symptom but did not have in the background the picture of an impending acute dilatation, may be cited.

AORTIC REGURGITATION WITH FAILING COMPENSATION.

CASE V.—M. C., aged forty-eight years; in Dr. S. Solis-Cohen's service at the Jefferson Medical College Hospital. This man suffered from aortic regurgitation of long standing. I was going through the wards with Dr. Solis-Cohen, when he found the patient markedly distressed with dyspnea and profound cyanosis. He at once ordered bleeding. The withdrawal of sixteen ounces of blood from a superficial vein brought about relief, which lasted not for a few days only but for the rest of the patient's stay in the hospital; and, when discharged, he was, and had been for two or three weeks, able to move freely about the ward. This result was impressive and is indeed largely responsible for this paper.

Acute dilatation.—Venesection is so clearly indicated that it scarcely needs comment. I would only say that it is often delayed too long.

UREMIA.

Uremia is an interesting field for venesection since it is an intoxication, whatever the toxic substances may be. There is usually an associated vascular hypertension, particularly when we are dealing with uremic dyspnea; and occasionally we are called upon to treat cerebral accidents simulating embolism and apoplexy, presenting a clinical picture of unconsciousness and paralysis or spasm; and, at times, convulsions; pulmonary edema may likewise occur in uremics.

In uremic dyspnea (8), when associated with high blood pressure, an effort should be made to relieve the left heart, either by vasodilators or bleeding. Bleeding gives better results than the vasodilators. The benefits derived from venesection are attributable to:

1. Relieving the burden of an overworked heart, by diminution both in the volume and the viscosity of blood.

2. Removal of toxins and toxic products.

3. The resultant drainage of the fluid from the tissues, thereby giving more or less aid to the tissue cells in their attempt to get rid of waste products.

UREMIC INTOXICATION WITH DYSPNEA.

CASE VI.—I. W., aged sixty years; admitted June 12, 1920, complaining of dyspnea and drowsiness. The eyes were baggy, temporals tortuous; peculiar foul odor in breath; tongue coated; skin dry; abdomen and extremities, no bearing on case; blood pressure; systolic 160, diastolic 68; oliguria; blood urea 90.

The patient did not respond to medication, nor to the usual procedures to stimulate elimination through the skin, e. g., hot packs, electric (hot air) cabinet, and pilocarpine. June 16th. Drowsiness more intense, approaching stupor; very restless; stertorous breathing. Venesection performed; sixteen ounces removed, with resulting improvement

of patient's condition, especially lessening of restlessness. However, all attempts to get the skin active were futile and the patient died June 30th.

This case is cited merely to show that bleeding may be indicated palliatively even if it does not give us a curative result. It cannot, of course, make a new heart or new kidneys.

I shall not take time to discuss in detail, but may mention that blood letting is indicated in uremic coma, in pulmonary edema occurring in uremics, in hypertension and early stages of uremic spasm and paralysis, particularly when they do not respond to the ordinary measures. Incidentally, I may call attention to muscular twitchings as an early and neglected symptom of uremic intoxication.

VASCULAR HYPERTENSION.

This measure need not be considered routinely when dealing with cases of hypertension, a condition about which so little is known from the etiological viewpoint. However, after we have treated our patients with the usual array of medication, electrotherapy, and cabinet baths, with little or no success, and they are beginning to show signs of discomfort from the general disturbance of circulation, then I do think venesection is indicated, being in reality a measure of last resort, which should result in more or less relief, particularly in cases in which pulmonary edema has developed. The following case may be cited:

HYPERTENSION AND CHRONIC DIFFUSE NEPHRITIS.

CASE VII.—H. S., aged thirty-five years; admitted June 11, 1920, with dyspnea. The patient had recently been discharged from the wards as improved. The hypertension had previously been treated with everything at our command, both medication and eliminative measures. The man responded at first, but later the blood pressure again reached its height. On readmission the blood pressure was 205-130; the urine showed a light cloud of albumin with a few hyalogramular casts. Blood urea was 39. During the night of June 12th, there developed an acute dyspnea followed by pulmonary edema; frothy, bloody fluid exuding from nose and mouth. Fortunately, a resident physician was at hand. Venesection was done promptly, sixteen to eighteen ounces of blood being taken. A hypodermic injection of morphine and atropine was given. The patient went to sleep and, in the morning, was none the worse for his experience. In this instance, the venesection was instrumental in tiding the patient over a critical period; but would it not have been more advisable to bleed earlier and thus avoid such accidents as the pulmonary edema, which if not managed promptly and judiciously, may end disastrously?

SUMMARY AND CONCLUSIONS.

To recapitulate. It is not my intention to urge blood letting in a haphazard manner. We should always have in mind some definite benefit reasonably to be expected from its immediate effect. In the course of the paper, I have endeavored to point out these effects and conditions wherein they are indicated. Bearing such qualifications in mind, venesection or other forms of blood letting may be useful in the conditions to be enumerated.

1. In the toxemias associated with influenza and in the grave stages of pneumonia, when the intoxication is overcoming the efforts of the heart and the circulatory system to maintain life; the clinical picture being that of a dilating right heart with rapid and feeble pulse of low tension, cyanosis, dyspnea and more or less stupor. Venesection, under these conditions, may be the deciding factor of recovery.

2. In cardiac affections. Blood letting for acute cardiac accident—acute dilatation—needs no comment. Here we may observe that when a patient, with chronic valvular or myocardial lesion, is decidedly uncomfortable, when the dyspnea is so persistently constant and severe as to make his existence one of torture, this manifestation usually having a clinical picture of failing compensation in the background, well timed blood letting will not only prolong life, but will give the patient a degree of comfort surpassing that obtainable through morphine.

3. In vascular hypertension. Blood letting will not remove the cause of trouble; but after all other methods, medicinal, electrotherapeutic and hydrotherapeutic, have failed to give relief, venesection does palliate, at least temporarily; and it may be instrumental in warding off complications, such as acute pulmonary edema and apoplexy. The question of the possible benefit of earlier and repeated minor blood lettings is raised but will not be discussed here.

4. In uremia. Venesection—sometimes leeching—is of benefit in the uremic cerebral accidents, such as coma, convulsions and paralysis or spastic contraction. It should be done earlier in uremic dyspnea, which is usually associated with hypertension; and the measure is especially indicated, as shown in Case VI, when we are dealing with an intense uremic poisoning, with no diaphoretic reaction to heat or pilocarpine. Blood letting is then the only means whereby toxic substances can be eliminated.

5. Other conditions. It is obvious that states, such as apoplexy, eclampsia, polycythemic cyanosis, certain phases of aneurysm, carbon monoxide poisoning and pulmonary edema, regardless of the underlying cause, afford suitable indications for blood letting.

TECHNIC.

Beyond asepsis, the technic of venesection is not highly important. Whether a large calibre needle is inserted into a superficial vein, or whether the vein is opened, with or without cutting down upon it, matters little. Personally, when there is time, I prefer to use a local anesthetic, and to cut down upon, dissect and open a vein of the elbow. It is a clean and not difficult way of going about it. The other details do not call for discussion. The amount to be withdrawn should be not less than eight to ten ounces and not more than sixteen to twenty-four ounces at a time, depending upon the pathological indications and the condition of the patient.

In concluding, I may say that this paper is simply a plea for a more frequent use of venesection when indicated. I do not profess to bring out anything original, but merely to emphasize the fact that blood letting is a useful measure, especially in conditions of poisoning and of embarrassment of the

circulation that other means have failed to, or obviously cannot, relieve; and that when applied judiciously it should give us the pleasing results that we strive for in medical practice.

THE RELATIONSHIP BETWEEN DISEASED TONSILS AND PULMONARY TUBERCULOSIS.

BY WILLIAM L. RHODES, M. D.,
Wichita Falls, Tex.

That diseased tonsils have a direct relationship to pulmonary tuberculosis in its initial stage is becoming more and more evident as time goes on and opportunities for the study of the great white plague present themselves. In a series of cases of pulmonary tuberculosis referred for nose and throat examination during the past six years, it has been my observation that practically every case gives a history of recurrent inflammation of the tonsils at some time or other, and upon examination, the crypts are found to be filled with a deposit of thickened pus. This history of a recurrent inflammation of the tonsils, in connection with a tuberculous infection of the lungs, does not always hold good. Some cases give no history of a tonsillar inflammation but upon examination of the tonsils we find the crypts filled with deposits of thickened pus.

While in the Army, I had the opportunity of doing practically all the eye, ear, nose, and throat work for the thirty-fifth division, approximately 28,000 men, and the opportunities for the study of the relationship between diseased tonsils and pulmonary tuberculosis, in its incipient stage, were manifold. In looking over the records of the various cases, I cannot find a single case of tuberculous infection which did not give a history of tonsillar involvement associated with it.

It is common knowledge that diseased tonsils may cause rheumatic conditions, and that upon removal of the tonsils, the rheumatic condition subsides a short time after operation. It is also common knowledge that the worst types of carrier case during a diphtheria epidemic are the types having hypertrophied and diseased tonsils preceding the diphtheritic attack. This was brought to our attention in a striking manner during an epidemic of diphtheria among the men of the thirty-fifth division in Alsace during the months of July and

August, 1918. The entire personnel of one field hospital during the epidemic devoted their whole time to the treatment and care of the infected men. A field laboratory, in charge of two able and experienced laboratory men, was added to the personnel of the company, and did good work in helping to eradicate the epidemic.

The division surgeon instituted a novel feature in the form of a gas chamber, in an attempt to eliminate the disease from the carrier cases. The men were subjected to the treatment of chlorine gas for several minutes each day for several days, but with no appreciable result. Following the gas treatment, cultures were made by the laboratory men, who reported the organisms as virulent as ever. These patients were then referred for tonsillectomy, after which they were again placed under the observation of the field laboratory men, and in the course of another week were sent back to duty as noncarriers.

It may be of interest to note, as a refutation of the theory that chlorine gas is of benefit in the treatment of carrier cases, that eventually a number of cultures, in open tubes, were placed in the gas chamber and exposed to the action of the gas for several hours each day, for a period of three or four days. The laboratory men reported absolutely no detrimental effect upon the organism.

Getting back to the subject of the relationship between diseased tonsils and pulmonary tuberculosis, I will state that men sent into the hospital with symptoms of an incipient pulmonary phthisis were referred for a nose and throat examination. These examinations consistently revealed diseased tonsils. In a number of cases, in fact as a routine measure, tonsillectomy was advised and performed as an adjunct to the treatment of the pulmonary condition. In the larger proportion of cases thus treated, beneficial results were obtained in the general physical wellbeing of the patient. Men were frequently returned to active duty, who otherwise would have been sent to the rear, and eventually lost to the service.

The opportunities for further study of these cases were limited, due to the rapid movement from sector to sector, together with the losses sustained in action, both from wounds and from sickness, so that it is impossible to state whether or not beneficial results of a permanent nature were obtained. However, since returning to private practice it is possible to study further the cases of incipient pulmonary tuberculosis in which tonsillectomies have been performed, with the result that up to date, in the majority of such cases, a decided improvement has been observed.

It is somewhat premature to assert that an actual cure took place in these cases, but it is safe to say that there is a notable improvement in the general physical wellbeing of the patients thus treated, where the pulmonary infection was not too far advanced at the time of operation.

It is not my intention to create the impression that I advocate the removal of the tonsils as a cure for pulmonary tuberculosis. It is advanced as a theory only, unsustained as yet by laboratory and clinical findings. I do maintain, however, that

there is a distinct relationship between diseased tonsils and pulmonary tuberculosis, and that marked beneficial results upon the general wellbeing of the patient are obtained by tonsillectomy when performed during the initial stage of the disease. It is my personal opinion that in at least fifty per cent. of all cases of pulmonary tuberculosis the infection is derived primarily from a focus of infection in the crypts of the tonsils, and that a tonsillectomy is a highly important and necessary procedure as an adjunct to the general treatment of this condition.

Postoperative Analgesia.—B. van Hoosen (*American Journal of Obstetrics*, December, 1919) states that the technic of postoperative analgesia should be directed toward the prevention rather than the relief of pain. It should include the avoidance of psychic trauma before and tissue trauma during the operation. Gas pains, thirst, emesis, and catheterization must become avoidable and infrequent occurrences. The procedure recommended comprises scopolamine morphine anesthesia—begun very early on the morning of the operation—no catharsis before or during the week following operation, and all preparation of the operative field, including catheterization, in the operating suite one half hour after the second hypodermic injection of scopolamine and morphine. The latter combination yields a period of analgesia of from eight to twelve hours after return of consciousness. If it is desirable to continue the analgesia for a longer time, one two hundredth grain of scopolamine and one thirty second grain of morphine, or one four hundredth grain of scopolamine and one sixty fourth grain of morphine, may be prescribed every four hours, beginning about four hours after the operation and continuing for twenty-four to forty-eight hours, according to the probable length of the period of postoperative pain. Relief of gas pains and of thirst, and avoidance of catheterization, are all obtained by a simple procedure:

While the patient is on the operating table and the abdomen is being closed, an enema of two quarts of water containing three hundred and sixty grains of sodium bicarbonate is rapidly administered—average time, two minutes—through a colon tube inserted into the rectum not farther than three inches. This enema is retained by all patients except in hemorrhoidectomies and in some thyroidectomies. After the patient has been taken to her room and is comfortable in bed—about twenty minutes after the first enema—another enema of two or three quarts with or without the bicarbonate, is given, but more slowly, viz., in ten to fifteen minutes. This enema is likewise retained. Pain in the wound should not be appreciable and is obviated by the use of sharp instruments during the operation, blunt dissection being avoided, and by gentle and infrequent sponging. The position in which the patient is placed after operation also plays a part in the relief of pain; it should be comfortable and such as to afford relaxation or support to the parts, according to the requirements in the individual case.

HYPNOTISM AND PSYCHOTHERAPY IN THE SIXTEENTH CENTURY

Dr. Camille Rouzeaud, in an interesting student's dissertation (*L'Hypnotisme et la Psychotherapie au XVI Siecle*, Camille Rouzeaud, Jouve & Co., Paris, 1918), throws new light on this subject as considered from a historical viewpoint. While the recognition of hypnosis as a true state dates well back into history, it has been commonly assumed that it did not excite serious scientific attention until the nineteenth century, when Charcot in his article on Faith Healing set the medical world by the ears in discussion for and against his theories. The accepted belief has been that although the influence of mind over matter was acknowledged at a much earlier date than this, the source of the power was accounted altogether supernatural: if beneficent, to be assumed as a miracle and if otherwise, to be laid at the door of sorcery. The principal interest in what Rouzeaud has written lies in the fact that he quotes as authorities for the affirmative side of his discussion the names of authors little known to the majority of the medical world. Paracelsus and Kircher are names which are familiar in connection with the subject, but those of Cornelius Agrippa, Pietro Pomponazzi, Cardan and Van Helmont do not appear in the lists of those who dealt with this subject. Braid, Esdaile and Elliotson, who saw service with the British Army in the East, learned of hypnotism from the Hindus and their contributions to the literature of the subject made hypnotism a going con-

cern in the nineteenth century but back of them there is little evidence to prove that in earlier times either hypnotism or psychotherapy was considered as a natural process rather than a supernatural manifestation.

While Rouzeaud readily admits that the deductions of Agrippa, Pomponazzi and the other observers quoted were in part crude and faulty, he makes the claim that they did recognize the fact that there was a distinct and natural relation between the mind and certain pathological states of the body and furthermore, that these mental processes could be utilized as therapeutic agents. Faulty reasoning was to be expected in times when scientific methods were vague and when, in addition, investigations along this line were difficult because they carried the stigma of witchcraft to those who pursued them. Rouzeaud quotes extensively from Agrippa and also from Pomponazzi in proof of the fact that these men recognized as fundamental truths what we know to exist from the more enlightened research of later years, and while transcription of all that he has cited would occupy undue space, it is allowable to extract from it in order to show that there was in the sixteenth century a recognition of the logic of cause and effect in the relation of certain states of the mind and the body.

Pietro Pomponazzi, professor at the University of Padua, wrote a treatise on enchantments which was published after his death in 1525 and was his answer to a question as to the possible explanation of miraculous cures. In this he says:

"The people are in the habit of attributing to Divine or demoniac origin those things which they are unable to understand. Every science grows by the aid of research and by recorded experience. Spirits can influence matter only by the exercise of material laws. It is possible for men to discover these natural laws and make use of them to obtain the same natural effects. Many learned men who have been regarded as magicians or necromancers have never had any intercourse with the spirit world, and it is further probable that they hold with Aristotle that spirits (*démons*) do not exist. It is entirely right and proper to look for the natural cause of these so-called supernatural cures and this cause is the imagination which gives rise to four important states—desire, pleasure, fear and pain." Pomponazzi goes on with the theory that the imagination can produce material changes in the material body and, perhaps heretically, suggests that it was through this means, rather than by any miraculous

agency that St. Francis acquired the marks of crucifixion borne by Christ. (Charcot, *The New Review*, December, 1893). He says, "We have already seen what influence faith and the imagination play in these cures and in their failures. The cures obtained by touching sacred relics are produced only by means of the imagination of one of great faith."

He cites the effect of prenatal influence on the child and asks if this be so why the production of the same effect should not take place in the body of one who refers the same mental effort to his own person. All in all, a very frank exposé of what is a recognized part of the psychotherapy of today—autosuggestion.

Cornelius Agrippa was the physician of Maria Theresa, mother of Francis I of France, and Rouzeaud in comparing his opinions with those of Pomponazzi says: "In *La Philosophie occulte* Cornelius Agrippa describes and explains the same extraordinary phenomena due to the action of the mind on organic life. His explanation in this work reminds us much of that of Pomponazzi: but it is much more complete and precise and furthermore he marshals a great number of facts as evidence. There were already enough, but he cites many more, and in this, according to our view, his originality lies. He essays to connect pathological and normal phenomena, convinced that the same laws govern each, something which modern science has conclusively demonstrated. He points out the effect on the body of joy, fear, grief and the other emotions; the anesthetic effect of extreme ecstasy and in regard to autosuggestion carries on the line of reasoning followed by Pomponazzi. As a means of inducing the hypnotic state he cites: 1, Narcotics and anesthetics; 2, amulets, talismans and similar objects; 3, strong imagination and 'animal magnetism'; 4, action on the sense of sight; 5, action on the sense of hearing; 6, effect on the emotions (fear, etc.)," and as Rouzeaud says, "This list is very complete and we of later years have added little if anything to it."

The later investigations of Bernard, Dusart, Janet and others confirmed the theories of these pioneers of the sixteenth century in the field of psychotherapy.

In addition to the quotations from medical men of the times, Rouzeaud cites as significant of the truth that other than a supernatural origin was ascribed to the relation between the mind and the body at this early date, the fact that in the writings of laymen of the period there is not infrequent reference to the very probable natural origin of these phenomena. In support of this he cites from Chapter XX of the first book of Montaigne's *Essays*, that on the imagination, and in parallel column, ex-

tracts from Agrippa which suggest that the great essayist borrowed freely from his scientific contemporary. He quotes further, from Rabelais (*Le cinquieme et dernier livre de faits et dictz heroiques du bon Pantagruel*, Chapters XLIII et XLVIII), in the same tenor.

In his conclusion, Rouzeaud says, "Finally, we may make one statement with conviction. Hypnotism was known in the sixteenth century. The writings of Pomponazzi, Cornelius Agrippa, Paracelsus, Cardan, Van Helmont and Kircher prove this. Interest in scientific matters was so keen that these new ideas, stripped of their clumsy Latinity, were popularized by lay writers and dressed in plain language for the French public. Montaigne, Charron and Rabelais all speak of the mysterious power of the imagination, which, as they say, explains miraculous cures, puzzling nervous states and the art of sorcery. The power of the imagination can be exercised over the body in two ways: on the body of him who imagines, in which event it is autosuggestion, and on the body of another, which is real hypnotism. The learned doctors whom we have quoted were familiar with both states. Even at that early period the influence which a word or a sensation might have on the human body was clearly known and demonstrated. It must be admitted that Pomponazzi, as well as Agrippa, knew all the power of autosuggestion. They explained by its action the occurrence of certain skin lesions (stigmata), and the many cures which up to that time had been accredited to supernatural power. We have seen that Agrippa was the first to employ the word suggestion, and furthermore he has left in his work on occult philosophy a most interesting study of the curative power of the imagination, of ecstasy, anesthesia, hallucinations and somnambulism. He confirmed, in a passing way, the existence of mental suggestion at a distance.

"One finds in these writings the absurd alongside what is rational. These medical men who represented the *élite* of their time tell us seriously, for example, that a little fish called the remora was able to stop the progress of a great ship and that the eating of garlic would weaken the power of a lover. Be that as it may, is it just to condemn their work, *en bloc*, when we can find in the writings of profound men such as Aristotle and Pliny statements equally fantastic?" As stated in the beginning of this note, the interest which attaches to the writings of Dr. Rouzeaud is due to the little known authors whom he quotes and because he seems to demonstrate with unquestionable clarity that Charcot, Freud and others were not digging in virgin fields.

PHYSICIAN-AUTHORS: HENRY
VAUGHAN.

It sometimes happens that a man writes something or other exceptionally well which is not appreciated by his contemporaries, and that as a result he falls into obscurity after his death and has to be discovered in a later generation. This is what happened in the case of Henry Vaughan, the Silurist. Although Vaughan at his best was the greatest of seventeenth century religious poets of England, for more than two hundred years his writings remained almost unnoticed. Not even the numerous anthologies of British poetry made mention of him. But now it is different. He is in all the anthologies and a whole flock of critics never seem to tire of singing his praises.

Henry Vaughan was rescued from obscurity chiefly through the instrumentality of the poet Wordsworth and the Reverend Henry Lyte, best known as the author of the hymn *Abide With Me*. Wordsworth came into possession of a rare old volume of Vaughan's poems and was fulsome in his appreciation of the beauty of its contents. That brought the long neglected Vaughan to the front and created a demand for his work, with the result that a volume of selections, edited by the Reverend Mr. Lyte, was published in 1847. Since then there have been several publications of Vaughan's work, singly and in sets, and no library is complete without them. As recently as 1892 his complete works were published in this country.

Wordsworth admitted that Vaughan had a great influence on his work, and confessed that Vaughan's most famous poem, *The Retreat*, was the germ of the *Ode on the Intimations of Immortality*. Both men loved to brood on immortality and muse about death and both were passionately fond of Nature and all her works. This mutual love of Nature and deep interest in immortality figures conspicuously in the work of both writers and gives them more than a common kinship in the field of letters. Vaughan's poems abound in delicate descriptions of natural beauty and in the historic valley of the river Wye, where he was born and spent most of his life, there was an abundance of natural beauty to inspire a pen so gifted.

But why was Vaughan in obscurity so long? Perhaps the best explanation is given by Edith Sichel in the *Monthly Review*. Miss Sichel points out that intermingled with his gold is much base metal and that a great deal of what he wrote was dull, tedious and obscure. He did not keep a steady level, and it was by his faulty work, which bulked large against his perfect work, that his contemporaries judged against him. Miss Sichel, in line

with other critics, classes Vaughan with George Herbert, author of *The Temple*. "But Vaughan is more intellectual, more highly strung than Herbert," she says. "Where Herbert is pious Vaughan is mystical. . . . Vaughan's mind is subtler, loftier, more imaginative than Herbert's, and therefore often more farfetched. At his best, when emotion has worked him up to a white heat, none can be simpler than he, and he moves out into depths in a way George Herbert can never do. But when he is not fully inspired he is likely to grow elaborate; and where Herbert's homely simplicity goes straight to the heart and gives a loving welcome to the soul, Vaughan may have nothing to offer but an abstruse thought magnificently embroidered." Thus Vaughan holds his place today not for the mass of his work but for a few unforgettable poems that outshine all others of their kind.

The failure of his contemporaries to appreciate him discouraged Vaughan to such an extent that he quit writing early in life and confined his activities to the practice of medicine. All told he wrote five volumes of poetry and prose. The first was a volume of amatory and nature poems together with a translation of the *Tenth Satire of Juvenal*. His next volume was *Silex Scintillans* (Sparks from the Flint), a book of religious verse which contains the bulk of his masterpieces. This was followed by *Olor Iscanus* (The Swan of the Usk), his second book of sacred verse; *The Mount of Olives*, a book of private devotions; and *Flores Solitudinas*, which contained religious prose translations and *The Life of Paulinas, Bishop of Nola*. All these were written when he was between twenty-nine and thirty-four years old, and all, except the first, were of a devotional nature. Although he still had some forty years to live, henceforth he wrote nothing and published nothing. However, in 1678 his twin brother, Thomas, the noted alchemist, issued, without Henry's knowledge or consent, a volume entitled *Thalia Rediviva, the Pastimes and Diversions of a Country Muse*. The book consisted chiefly of amatory and pastoral poems which Henry had written early in life and had condemned to oblivion because of the lack of the religious element in them. Vaughan's religious fervor had deepened during a severe illness following the publication of his first book, and he turned absolutely away from worldly writings. Herbert's poetry, read during his convalescence, also deepened his religious convictions and molded the form of his future work.

Vaughan was a direct descendant of those royal Celtic princes of southern Wales whom Tacitus mentioned and whose abode in the days of the Roman domination of Britain was in the district

called Siluria. Vaughan always called himself "the Silurist." He and his twin brother were born on April 17, 1622, at Newton St. Briget, within the shadow of the ruined castle of Tretower, where their royal ancestors had held forth. Both brothers were active on the Royalist side during the civil war which ended in the triumph of Cromwell and both attended Jesus College, Oxford. Henry received his medical education in London, and began practising about 1645 at Brecknock, a country town near his birthplace, where he died at the age of seventy-three on April 23, 1695.

LARGE PLACENTAS AND SYPHILIS.

The problem to solve in regard to large placentas and syphilis is to ascertain if every child born with a large placenta should be regarded as a syphilitic and treated as such in future life. Recent researches, particularly those of Labourdette, seem to show that when syphilis is a certainty the placenta, far from being unusually heavy, only presents this condition in a relatively small number of cases, at least when the child is born at term and, secondly, if careful research is made for syphilis in women who have large placentas, the affection can rarely be detected. If all the children born at term were taken indiscriminately in the statistics published by either Blanchet or Labourdette, it will be found that out of a hundred and thirty-nine deliveries of females with unquestionable syphilis there was a large placenta in fourteen. If, on the other hand, we take all the Blanchet cases, it will be found that the average weight of the placenta to that of the child is 1:7, which is below normal and, according to Labourdette's statistics, the average ratio of the placental weight to that of the child is 1:5.8, corresponding to an increase in the weight of the placenta of thirteen grams above the average.

In these circumstances it would seem only logical to regard an increase in the placental weight to have no bearing whatever as to possible syphilis in parent and offspring. The exceptions are far too numerous to make large placentas a diagnostic sign of lues. In all of Labourdette's cases a Wassermann test was performed with the same antigen, namely, an alcoholic extract of the liver of an hereditary syphilitic fetus. The result of the Wassermann reaction in the offspring need not be considered, since in the newly born it has no value whatever. It is manifest that the results of the reaction in mother and child do not always agree, as Bar and Daunay have shown, and a negative reaction in a newly born infant does not mean that he is asyphilitic, even if he appears per-

fectly healthy. Likewise, the Wassermann may be frankly positive in an asyphilitic infant, especially when icterus is present.

In the mother, the Wassermann has only an absolute value when the spirocheta and its culture furnish the antigen and every element not of human origin has been removed from the reaction. These reservations made, it is probable that considerable value may be placed on the indications furnished by the Wassermann. It is evident that the number of positive Wassermanns attain their maximum in the secondary phase of syphilis—87 per cent. Brück, 92 per cent. Levaditi, 96 per cent. Blumenthal, 98 per cent. Blaschkeo, 100 per cent. Schmenfeld—and these figures are all the more important because the statistics relating to the question under consideration relate to a large number of cases. The age of the syphilis has a great influence over the Wassermann reaction, so much so that Kirschbaum maintains that it is positive in only sixty-eight per cent. of old syphilitics, but in Labourdette's statistics the negative results obtained in the mothers could not have been due to an old syphilis in a latent stage, because the average age of the women was twenty-three years.

A thorough, energetic treatment will render the Wassermann reaction negative and in the pregnant female with active luetic accidents, treatment will lower the number of positive reactions to less than fifty per cent. This does not, however, apply to Labourdette's statistics, because he only took those women into consideration who never had undergone antisyphilitic treatment in any form. In six cases this observer was able to corroborate the data obtained by the Wassermann with a very prolonged control of the infant. The six infants whose placental weight ratio was respectively 1:4.4, 1:4.5, 1:4.7, 1:4.6, 1:5.2, and 1:5.2, never presented the slightest evidence of syphilis. This may be a simple coincidence and it is certain that the results obtained would be much more conclusive had the number of infants been larger, but Labourdette only took into consideration those infants which he was able to follow beyond an age where syphilitic accidents would not be likely to appear. It might be said that the large placentas were due to syphilis in the father, and that, therefore, the mother would not offer any evidence of the infection, but Bauer's researches unquestionably show that Wassermann was positive in so-called immunized women, according to Colles's law. For all these reasons it is safe to rely on Wassermann's reaction. According to Labourdette's statistics it would appear that syphilis was rarely the cause of large placentas in eight women, as it occurred in only twenty-two and five

tenths per cent. of the cases and usually these were not unusually heavy placentas, so that as a sign of syphilis relatively little importance should be attributed to it, especially when the offspring is strong and vigorous. On the other hand, if the infant is puny and weakly, Wassermann reactions should be done to affirm the diagnosis in order to ascertain the true condition of affairs.

MIDDLE CLASS FERTILITY.

Our journals dealing with mentality, sane or insane, present today a delirious, bewildering set of charts of no use to anyone but the owner; that is, they need the author to explicate the waves traced apparently by an intoxicated thermometer. We advise those interested in *The Fertility of the English Middle Classes* (*Eugenics Review*, October, 1920) to leave the charts and take the conclusions, which are, that there is no essential difference between the fertility of university and nonuniversity women. Also, it is found that the mean size of the family is small and a considerable proportion of the parents restrict fertility, and the whole study of sampling middle class families has led to no result incompatible with the conclusions drawn by Karl Pearson and his collaborators from wider data of a different kind.

It is left to the reader to determine whether these results, or any results of wider analysis, suggest that neglect of eugenic principia is leading to a steady deterioration of the race or likely to influence the reproductive habits of the educated classes. There is much subject for reflection. We were sure that, having set out on exploring that horrible jungle revealed by the mental and moral condition of childbearing women in the criminal, mentally deficient, and poverty haunted classes; that the severely respectable, detached from the world's strife in a semidetached villa, would not long escape an analysis.

News Items.

Asthma and Hay Fever Clinic.—A public clinic for asthma and hay fever has been established at the New York Hospital. Dr. Robert A. Cooke is in charge of the clinic and will give treatments Monday and Friday afternoons.

The Mütter Lectures.—The Mütter Lecture on Surgical Pathology of the College of Physicians of Philadelphia, for 1920, will be delivered on Friday, December 10th, by Dr. J. C. Chalmers Da Costa, Samuel D. Gross Professor of Surgery, Jefferson Medical College of Philadelphia. His subject will be Paget's Diseases of the Bones.

Harvey Society Lectures.—Dr. Carl J. Wiggers, of the Western Reserve University, Cleveland, will deliver the fourth Harvey Society Lecture at the New York Academy of Medicine, Saturday evening, December 11th. His subject will be the Present Status of Cardiodynamic Studies on Normal and Pathological Hearts.

Personal.—Dr. and Mrs. Abraham Jablons, of New York, announce the birth of a son, Friday, November 26th.

Japanese Leper Colony in Need of a Microscope.—The Leper Colony at Kusatsu Mission, Japan, is urgently in need of a microscope powerful enough to detect leprosy bacillus. Should any of our readers know of anyone who would be willing to donate such a microscope, or where one could be purchased for a small price, we should be glad to hear from him.

High Death Rate in Austria.—According to press dispatches from Vienna, dated November 26th, deaths are exceeding births in Austria by 100 per cent. and the mortality rate is without parallel in history. This condition has resulted from the food shortage and the attendant undernourishment of the population, only a small percentage of the deaths being due to diseases not directly attributed to malnutrition.

University Course in Public Health Nursing.—A Department of Instruction in Public Health Nursing has been established in the University of Toronto in connection with the Faculty of Medicine. This course requires the attendance of graduate nurses at the university for one year. The Ontario Red Cross is providing ten scholarships of \$350 each, five of which are to be assigned to nurses who served overseas.

Medical Society of the County of New York.—At the annual meeting of the society, held Monday evening, November 22nd, the following officers were elected to serve for the ensuing year: President, Dr. George Gray Ward, Jr.; first vice-president, Dr. Orrin S. Wightman; second vice-president, Dr. Arthur F. Chace; secretary, Dr. Daniel S. Dougherty; assistant secretary, Dr. J. Millon Mabbott; treasurer, Dr. James Pedersen; censors for three years, Dr. Edward M. Colie, Dr. Gustav G. Fisch, and Dr. De Witt Stetten.

Medical Society of the County of Kings.—The following officers of the Medical Society of the County of Kings have been nominated for election at the next meeting of the society. Dr. Arthur H. Bogart, president; Dr. Frank D. Jennings and Dr. William V. Brinsmade, vice-presidents; Dr. Lewis P. Addoms, secretary; Dr. John Shields, associate secretary; Dr. Robert L. Moorehead, treasurer; Dr. Alfred Bell, associate treasurer; Dr. William Browning, directing librarian; Dr. William Webster and Dr. William Lindner, trustees.

French Surgeon Dies of X Ray Burns.—Announcement was made in Paris on November 29th that Dr. Charles Infroit had died from the effects of x ray burns. One of Dr. Infroit's hands became infected in 1898 as a result of his constant use of the x ray, and an operation was performed. Since that time he had undergone twenty-four operations, twenty-two of which were performed in the last ten years. The last was on August 1st, when his right arm and left wrist were amputated. Dr. Infroit was a celebrated surgeon, and his announcement in 1915 in the Academy of Medicine of Paris that he had extracted a bullet from the heart of a soldier was read with interest throughout the world.

American Child Hygiene Association.—At the annual meeting of this organization, which was formerly called the American Association for the Study and Prevention of Infant Mortality, the following officers were elected: Dr. Henry L. K. Shaw, of Albany, president; Mr. Herbert Hoover, of New York, president-elect; Miss Minnie H. Ahrens, of Chicago, and Mr. Sherman C. Kingsley, of Cleveland, vice-presidents; Dr. Harry F. Helmholz, of the Mayo Clinic, Rochester, Minn., secretary. Dr. Richard A. Bolt is general director of the executive staff and Dr. Philip Van Ieger is chairman of the executive committee.

Janssen Medal Awarded to American Physicist.—The French Academy of Sciences, Paris, has awarded the Janssen medal to William W. Coblenz, physicist in the Bureau of Standards, in Washington, for his discoveries in connection with rays emanating from the earth and stars. Mr. Coblenz has been attached to the Bureau of Standards for twelve years, and has developed a method of measuring radiant heat by infrared and ultraviolet rays. He has devised an instrument for astronomers with which to measure heat from the stars, and also developed in the course of the war signal instruments for ships at sea and an instrument for detecting moving bodies, such as ships, by their heat emanations in the dark.

Dr. Brush Commended for Relief Work in Near East.—Dr. Barton W. Brush, of Elmhurst, L. I., who for more than a year past has been engaged in relief work in Transcaucasia, has been commended by the Near East Relief, for his courage and devotion in refusing to abandon his post when the city of Kars, Armenia, fell to the Turkish Nationalists. Captain Ernest A. Yarrow, director general of the relief activities in the Caucasus area, said, in a letter to Dr. Brush, that he could not too highly commend him for remaining at his post in the very serious and dangerous crisis, and that on behalf of the Near East Relief he wished to express their profoundest gratitude and appreciation.

Red Cross League Appointments.—The following appointments are announced in the October *Bulletin* of the League of Red Cross Societies:

Dr. Hermann M. Biggs, health commissioner of New York State, has temporarily assumed the duties of General Medical Director, to succeed Dr. Richard P. Strong, who has resigned this position to resume his duties as professor of tropical medicine at Harvard University.

Dr. William H. Park, director of the Bureau of Laboratories, Department of Health, New York City, has been for several weeks in Geneva, where he has been giving assistance and advice regarding the work of the medical department.

Dr. William W. Francis, assistant chief of the Department of Medical Information, has been appointed editor of the *International Journal of Public Health*.

Professor George C. Whipple, who has been chief of the Department of Sanitation, is returning to the United States to take up his work again at Harvard University. He retains his connection with the League of Red Cross Societies in the capacity of consulting sanitary engineer.

Health Commissioners Attend Housing Conference.—Dr. Royal S. Copeland, Health Commissioner of New York, presided at a housing conference held in Detroit, Mich., last Tuesday and Wednesday. The health commissioners of thirty-three cities were in attendance. The conference was held for the purpose of determining so far as possible the exact effect on public health of the present housing situation in the United States. Dr. Copeland said that the survey of New York City had been completed by the Health Department, and that about 75,000 homes were visited.

Chief, Section of Medical Referees.—The United States Civil Service Commission announces an examination for Chief, Section of Medical Referees, to fill a vacancy in the Bureau of War Risk Insurance, Washington, D. C., at \$4,000 to \$6,000 a year. The duties of the appointee will consist of supervision of the Section of Medical Referees engaged in examining case files and making disability ratings based upon medical evidence contained in reports of physical examinations obtained from medical officers in the field, answering correspondence relative to claimants, and performing routine work connected with the medical aspect of claimants. Applications will be received up to January 11, 1921.

Meetings of Local Medical Societies.—The following medical societies will meet in New York during the coming week:

MONDAY, *December 6th.*—Clinical Society of the New York Polyclinic Medical School and Hospital; New York German Medical Society (annual).

TUESDAY, *December 7th.*—New York Academy of Medicine (Section in Dermatology and Syphilis); Clinical Society of Harlem Hospital; New York Neurological Society; Society of Alumni of Lebanon Hospital (annual).

WEDNESDAY, *December 8th.*—Medical Society of the Borough of the Bronx; New York Pathological Society; New York Surgical Society; Alumni Association of Norwegian Hospital (annual); Brooklyn Medical Association.

THURSDAY, *December 9th.*—New York Academy of Medicine (Section in Pediatrics); West End Clinical Society (annual); Brooklyn Pathological Society.

FRIDAY, *December 10th.*—New York Academy of Medicine (Section in Otolaryngology); Eastern Medical Society of the City of New York (annual); Flatbush Medical Society; Society of Externs of the German Hospital in Brooklyn.

Died.

DAY.—In Waterloo, N. Y., on Monday, November 15th, Dr. John W. Day, aged seventy-four years.

FERRACO.—In Southampton, L. I., on Thursday, November 25th, Dr. Almedes F. Ferraco, of Brooklyn, N. Y., aged twenty-seven years.

HOPKE.—In Brooklyn, N. Y., on Tuesday, November 23rd, Dr. F. E. Hopke, aged forty-six years.

KIRKPATRICK.—In Philadelphia, Pa., on Sunday, November 21st, Dr. Andrew B. Kirkpatrick, aged sixty-six years.

KNAPP.—In Brooklyn, N. Y., on Friday, November 26th, Dr. Mark Israel Knapp, aged fifty-two years.

LUCE.—In Oneonta, N. Y., on Tuesday, November 16th, Dr. Daniel Luce, aged fifty-seven years.

MCBEAN.—In Los Angeles, Cal., on Friday, November 12th, Dr. Anna G. McBean, aged thirty-seven years.

MYERS.—In Twin Falls, Idaho, on Friday, November 12th, Dr. J. P. Myers.

SPRAGG.—In Wheeling, W. Va., on Sunday, November 21st, Dr. Sylvanus L. S. Spragg, aged sixty-eight years.

THORN.—In Deerfield, Mass., on Friday, November 12th, Dr. Edwin C. Thorn, Jr., aged forty-six years.

WALP.—In Philadelphia, Pa., on Thursday, November 18th, Dr. George L. Walp, aged forty-four years.

Book Reviews

VACCINE TREATMENT.

Practical Vaccine Treatment. For the General Practitioner. By R. W. ALLEN, M. A., M. D., B. S., Late Captain, N. Z. M. C. New York: Paul B. Hoeber, 1920. Pp. xii-308.

Dr. Allen pleads for a fair hearing. For many years he "preached the doctrine of doses capable of exciting a reaction, of doses and intervals controlled by close clinical observation." He hopes a strict observation of his methods will help reconstruct vaccine treatment and enable it to take its rightful position as the most truly scientific therapeutic agency in the doctor's armamentarium. He very politely but definitely shows Sir Almoth Wright's definition of a vaccine to be the classic one, but cumbrous, now inaccurate, and in the future likely to be more so. Sir Almoth, quoted, says: "Bacterial vaccines are sterilized and enumerated suspensions of bacteria which furnish, when dissolved, substances which stimulate the healthy tissues to a production of specific bacteriotropins, substances which fasten upon and directly or indirectly contribute to the destruction of the corresponding bacteria." They are not, says Allen, always sterilized, nor always enumerated. Sera, again, are often confused by many with vaccines, whereas the immunity a serum brings about is passive—that by vaccines active.

As to the aim of vaccine treatment, he says: "The injection of a vaccine into healthy tissues results in the elaboration in the tissues of certain protective substances inimical to the wellbeing of these particular microbes which is being injected. This process we imitate when vaccinating the human subject—we exploit the healthy tissues in the interest of those which are infected and unhealthy."

He particularly emphasizes that the protective substances elaborated by the healthy tissues in response to the stimulus of the introduction of a certain microbe, are highly specific, i. e., of protective use only against that particular one. Thus, the *Bacillus typhosus* only avails with the *Bacillus typhosus* and holds no protection against the paratyphoid fevers. Many doctors, not realizing this, are often greatly disappointed with results.

Immunity against several microbes must be treated with a combined or compound vaccine. The first used—then much derided—was the author's own, though several imitations got on the market and the most worthless was adopted by the military authorities for Army use. It has been proved that the combination has the same effect as using separate bacilli for each microbe.

Prophylactic inoculation, too, has made great strides, evidenced by the successful fight against some dozen diseases by the author himself, though he had a wearying fight for the use of the combined vaccines during the Boer War, thousands of men being rendered unfit for service. Castellani was with him finally, and other bacteriologists. He alludes to the successful treatment of that strong enemy, rheumatoid arthritis, of which no one has yet succeeded in finding a specific bacterial origin, though it has for causative factors toxins derived from bacteria resident somewhere in the tissues, its

vaccine treatment must be that dealing with the associated primary focus of toxic absorption. This is given. There are useful chapters on Therapeutic Immunization and one of actual questions asked and the answers given. Diseases of the circulatory system, the genitourinary system, the intestinal tract, and ductless glands, are some of the interesting studies presented. Because written by an eager fighter and not by a mere looker on, the book is vital and merits both praise and a good welcome.

THE NEW PHYSIOLOGY.

The New Physiology in Surgical and General Practice. By A. RENDLE SHORT, M. D., B. S., B. Sc. (Lond.), F. R. C. S. (Eng.), Examiner in Physiology for the F. R. C. S., etc. Fourth Edition, Revised and Enlarged. Illustrated. New York: William Wood & Co., 1920. Pp. xi-291.

Many new editions do not justify their existence, the new pages being culled by subordinates and insufficiently edited, and the fresh original matter is not important enough to tax the purse of an impecunious doctor who conscientiously tries to have the very latest in his library. But men must have found what they sought in the three previous editions of this physiology, the revisions must have been honestly done, or a fourth would not have been sure of a welcome.

The first chapter is on food deficiency diseases, emphasis being laid on the fact that a capability for living even a long time on little does not prove the wisdom of so doing, nor that of keeping to a certain quantity, if the quality is not nourishing.

The old questions of rice polished and unpolished are ventilated, also that of lemon and lime juice as an antiscorbutic. Babies and lion cubs, where causes of rickets were investigated, were found to have had too much starch and sugar and too little fat and protein. The cubs, by the way, had been fed on London cab horse—doubtless the babies had had some, too—and anyone who is familiar with the appearance of that curious animal will doubt its efficiency as diet, the tires of a motor car being quite as satisfactory. In Greenland's icy mountains, where babies are given and vocally emit, plenty of blubber, rickets do not exist.

The author alludes, in his chapter on Researches on Blood, to the greater researches in America as compared with those in Britain, particularly when writing of an enemy during the war which had only been scotched, not killed, in civil practice, and now wrought havoc, that is, secondary hemorrhage. He speaks of the still active efficacy of red corpuscles kept for two or three weeks in an ice chest, confirming Rous and Turner's experiments. On one occasion, forty pints of blood, including one from a wellknown surgeon, were sent to him at a casualty station just before the battle of Cambrai. It was stored in ice, in a citrate-dextrose solution. In a week, the supernatant plasma was drawn off, as it might have proved dangerous after keeping, and the blood used was just as efficacious as that which was fresh.

Surgical shock, though illuminated by the flaring torches of war and studied by the best young brains

in Europe and America, leaves the surgical world not much nearer solving some of its problems, and this Short frankly admits, though he rewrites the chapter, giving the best of the newer knowledge. It is this comfortable stating in each chapter what to expect that is new and where only a clearer stating of the old can be given which renders the book valuable as a reference. From the great junction of physiological problems there are starting new trains of thought every year. How far they will safely run, wherewith they will connect, depends partly on the capable study by young men of the work already done, and in Short and the men whose names he gives, much help will be found, much weariness in research avoided.

TUBERCULOSIS.

Zeitschrift für Tuberkulose. Unter Mitwirkung der Herrn Prof. BABES (Bukarest), Prof. BANG (Kopenhagen), Geh. Med. Rat. Dr. BEHLA (Charlottenburg), Dr. LEO BERTHENSEN (St. Petersburg), und so weiter. Herausgegeben von M. KIRCHNER, F. KRAUS, W. V. LEUBE, J. ORTH, F. PENZOLDT. Leipzig: Verlag von Johann Ambrosius Barth, 1920. Seiten 64.

The editorial office of the *NEW YORK MEDICAL JOURNAL* has recently received a copy of the *Zeitschrift für Tuberkulose*, published by Johann Ambrosius Barth, Leipzig, Germany. To the best of the reviewer's knowledge, this is the first copy which has reached this country since we entered the world war. We welcome it again because of the quality of its contributions. In the number before us, being issue No. 1 of Vol. 33, October, 1920, there are two excellent articles on Chest Wounds and Pulmonary Tuberculosis. Dr. O. Seitler, who wrote the first article comes to the conclusion that a tuberculous lesion is much more likely to become activated as the result of the trauma than has been heretofore noted. In the second article by Dr. Gerhard Frischbier, these conclusions are confirmed. He makes the statement that even an absolutely latent case of pulmonary tuberculosis frequently becomes active as the result of a bullet wound.

Another article in this number treats of tuberculosis of the kidney, and others are devoted to antigen therapy and the symptomatic forms of chronic tuberculosis. Interesting is a contribution, by Gruber, of Mainz, concerning a number of post-mortem examinations on tuberculous French negro soldiers of the Army of Occupation. The author comes to the conclusion that in these African tuberculous patients the tuberculous infection almost invariably follows in the direction of the lymphatic vessels and that pneumoconiosis has not then appeared in their lungs. The remainder of the magazine is devoted to reviews of contributions on the subject of tuberculosis from all over the world. In prewar times original contributions in English and French appeared side by side with German articles in this magazine.

Authorities from nearly all the allied countries and former Central Powers are still mentioned as coeditors, only France is not again represented since the death of the great Landouzy. The managing editors of the *Zeitschrift* are Prof. Dr. A. Kuttner and Prof. Dr. Lydia Rabinowitsch; the latter is particularly well known to American tuberculosis

workers from her former residence in Philadelphia. The *Zeitschrift für Tuberkulose* is up to date in all its contributions and it is to be hoped that when peace will at last again unite the science of medicine throughout the civilized world, the magazine will again be the avenue for the interchange of ideas for the welfare of tuberculous sufferers.

THE DUODENAL TUBE.

The Duodenal Tube and Its Possibilities. By MAX EINHORN, M.D., Professor of Medicine at the New York Post-Graduate Medical School; Visiting Physician to the Lenox Hill Hospital, New York. Illustrated. Philadelphia and London: W. B. Saunders Company, 1920. Pp. xiii-122.

Originally Dr. Einhorn perfected the duodenal tube for the purpose of having a convenient method of diagnosis. Recently the field of usefulness for the tube has been extended so that it may be used therapeutically. Much light has been shed upon the nature of the secretions in the vicinity of the duodenum by the use of this method. Some of these findings have been presented by Dr. Einhorn from time to time in the *NEW YORK MEDICAL JOURNAL*. In the hands of a careful worker like Dr. Einhorn it has proved to be a most useful appliance. It has proved to be a useful adjunct in diagnosis to the x ray, stomach pump and duodenal bucket. Another useful purpose the tube serves is as a conductor of alimentation to the patient. Stretching of the pylorus by means of the pyloric dilator has also proved of value, as well as stretching of the cardia in impermeable cardiospasm.

The book is replete with illustrations showing the various methods of application for the tube, as well as x ray photographs showing the tube in various parts of the intestinal canal. The illustrations in color show specimens of normal and abnormal duodenal contents after they have been removed by means of the tube.

LIFE.

Life. By JOHAN BOJER. Translated from the Norwegian by JESSIE MUIR. New York: Moffat, Yard & Co., 1920. Pp. 339.

Life. Our first impressions, our first fears, have more to do with death than with that more mysterious state, life. Death and far off things were studied more by the ancients than life and self. More recently man has begun seriously to be introspective. So Bojer, who comes to us with worthy studies translated from the Norwegian, attempts the presentation of a few of the actions and reactions of a certain group of people and calls it life. Let the title stand; we shall endeavor to follow him and see what he has to do.

He gathers up an armful of characters and shows us how they behave under certain stressful conditions. Here, one has an old grudge, a captain in the army; his fellows go on to advancement while he remains a captain. The world is against him, all are plotting to prevent his promotion. He seeks a retreat and plans revenge. He draws plans for the reorganization of the army, he compensates for his inferiority, he is greater than all the generals, he who has been overlooked and downtrodden. In this half fantasy world he finds his haven of refuge. In his defeat during the struggle with reality and in

his retreat he drags others down with him; his son and daughter. But they too have their difficulties aside from their environment and the heritage from their paternal ancestor. The difficulties of his daughter's mother while not depicted are alluded to frequently. She too finds the struggle for existence and expression a difficult one and at a critical period yields to one man while she transforms him through a process of mental imagery, reinforced by circumstance, into the man she really cares for. This momentary weakness hangs like a heavy cloud over her and when finally she achieves her dreams of marriage to the man she really loves, and emancipation, she finds herself too weak to face the situation and, through an unconscious process, solves her problems through a foolhardy adventure in a small boat. Her minor difficulties were met by white lies and evasions, each one leaving her weaker and less able to meet the real problems when they came up to her for solution.

With great skill Bojer shows how the weaknesses of one character involve the lives and happiness of all who with them may happen to come in contact. Those who refuse to stand on their own feet push down others upon whom they lean. Bojer's sketches are like dry point etchings, clear cut and not flamboyant. His hope for a newer and finer social structure, which he bases on the development of men and women by their interest in healthful outdoor living and an interest in things beautiful, is all very well but he completely ignores changes in social structures and environmental factors which go so far in determining the conditioning of all human beings. He contends that the individual is always stronger than his environment and can model his life as he wills. This may be true in certain, or if he will, in many individual cases, but no matter how finely he may divide iron the specific gravity will always be greater than water. It is true that ice will sustain iron and a ship made of iron will float, but the ice one day will melt and the ship, one day, may leak. While we may not agree on all points with the philosophy of our Norwegian author, we must admit the power of his writings and grant him a place among the foremost novelists of today. He has not exactly presented life to us; just a few of the problems of man; just a few, but important ones nevertheless.

New Publications Received.

[We publish full lists of books received, but we acknowledge no obligation to review them all. Nevertheless, so far as space permits, we review those in which we think our readers are likely to be interested.]

DIABETES. A Handbook for Physicians and Their Patients. By PHILIP HOROWITZ, M.D. With Twenty-Seven Text Illustrations and Two Colored Plates. New York: Paul B. Hoeber, 1920. Pp. xii-196.

SHORT TALKS ON PERSONAL AND COMMUNITY HEALTH. By LOUIS LEHRFELD, A.M., M.D., Agent for the Prevention of Diseases, Department of Public Health, Philadelphia, with an Introduction by WILMER KRUSEN, M.D., LL.D., Director (1916-1919), Department of Public Health and Charities, Philadelphia. Philadelphia: F. A. Davis Company, Publishers, 1920. Pp. xii-271.

THE HYPHEN. By LIDA C. SCHEM. In Two Volumes. New York: E. P. Dutton & Co., 1920. Pp. 1052.

HUNGRY HEARTS. By ANZIA YEZIERSKA. Boston and New York: Houghton Mifflin Company, 1920. Pp. 297.

CAIUS GRACCHUS. A Tragedy. By ODIN GREGORY. With an Introduction by Theodore Dreiser. New York: Boni & Liveright, 1920. Pp. 172.

THE JEWISH FAIRY BOOK. Translated and Adapted by GERALD FRIEDLANDER. With Eight Illustrations in Color by GEORGE W. HOOD. New York: Frederick A. Stokes Company, 1920. Pp. 188.

SATAN'S DIARY. By LEONID ANDREYEV. Authorized Translation Never Before Published in Any Language, with a Preface by HERMAN BERNSTEIN. New York: Boni & Liveright. Pp. xvii-263.

THE BRIDE OF CORINTH AND OTHER POEMS AND PLAYS. By ANATOLE FRANCE. A Translation by WILFRED JACKSON and EMILIE JACKSON. London and New York: John Lane Company, 1920. Pp. xv-285.

EINFÜHRUNG VON EMIL ABDERHALDEN. Halle a. d. Saale, nebst einer vollständigen und ausführlichen Inhaltsübersicht der 13 Abteilungen des Gesamtwerkes. Berlin-Wien: Urban & Schwarzenberg, 1920. Seiten 84.

THE STORY OF DOCTOR DOLITTLE. Being the History of His Peculiar Life at Home and Astonishing Adventures in Foreign Parts. Never Before Printed. Told by HUGH LOFTING. Illustrated by the Author. New York: Frederick A. Stokes Company, 1920. Pp. 180.

HOOKEWORM AND MALARIA RESEARCH IN MALAYA, JAVA, AND THE FIJI ISLANDS. Report of Uncinariasis Commission to the Orient, 1915-1917. By S. T. DARLING, M.D.; M. A. BARBER, Ph.D., and H. P. HACKER, M.D.. Publication No. 9. New York: The Rockefeller Foundation International Health Board, 1920. Pp. x-191.

A HISTORY OF THE CONCEPTIONS OF LIMITS AND FLUXIONS IN GREAT BRITAIN FROM NEWTON TO WOODHOUSE. By FLORIAN CAJORI, Ph.D., Professor of History of Mathematics in the University of California. With Portraits of Berkeley and Maclaurin. Chicago and London: The Open Court Publishing Company, 1919. Pp. viii-299.

AN INTRODUCTION TO BACTERIOLOGY FOR NURSES. By HARRY W. CAREY, A.B., M.D., Assistant Bacteriologist, Bender Hygienic Laboratory, Albany, N. Y. (1901-3); Pathologist to the Samaritan (Troy) and Cohoes Hospitals, and City Bacteriologist, Troy, N. Y. Second Revised Edition. Philadelphia: F. A. Davis Company, Publisher. English Depot: Stanley Phillips, London, 1920. Pp. vii-149.

REFRACTION AND MOTILITY OF THE EYE. With Chapters on Color Blindness and the Field of Vision. Designed for Students and Practitioners. By ELLICE M. ALGER, M.D., F. A. C. S., Professor of Ophthalmology at the New York Postgraduate Medical School, etc. With One Hundred and Twenty-five Illustrations. Second Revised Edition. Philadelphia: F. A. Davis Company, Publishers. English Depot: Stanley Phillips, London, 1920. Pp. xiv-394.

PRACTICAL MASSAGE AND CORRECTIVE EXERCISES WITH APPLIED ANATOMY. By HARTVIG NISSEN, President of Posse Normal School of Gymnastics; Superintendent of Hospital Clinics in Massage and Medical Gymnastics; For Twenty-four Years Lecturer and Instructor of Massage and Swedish Gymnastics at Harvard University Summer School, etc., etc. Fourth Revised Edition, with Sixty-eight Original Illustrations, Including Several Full Page Half Tone Plates. Philadelphia: F. A. Davis Company, Publishers. English Depot: Stanley Phillips, London, 1920. Pp. xii-225.

OCCUPATIONAL AFFECTIONS OF THE SKIN. Their Prevention and Treatment. With an Account of the Trade Processes and Agents which Give Rise to Them. By R. PROSSER WHITE, M.D. (Ed.), M. R. C. S. (Lond.), Life Vice-President, Dermatologist, Senior Physician, and Ethetic Officer, Royal Edward Infirmary, Wigan; Vice-President, Association Factory Surgeons, etc. Second Edition. With Twenty-four Plates (Comprising Twenty-eight Figures). New York: Paul B. Hoeber, 1920. Pp. xiv-360.

Practical Therapeutics and Preventive Medicine

A Compendium of Treatment and Prophylaxis, Original and Adapted

Dilatation of the Lateral Ventricles as a Common Brain Lesion in Epilepsy.—Dr. A. Thoms (*Journal of Nervous and Mental Disease*, January, 1920) finds from observation that dilatation of the lateral ventricles is a common abnormality of the brain in epileptic subjects, but fails to find in literature mention of this phenomenon. A study of the brains of seventy-five epileptic subjects made during the past seven years showed that seventy-six per cent or fifty-seven cases had gross brain lesions. Thirty-one of these fifty-seven cases presented cortical lesions as well as dilated ventricles, sixteen showed lesions of the cortex alone, and fourteen had dilated lateral ventricles, though the cortex looked normal. In the cases with cortical lesions the hind part of the brain, especially the occipital lobe, was most frequently affected. General cerebral gliosis involving the entire cerebrum was the next most frequent manifestation. Softenings, usually localized, were noted in surprisingly few instances.

The dilated ventricle group comprising forty-one cases, or 54.6 per cent, showed abnormalities of the cortex in twenty-seven brains, which cortical lesions were the probable cause of the convulsions. The ventricular dilatation in the remaining fourteen cases in which there was no cortical involvement, raises the question as to whether lesions affecting primarily the white matter may not be a factor in producing epilepsy. A summary of the ages at which convulsions began in the group with both dilated ventricles and cortical lesions showed that the onset occurred before twenty years of age in sixty-three per cent of the cases, whereas it occurred at this period in only forty-three per cent of the cases in which there were no cortical lesions. In cases presenting dilated ventricles without cortical lesions the greatest number of onsets after thirty years of age occurred.

The Therapeutics of Essential Epilepsy.—L. Pierce Clark (*Boston Medical and Surgical Journal*, September 30, 1920) says that in handling the individual epileptic it is first necessary to analyze the specific conflicts which he has to meet in life and note his type of mismanagement of them. Then consciously to increase the patient's insight into the situation is absolutely necessary. It has been the custom so long merely to note the epileptic defect and not make him aware of his own inherent fault that this method alone is almost revolutionary. Heretofore this kind of autognosis, or selfknowledge, has been left to wellmeaning friends, nurses, religious instructors or tutors, and has not been brought into the physician's own armamentarium. Perhaps it has been held to be of so little medical importance, or that the process of wise teaching entailed has been thought to be so time consuming that the physician has neglected his plain duty. But since the newer principles of reeducation and psychoanalysis in the neuroses have been established, similar methods are really found to be of service in

essential epilepsy. Proceeding with this method sooner or later one finds that the epileptic individual possesses a crude type of personality. No explanatory talk about his character defect will remove it.

Essential epilepsy in its inability to be analyzed away demonstrates that it is not a neurosis but a profound disorder of the instinctive life. Analysis but points out the glaring defect and it is then possible to lay down a daily schedule of character training and practice in concrete instances wherein the epileptic may learn day by day, little by little, the means of overcoming his faults of character. Analysis only points out the specific reeducation possible. In many instances notes of the analyzed defects should be taken by the patient himself or summarized by the teaching physician so that the epileptic individual may go over it again and again. He is likely to forget the explanatory talks as a protective mechanism common to all humanity. The fit itself obliterates the imprint of the corrective advices. Thus it would seem that the epileptic seizure is a magic talisman in more than one direction. It reduces the sting of the affective stress which springs the epileptic reaction. Be it fit or explosive temper, it carries off the keenness of the epileptic initiation of helping himself and obliterates the teachings formerly given him.

Potassium Borotartrate in Epilepsy.—Pierre Marie, Crouzon and Bouttier (*Bulletin d'Académie de médecine*, June 1, 1920) report clinical tests demonstrating that boron compounds, and in particular potassium borotartrate—sometimes termed soluble cream of tartar—exert an effect in epilepsy much like the bromides, but without the drawbacks attending the use of the latter. A marked reduction in the intensity and frequency of the seizures was obtained. Potassium borotartrate occurs in transparent scaly crystals, colorless, with an acid taste, and very soluble in water. Where, owing to a change in the molecular condition, the solubility diminishes, it can be promptly restored by treating the compound with hot water. The dose of the drug administered was generally three grains a day, given in three tablespoonfuls of the following solution: Potassium borotartrate, twenty grams; chemically pure glycerin, ten grams, and distilled water, enough to make three hundred mils. This dose could, if necessary, be largely increased, as formularies generally give the dose of potassium borotartrate as a purgative as twenty to thirty grams a day. In the clinical tests, ten chronic epileptics, previously under prolonged observation and many of them no longer amenable to bromides, were given three grams a day of either the salt mentioned, sodium tetraborate, or ordinary borax. As with bromides, the benefit appeared first as a transformation of the seizures to mere dizziness, and later by progressive diminution of the intensity of the latter. The average number of seizures a month in these ten patients was 30.5 before the boric treatment, eighteen

during the first month of treatment, 11.5 during the second month, and nine in the third month. Only once or twice was there any vomiting, and when it occurred it yielded promptly to cessation of the drug, as did also looseness of the bowels. An important advantage over the bromides was the entire absence of any evidences of mental depression by the drug, which seems to act directly upon the primary pathological cause of epilepsy rather than by depressing the nerve centres. The fact that three grams of potassium bromide contain two grams of bromine, whereas three grams of potassium borotartrate contain only 0.155 gram of boron, also points to a different mode of action on the part of the two agents. Possibly the boron acts after the manner of a catalyzer. Potassium borotartrate was well borne, alike in children and aged individuals, but borax sometimes brought on eczema. The former agent is almost invariably to be preferred to borax or sodium tetraborate. The latter, however, gives better results than borax. Favorable clinical effects were likewise obtained in traumatic epilepsy and in epilepsy due to brain tumor.

A Consideration of the Aftercare in Arrested Cases of Essential Epilepsy.—L. Pierce Clark (*American Journal of the Medical Sciences*, October, 1920) concludes as follows: 1. So-called cures or arrests in essential epilepsies are brought about only by the most thoroughgoing and prolonged plan of neurological and hygienic training treatment in which reeducation is the basic factor. 2. Relapses in arrested cases occur through negligence or disregard of the essential factors. There is renewed and intensive physical and mental stress and proper and appropriate medical supervision should be continued throughout the lives of such individuals. Such a plan of aftercare in private and institutional practice would greatly diminish the possibilities of relapse. 3. A more or less enduring arrest and cure in essential epilepsy may be considered permanent when the environment and life reactions as regards the secondary epileptic reactions are approximately normal. No mere cessation of epileptic fits under sedatives should be held out as an enduring arrest unless the individual shows a corresponding absence of epileptic reactions.

Sympathetic Disturbances in the Upper Extremities in Middle or Lower Dorsal Involvements of the Spinal Cord.—J. A. Barré and R. Schrapf (*Presse médicale*, April 28, 1920) call attention to certain disturbances, in all likelihood of sympathetic origin, which occur in the upper extremities and are caused by a lesion of the spinal nerve roots not in the cervical but in the middle or lower dorsal region. These disturbances affect the ulnar area of the extremities and especially the last fingers. They may constitute a forerunner of a spinal symptom complex and precede the oncoming of paralysis of the lower extremities. Failure to recognize the site of the disturbance in the middorsal region may lead to mistaken localization in the cervicodorsal region of a pathological cause actually located between the sixth and eleventh dorsal segments. In the presence of these apparently sympathetic disturbances, the possibility of a lesion of the spinal nerve roots in the dorsal region should be borne in mind.

The Significance of Meningeal Symptoms.—A. C. Eastman (*Boston Medical and Surgical Journal*, October 28, 1920) says that meningeal symptoms are frequently present in many of the infections of childhood and may represent either a meningism or a meningitis. Unless definitely positive of some diagnosis besides meningitis, the only means of determining their significance is by lumbar puncture, which, in many cases, requires several repetitions before a definite diagnosis can be made. Like other laboratory examinations, the findings in the cerebrospinal fluid must be considered in conjunction with the clinical progress of the disease. In the final analysis we must depend upon the bacteriological examination to furnish a positive diagnosis.

Cause and Prevention of Overstimulation of the Modern American Child.—Erik St. J. Johnson (*Boston Medical and Surgical Journal*, October 28, 1920) asserts that the automobile, the motor boat, graphophones, pianolas, and cinematographs, together with wrongly proportioned extravagance in ambition and money, in schools and in homes, are all, in certain ways, seriously harmful to the existence and development of normal children. Chiefly so in that unless used with more than average care and forethought, they render children dissatisfied with normal home life. There, and there only, are laid the true foundations for natural strength and lasting qualities in mind and body. Though economic checks, such as the high cost of living, and future shortage of gasolene, are bound to operate before long in the line of general stabilization, medical men should use every opportunity to warn parents of the causes and evil results of overstimulation of children outside the home. Children need a less hurried, more simple existence in order to build up lasting qualities.

Acute Myoclonic Encephalitis.—Sicard and Kuddelski (*Bulletins et mémoires de la Société médicale des hôpitaux de Paris*, January 29, 1920) describe a recently observed clinical condition characterized by lassitude and malaise, severe lancinating pains in all parts of the body, a rise of temperature to about 38° C., and occasionally slight headache. After about a week there appear brief, quick, explosive muscular contractions of the limbs, face, and diaphragm, sometimes localized in one portion of the body. The myoclonic seizures affect a single entire muscle or group of muscles, and are not accompanied by fibrillary contractions. The pains in various parts and the slight fever persist. There is no eye symptom or somnolence; as a rule, insomnia is present. About the third week slight delirium appears. The reflexes, objective sensibility, and pupils remain normal. In the terminal stage, lasting three or four days, speech becomes difficult and jerky. There are automatic gestures, nearly continuous delirium, lessened intensity of the myoclonic seizures, and finally coma and death. The cerebrospinal fluid is nearly normal; at times, particularly toward the close of the case, it shows slight albuminosis and lymphocytosis. The Bordet-Wassermann test of the spinal fluid and blood is negative. In one case the myoclonic seizures were followed by paresis of the extensors in the upper extremities.

Intravenous Injection of Ammoniacal Copper Sulphate Solution in Puerperal Sepsis.—H. Noiré (*Presse médicale*, June 5, 1920), at Manté's behest, treated an apparently hopeless case of puerperal sepsis by this measure and was amazed to see the patient recover. He later employed the treatment in three other cases, with like success. The ammoniacal copper sulphate yields absolutely clear solutions if not made more dilute than four per cent., whereas solutions of ordinary copper sulphate, whether concentrated or dilute, are always turbid and sometimes cause reactions similar to those following injections of the colloidal metals. The ammoniacal copper sulphate solution mixes in all ratios with blood serum without causing the least turbidity, and its intravenous administration awakens no reaction. The preparation of the solution consists in placing anhydrous copper sulphate and ammonia water in a bottle so as to form a saturated solution, the bottle being meanwhile corked. An equal volume of ninety per cent. alcohol is then added, the two liquids being separated by dialyzing paper. After twenty-four hours, crystals of ammoniacal copper sulphate are formed. These are rapidly dried in blotting paper, after having been washed with alcohol, and are kept in well stoppered bottles. In injecting the solution, care should be taken that all of it passes into the vein, as the least amount passing beneath the skin will cause sloughing. In puerperal fever the author injects two mls of the solution, i. e., eight centigrams of the salt, morning and evening, until the temperature descends to normal.

Injury of Intraabdominal Viscera.—Frank T. Fort (*International Journal of Surgery*, September, 1920) in a plea for early surgical intervention in unrecognized wounds of the intraabdominal viscera presents the following arguments: The increasing frequency with which preventable fatalities are observed from injury to intraabdominal viscera accompanying external trauma without production of positively indicative local or general symptoms, should cause every conscientious practitioner of medicine to indulge in serious introspective study and reflection: the medical man, because he oftentimes first sees the injured individual and much depends upon the promptness and thoroughness of his investigation and his diagnostic and prognostic acumen; the surgeon, because upon his diagnostic confirmation, his technical ability and keen surgical sense will usually depend the life (or death) of the individual.

It is important that an accurate history of the accident be obtained in every instance where external abdominal trauma has been inflicted: the nature of the traumatizing agent, the attitude of the individual when injured, the exact anatomical region implicated, the probable force and direction of the violence, and the time with relation to food ingestion. The data thus collected should be carefully considered in connection with existing local and general symptoms in estimating the possibilities of coincident internal injury. The pertinent fact must not be forgotten, however, that extensive visceral damage may be produced by apparently slight external trauma; also, that there may be no coincident internal damage despite violent external injury.

There being no pathognomonic early signs by which visceral injury may be recognized, early accurate diagnosis is often delayed or rendered impossible. This fact, however, is unimportant since it is the imperative duty of the surgeon to intervene provided there exists even presumptive evidence of internal damage. Procrastination more often than otherwise means a fatal issue, and properly executed celiotomy is practically devoid of clinical risk. Where visceral damage has occurred the mortality under expectant treatment is nearly 100 per cent. as illustrated by statistics cited.

Promptly instituted surgical intervention, based upon suspicion or presumption of internal injury after exhausting reasonable efforts to complete an accurate diagnosis, with adequate repair of visceral damage when such has occurred, should markedly reduce the unreasonably high mortality prevailing in the class of cases under discussion. The dictum "the earlier operative treatment is instituted where visceral injury has occurred, the greater the probability of saving the life of the individual," should be accorded more consideration than has hitherto obtained.

Diagnosis and Treatment of Hydrocephalus.—Walter E. Dandy (*Surgery, Gynecology and Obstetrics*, October, 1920) discusses the diagnosis and treatment of hydrocephalus resulting from strictures of the aqueduct of Sylvius and presents the following conclusions: 1. Cicatricial stenosis of the aqueduct of Sylvius is the most frequent lesion in congenital hydrocephalus (about fifty per cent.), and is found in a large percentage of cases of hydrocephalus occurring in infancy and early childhood. It may occur (though rarely) in adult life.

2. Hydrocephalus always follows occlusion of the aqueduct. The third and both lateral ventricles progressively dilate. The fourth ventricle, being posterior to the obstruction, does not enlarge.

3. In the gross, the occluded aqueduct appears to be replaced by a fibrous tissue which microscopically is neuroglia. Microscopic remnants of the aqueduct are usually but not invariably found.

4. The stenosis may occupy the entire length of the aqueduct, or varying parts; it may be only a thin even transparent membrane. Again, the stricture may be only partial.

5. Strictures of the aqueduct of Sylvius can be diagnosed and accurately localized. The indigo-carmin test will indicate that an obstruction is present; ventriculography will be the means of precisely locating the obstruction.

6. Spontaneous relief is not possible. Surgical attempts to drain the fluid from the third ventricle to the exterior of the brain have all proved futile. The openings invariably close and the fluid cannot absorb in the subdural space.

7. A surgical procedure is suggested which is directed toward the cause. A new aqueduct of Sylvius is constructed; a tube is left in place for two to three weeks. It is hoped the epithelium will regenerate and establish a new canal.

8. This operation has been performed in two cases, both patients recovering from the operation. One patient died of pneumonia several weeks later, the second seemed well one year after the operation.

Rôle of Cancellous Tissue in Healing Bone.—

T. Wingate Tood (*Annals of Surgery*, October, 1920) gives the following résumé of his studies of the rôle of cancellous tissue in bone healing: 1. Cancellous tissue is one of the chief agents in regeneration of bone, and like the cambium layer of periosteum, should be treated at operation in the most conservative manner, consistent with thorough exploration and drainage. 2. In regeneration the cancellous tissue nearest the midlength of the bone grows most rapidly, whereas that in or near the articular extremities shows less readiness to proliferate and fill the cavity. 3. Septic bone cavities should be permitted to heal from the bottom, the wound in the soft tissues being kept widely open until this has occurred. The least possible mechanical disturbance of the cancellous tissue should be employed and no disinfection of the cavity attempted, for this simply kills the remaining tissue from which regeneration is expected. 4. Regenerating bone is very sensitive to and easily affected by pressure, even of soft tissues, and by inefficient drainage. It is not adversely affected by the ambulatory method of treatment. 5. Compact bone plays a very minor part in regeneration.

Gonococcemic Pseudomalarial Fever.—M. Bloch and P. Hébert (*Bulletins et mémoires de la Société médicale des hôpitaux de Paris*, March 4, 1920) report the case of a man aged twenty-five in whom various clinical features, such as pseudomalarial fever, arthralgia, and maculonodose and even purpuric eruptions, reproduced precisely the picture of meningococcemia as described by Netter, Marie, and others. Attention not having been drawn at the beginning to an existing chronic gonorrhoea, and the blood culture having revealed a gram negative coffee grain diplococcus, intensive antimeningococcic serum therapy was at once instituted, but yielded no results. On the other hand, injection of a vaccine made from the germ found in the patient's blood brought about rapid recovery from the septicemia, though the genitourinary foci apparently failed to benefit from it. In such a case the diagnosis could be made only by agglutination tests, the diplococcus from the blood being found inagglutinable by antimeningococcic serums though agglutinable by antigenococcic serum. The complete failure of antimeningococcic serum in this case would seem to negative the good results claimed for it in gonococcal arthritis by certain observers.

Treatment of Fracture of Femur.—Moorhead (*Surgery, Gynecology and Obstetrics*, September, 1920) gives the following treatment for fracture of the femur: 1. Treatment of fracture of the femur starts with first aid designed to place the limb at rest in traction in a Thomas splint, or in traction straps with weights attached. Ambulance surgeons and first aid men should be supplied with Thomas splints. 2. The patient and not the fracture will demand most attention in the feeble or diseased. 3. Any method that does not combine reduction with early massage and motion fails to give the maximum service. 4. The former idea that deformity and disability are inevitable in femur fractures should be abandoned. 5. Two attempts at reduction should be made before skeletal traction

or open operation is performed. 6. For the non-displaced and reducible group, plaster of Paris (spica or molded) is an efficient form of splintage. 7. In the irreducible group described, skeletal traction by transfixion offers a safe, efficient method. 8. This fracture entitles the patient to a high grade of surgical care and exacts from the surgeon a degree of diligence and skill at least equal to that necessary in the management of many other major surgical problems. 9. Fractures have been too much slighted by surgeons and for that reason the fracture field is being encroached upon by orthopedists who by their training are better fitted for the aftercare than for the initial care of this acute variety of traumatic surgery. 10. There is great need for standardization and uniformity in fracture work and in no group is this more necessary than in fractures of the femur.

Intoxication from the Rectum.—L. Dreyfus (*Presse médicale*, February 18, 1920) states that the possibility of intestinal intoxication by bacterial toxins or toxic products resulting from the decomposition or putrefaction of proteins has not yet been experimentally demonstrated. He has personally succeeded, however, in demonstrating experimentally the possibility of intestinal intoxication by acids. This occurs almost exclusively in the large intestine, and chiefly in the rectum. Clinical occurrence of such a condition may be considered very probable, as there exist in the feces many acids which might give rise to it. Under normal conditions the stools should be neutral in reaction. The principal factors that may render them acid are a too copious or exclusive carbohydrate diet and insufficient secretion of bile. These conclusions open up a new field in the treatment of acute or chronic intestinal intoxication and the disturbances of health dependent upon such intoxication.

Treatment of Carbon Monoxide Intoxication.—Léon Binet (*Presse médicale*, May 15, 1920) emphasizes the fact that the simplest and best plan of treatment in this condition is to break down the carbon monoxide hemoglobin *in vitro*. The combination of the gas with hemoglobin is an unstable one, which can be broken up by oxygen provided the latter is administered in pure form, as shown by Nicloux. Achard has pointed out that inhalation of pure oxygen is capable of yielding a maximum therapeutic effect from the start in this condition. The respiratory capacity of the blood comes back to normal under these conditions and cannot be further raised by a second inhalation of oxygen gas. It is never too late in a case of carbon monoxide poisoning to use pure oxygen, for even several days after the intoxication the poison is displaced from the hemoglobin combination just as readily as it is immediately after the intoxication. The richer the air respired in oxygen, the more rapidly the displacement of carbon monoxide from the combined hemoglobin will proceed. Giving oxygen through the usual cannula held in front of the patient's mouth and nose is definitely insufficient in these cases. A chloroform mask or emergency pasteboard mask must be used, and if the gas is inhaled in large amounts, recovery may be procured within a few minutes.

Proceedings of National and Local Societies

NEW YORK NEUROLOGICAL SOCIETY.

*Three Hundred and Seventy-ninth Regular Meeting,
Held March 2, 1920.*

The President, DR. WALTER TIMME, in the Chair.

Chronic Nondegenerative Hereditary Chorea.

—Dr. I. S. WECHSLER presented a case showing a clinical picture closely resembling Huntington's disease, but certain distinctive features removed it from that category and suggested that it might be a distinct clinical entity. An American, female, married, aged thirty-six, had had peculiar movements of arms, hands, body and legs, twitchings of the face, for some sixteen years, gradually increasing in intensity for a time, then remaining comparatively unprogressive. A slight weakness of the heart, with faintness, was complained of about the time of the onset, which was said to have followed a miscarriage. There were no convulsions, biting of tongue, nor amnesia. The attacks were closely linked with the patient's emotional state, suggesting a possible hysterical condition. The patient's father, who was the uncle of her mother, also suffered from chorea for twenty years. One brother had shakings. Of her children one daughter was not nervous, but had poor eyesight and nystagmus; the second daughter had twitching and attacks of weakness. The shaking was not choreic. Two small boys had chorea and nystagmus.

The patient showed a number of abnormal involuntary movements; irregular, jerky, purposeless movements of whole parts, arms, legs, body, hands; twisting of the whole body. The eyeballs wandered in irregular fashion in their sockets. All these movements were intensified by emotion, while control inhibited them for a short time. The movements were in general more rapid than in chorea. No pathological reflexes were found. Vision and hearing were normal, except for the choreic nonrhythmic movement of the eyes. Mental status was perfectly normal, with a slight tendency to forgetting, probably due to lack of attention.

In the oldest boy, aged nine and a half, a condition diagnosed at the hospital as acute chorea developed at the age of seven. The condition improved somewhat after six months, but two years ago there was a second acute attack. The younger boy, aged six, had had slight twitchings since he was three. Slight unsteadiness in equilibratory and nonequilibratory tests, of a choreic nature, was obtained on examination. Some nystagmus on looking forward and trying to fix the gaze was also noted.

Unlike the condition usually met with in Huntington's chorea the onset of the attack was at the early age of twenty. The movements were quicker, the face showed more grimaces, speech was differently affected, somewhat forced and slow but not scanning. The gait was clownish. Mental degeneration was absolutely absent. Hysteria might be adduced as a cause, especially hysteria associated with chorea, while other forms of chronic chorea, such as chorea gravidarum and paramyoclonus

multiplex, had features suggestive of this case, but did not correspond sufficiently to warrant the diagnosis. The point of particular interest in this case was that it was a nondegenerative, nonprogressive type of hereditary chorea.

Hyperthyroidism in a Girl Nine Years of Age.

—Dr. MORRIS H. FRANTZ presented a case which he considered was of interest because of the infrequency of the condition in children. The patient had come to the Neurological Institute clinic a year before. She was fidgety, would get into rages, and had palpitation on violent exercise. Muscular sthenia, ocular manifestations and a distinct exophthalmus were present. Tachycardia and slight tremor of the hand were also noted. Laboratory findings were negative; mental age was twelve and a half.

The patient's father had had rheumatic arthritis, the mother suffered from hyperthyroidism. Goitre had been present in a maternal aunt. The child was born in a little town in Germany where goitre was prevalent. At the time of the child's birth a goitre developed in her mother, and the same condition was diagnosed in the child at the age of one and a half. The condition became aggravated at the time of the emigration of the family to America during the submarine blockade.

Acute Infectious Myoclonus Multiplex and Epidemic Myoclonus Multiplex.

—Dr. J. RAMSAY HUNT called attention to the problem of localization of acute infections in some part of the nervous system. The varieties of clinical types in Heine-Medin's disease, for instance, emphasized the fact that certain strains of the same infective organism might have special affinities for certain tissues of the nervous system, and thus bring about the special clinical type of reaction. Such special forms of localization of an acute infection, he said, were to be found in acute infectious myoclonus multiplex and epidemic myoclonus multiplex. The form was characterized by lancinating pains, muscular contractions and twitchings, and a delirium of toxic origin. This group of symptoms, Doctor Hunt found, constituted a well defined clinical type of neural infection which differed from those previously recognized and was encountered both in sporadic and epidemic form.

The onset of the disease was acute and was characterized by shooting pains of great intensity in the trunk and extremities. Spinal pains were sometimes present. The pains were followed by characteristic muscle jerks, waves and twitchings (myoclonus multiplex, myokymia, and fibrillary contractions.) The contractions made their appearance first in the parts where the pains were first felt. A week might elapse in some cases between the appearance of the pains and the myoclonus and myokymia. The twitchings were bilateral, multiple, and might become generalized. There was sometimes a tendency to localization in certain regions of the body, especially in the abdominal musculature. The contractions were quick and of

short duration, individual muscles or portions of muscles were involved, but not synergic groups. Slight movements of the toes, fingers, and extremities might occur in severe myoclonic twitchings, but never to the extent found in chorea or cortical myoclonia.

There was usually moderate fever. In some cases that proved fatal the temperature rose in the later stage of the disease. An acceleration of the pulse rate was noted and, in most cases, a delirium which varied in duration and intensity with the degree of infection. There was often marked hyperidrosis, and the degree of sweating seemed to bear some relation to the activity of the myoclonus phenomena. There was no paralysis or paresis of any muscle or group of muscles; no anesthesia was encountered with the exception of occasional transient areas of hypalgesia. There was no ataxia nor loss of deep sensibility; tendon reflexes were present and active. Rarely the knee jerks might be diminished and the Achilles jerks absent during the height of the disease. The cranial nerves showed no evidences of involvement except for the myokymic twitchings. The optic nerves were normal. Skin reflexes were present and equal (no Babinski). When abdominal myokymia was present, the abdominal reflexes were exaggerated.

Doctor Hunt had observed twelve cases of this affection in the past sixteen years; two cases were seen more than ten years ago, and the remaining ten within the last three months. The first cases were evidently sporadic, the latter epidemic. The distinguishing features, acute pain of lancinating variety, with muscular waves and twitchings, were always present. Delirium was present in eight of the cases. The myoclonus delirium was a characteristic toxic delirium with hallucinations, illusions, and transitory delusions. Restlessness, insomnia, apprehension, disconnected thought and mental confusion were present. Apathy and a tendency to stupor were sometimes met with in the late stage. In the four cases without distinct delirium there were insomnia, restlessness, irritability and excitement in this early stage and later a tendency to apathy and dulness.

That an infectious disease was under discussion was clear from the character of the onset, the fever and delirium. Multiple neuritis and acute poliomyelitis might be excluded as diagnoses since the paralysis or weakness of the muscles associated with these diseases was absent. There was no appreciable tenderness along nerve trunks. Dubini's disease might also be excluded since it involved paralysis. Epidemic encephalitis or lethargic encephalitis were especially interesting possibilities. The epidemic myoclonus multiplex probably belonged to this group and represented a special myoclonus type of the affection. The infectious agent of epidemic encephalitis and epidemic myoclonus multiplex was apparently the same.

The motor and sensory symptoms of the disease studied by Doctor Hunt were only irritative in character, in spite of the very severe and sometimes lethal infection of the nervous system. There was no paralysis or anesthesia, and this fact gave the disease an added interest, since the myoclonus

symptom complex was not found in other forms of spinal and neural infections.

Two Cases of Brain Tumor.—Dr. C. C. BELING, Dr. H. W. Martland, and Dr. W. B. Eagleton reported on the neurological findings, the pathology and autopsy results, and the surgical procedure respectively, in two cases, the first, tumor of the pineal gland, which was presented as a clinical entity, the second, cerebellar tumor, presented as a pathological and clinical entity. The first patient, a man aged twenty-five, an experimental engineer with negative personal history, suffered superficial burns of both corneas in an explosion of barium chlorate in 1913. Recovery was complete. In October, 1913, he began to see double, and lenses and general treatment failed to produce any improvement. In March, 1919, an examination by Dr. Eagleton showed R. V. 20/100. L. V. 20/50. There existed marked papillitis of the right optic nerve, diplopia as a result of paralysis of the superior rectus of the right eye, and a spontaneous nystagmus. There was an increasing difficulty in looking upward. When Doctor Beling examined this patient the papillitis of the right optic nerve was very marked. There was no deviation of the tongue or tremor. Knee jerks and plantar reflexes were normal except for a slight tendency to slow reaction on the right side in the latter. On May 15th the patient contracted grippe and was sick from that time on. From July 1st a dull pain in the top of his head with slight frontal headaches persisted. His mental condition seemed to deteriorate. He was often nauseated and vomited. He could walk for a short time, then his body would stiffen and his head jerk back.

A left subtemporal decompression was performed by Dr. Eagleton. The brain was under great tension, the dura widely exposed. The operation was followed by an uninterrupted recovery, and the man's condition improved, although the papilledema persisted. Several weeks later, however, greatly increased intracranial pressure was apparent, and for the first time he showed a tendency to fall backward. The examination at this time showed an intense double papilledema. There was generalized tremor, with profuse hyperidrosis and tonic contraction of the muscles. Knee reflexes were exaggerated. There was clonus of the toes. Mental state was somewhat confused, he had lost track of dates, but knew the year and that he was in a hospital. Cerebration was difficult and tremor was produced by attempts to answer questions. Priapism was noted; no abnormal psychosexual phenomena. His condition became steadily worse, the tremor increased, eyes bulged, jaws were set. On November 8th he began to have convulsions in rapid succession, with profuse perspiration, and he began to grow cyanotic. He died a few hours later.

Slides of the hospital history and the autopsy findings were shown by Doctor Martland. The diagnosis had been tumor of the midbrain. It was found, however, that there was a small psammoma of the pineal gland. An enormous dilatation of the third ventricle had resulted. The pineal gland was visible in the x ray. Doctor Eagleton in discussing the surgical features of this case pointed out how

useless further decompression would have been. The possibility of a pineal gland tumor had never been suggested, since the usual symptom of headache was lacking. Relief for the increased intracranial pressure was sought by the left sided decompression earlier in the case, since Doctor Eagleton had come to the conclusion that the patient was left handed. But this had had no effect on the papilledema.

The second case, one of cerebellar tumor, was in a man of forty who began to lose weight, vomited every morning, had increasing dizziness, and began to see double. There were severe headaches. Examination by Doctor Befing showed slight swelling of r. papilla, vertigo, ataxia, and asynergia of the right side; deviation to the right on walking; nystagmus with rapid movements to the left and slow to the right. Hearing was about equal. Symptoms pointed to a lesion in the posterior chamber, subtentorial pressure. There was probably a cerebellar tumor with slight involvement of the pons since the left face and hearing showed slight affection.

Doctor Eagleton noted the following phenomena: The patient showed a Romberg; spontaneous pointing deviation of the right hand to the right; more marked spontaneous nystagmus on looking to the right. Rotation to the right produced nystagmus and possibly to the left, though whether spontaneous or induced could not be determined, duration apparently about eighteen seconds. Rotation to the left produced nystagmus of fifteen seconds' duration. There was deviation of both hands to the left; no dizziness in either rotation. Cold caloric in the right produced no nystagmus, no past pointing, or dizziness. Cold caloric in the left had no effect either. Nystagmus could be induced by turning the head backward, showing that tracts of the vertical canals were not functioning while the horizontal were functioning.

The tumor was thought to be pressing somewhat on both sides. Cases of this sort, Doctor Eagleton felt, where the exact nature of the tumor was not recognized were better left unoperated.

Trauma and Other Nonluetic Influences in Paresis.—Literature, Dr. MICHAEL OSNATO said, could yield practically nothing on the question of the influence of trauma in the production or precipitation of neurosyphilis, in view of the brief time that it had been possible to diagnose the condition. From a study of the very few cases that could be included under this category at the Vanderbilt Clinic in the past three or four years since careful histories had been kept, and from Doctor Osnato's own files, only thirteen cases could be assembled for study. These were all proved cases, proved either by laboratory examinations or by autopsy. This deficiency of cases in which trauma was an associated factor whether recognized or not, was to be noted in Southard and Solomon's *Case History Series*, where a few cases only were mentioned. The posttraumatic paresis usually occurred, these authors stated, citing Mott's study of the same subject, after at least a week's interval, since the time required for the destruction in the brain productive of the necessary symptoms would seem to

be at least that. Three months was the limit of time that Southard felt should be set to determine the influence of trauma as a causative factor. An increase in the number of cases of neurosyphilis during the war noted by the Canadian medical officers was thought to have been due to the great strain at the front, and the frequent physical injuries resultant upon being buried, etc.

A possible influence in the production or stimulation of paresis was accordingly granted by other observers. Doctor Osnato described the following cases in support of the traumatic theory: In a patient who had been struck on the back of the head eighteen months before by a heavy object, mental inefficiency soon became apparent. The only mental signs presented were perseveration of thought and speech and memory defect. The physical signs of paresis were present. A second patient, in whom the trauma was emotional, had been entirely efficient and dependable in his work until he was drafted into the army. His mental reaction was like a war neurosis in every respect. After his diagnosis as a psychoneurotic and after his discharge he continued to fail and finally came to the clinic complaining of gross memory defects, fifteen minute attacks of amnesia, dullness and retardation amounting almost to negativism, loss of interest. The mental picture was that of a psychoneurosis of the phobic type; a diagnosis of general paresis was made from investigation of the blood and spinal fluid. The problem of the emotional factors in the production of this condition was forcibly introduced here. The study must be speculative since the exact physiological changes that might take place as a result of fear or other emotions were not known.

In a third patient, a woman, the paretic picture developed after a prolonged etherization. Following an operation she complained of pains in the chest, legs, and abdomen, and right upper extremity. Grave memory defects also appeared. The physical signs of tabes were present, but mentally the patient was a general paretic. She was under treatment and showed progressive mental deterioration, without delusions or hallucinations. The fourth patient had a severe attack of influenza and complained of lancinating pains in the right arm and both legs shortly after. She became depressed, slept badly, had tremor of face, hands and tongue, was ataxic, and had a moderate memory defect. The blood Wassermann and spinal fluid findings in this case were those of a cerebrospinal syphilis rather than general paresis. Before the attack of influenza she had been perfectly well. In the last patient cited the trauma had been caused by a falling plank which struck the right parietal skull and glanced off striking the dorsal region of the spine. He was in Bellevue Hospital three days. There was evidence of a depressed fracture of the right vault of the skull in the frontoparietal region, over the Rolandic area. Left hemiplegia had developed when he left the hospital. A few days later there was unsteadiness of gait, ataxia, Romberg, typical paretic speech, stuttering memory defect, tremor. The initial hemiplegia was undoubtedly due to the trauma. Up to the date of his injury he had worked

steadily, and had shown no apparent signs of paresis.

In conclusion Doctor Osnato emphasized the fact that there were undoubted acute and chronic pathological lesions of the brain ascribable to trauma of the head. Something seemed to alter the permeability of the blood vessels of the brain, thus enabling the attack of the spirochetes upon the brain tissue. In the cases described craniocerebral injury seemed to have precipitated cases of paresis or adversely influenced them. The toxin of influenza, infections, or ether, might have an effect similar to trauma, while the effect of emotional stress offers food for interesting investigation.

Meeting Held on April 6, 1920.

Familial Dystonia Musculorum of Oppenheim.

—Dr. ISADORE ABRAHAMSON presented three patients from one family with dystonia musculorum of Oppenheim. The progressive stages of the disease were singularly well demonstrated. They were of the pure idiopathic variety, noteworthy, first, for their definite familial character; second, for their resemblance in the deviations from type that are to be met with in all familial diseases; third, for a distinct involvement of speech, which Oppenheim denied in his cases; fourth, for the involvement of the musculature of the neck not common in these cases; fifth, for the varying mental attitude in the three patients, and sixth, for the unusual propulsive phenomenon which had not previously been noted in cases of this sort.

The first patient, a Russian woman aged twenty, with unimportant family and personal history, at the age of twelve experienced difficulty in writing and became clumsy in her gait. The muscles of her legs would stiffen, this stiffening gradually spreading to other muscles and increased by effort or emotion. On attempting to grasp an object a coarse tremor appeared. Her symptoms had become aggravated during the last three months so that she could neither sit nor walk. During sleep all symptoms disappeared. The muscles were hypotonic. There was no paralysis. An abnormal wrinkling of the forehead existed and general anxiety, which was a deviation from the usual Oppenheim manifestations. Speech was dysarthric, bulbar type. The legs were paraplegic, were usually kept crossed, the typical inward rotation of the thigh was clearly apparent, and the feet were turned down. A marked involvement of the neck was of interest, the Adam's apple was prominent, and she showed torticollis. Dystonia, tortipelvis, lordosis, clonic movements of the left hand with tonic movements in legs, and a rhythmical tremor characterized the disease in this patient.

In the second sister, aged eighteen, the disease had an insidious onset. She first noticed difficulty in writing, her muscles began to stiffen involuntarily, the left arm was drawn up in a flexor spasm, and the hand turned outward. She complained that the hip joint on the right would not stay in place, and a drawing feeling above the knee was experienced which produced in her a type of propulsion that was very interesting. Her body was thus bent forward and laterally twisted around the

vertical axis of the spine. There was inward rotation of the thigh. The gait was bounding. Her condition was much improved when she felt well and rested.

The third member of the family, a boy of fifteen, showed the disease in its early stages. He had the inward rotation of the thigh, the toes pointed down, the heel was carried high. This condition had been getting slowly worse for the last two years. His first difficulty was also with writing. In walking he swished his foot, and there was a very slight forward bend. He could run well but had difficulty in stopping. Some hand movements could be accomplished, such as threading a needle and playing marbles. A fine tremor was noted. Scoliosis and tortipelvis were present.

The three patients showed interesting differences in emotional states. The first was extremely anxious, emotional, and worried about her condition. The second was optimistic and wanted to get well. The boy was apathetic, had no interest in his condition, and in general showed the mental state usually found in such cases, which caused them sometimes to be classed as hysterics.

Dr. SMITH ELY JELLIFFE expressed the opinion that it had been a rare opportunity for himself, and also, he thought, for other members of the society, to have presented in so thorough a manner the developmental history of this interesting syndrome. It was unique to have three members of a family showing the beginning, middle, and developed phases as had been demonstrated. Doctor Abrahamson had mentioned Ziehen's familial group, which Doctor Jelliffe had had the good fortune to study in Berlin. There were three in that group also, and Schwalbe's monograph had presented the features, but in Ziehen's group the disorder had progressed to a more or less uniform pattern and no developmental study was possible such as the present presentation offered.

Doctor Jelliffe was disposed to emphasize the varying clinical trends of a larger group of striatum syndromes of which these cases were but one of the striking types. It had become increasingly evident that dystonia musculorum, Vogt's double athetosis, Westphal's pseudosclerosis, Wilson's lenticular degeneration, Huntington's chorea, tuberous sclerotic idiocy, and even paralysis agitans were to be regarded as but variants in this larger picture of striatum syndromes.

It was recalled that one of Ziehen's patients had come to autopsy and negative findings had been reported, but more recently one of Flatau and Sterling's cases had been autopsied and Thomalla, Schneider, and v. Economo had respectively studied the striatum pathology and the liver, for the case of Flatau and Sterling had afforded a combination of the Ziehen-Oppenheim group of dystonia musculorum types and Wilson's lenticular degeneration types, since the clinical picture was characteristic of the former trend, while the hypertrophic sclerosis of the liver was of the Wilson lenticular degeneration type. The pathological picture of the striatum was one of an abiotrophic atrophy of the cells of the putamen.

(To be concluded.)

THE FACULTY AND THE STUDENT.*

BY JOHN A. FORDYCE, M. D.,
New York.

Many classes at this time are striving to find their proper place in the partially reorganized and transitional state of society. Under the pressing demands of war a comparatively short time was required to enlist the man power, the technical knowledge and skill of the country to meet the national emergency. The mental and physical forces necessary to organize and achieve were direct and effective. The problems which were so promptly and efficiently met and solved by our profession in war times were no more serious than those arising in the reconstructive era through which we are now passing.

The after war reorganization of existing social conditions requires no less the directing force of a dominant idea. It must first of all take cognizance of the individual as influenced by his education, work, environment, and recreations. The large percentage of young men rejected by our draft boards as unfit for military service points to something radically at fault in the education and physical training of the youth of our country.

The prosperity and contentment of each class in a community means the prosperity of all. When this fundamental fact is generally recognized the search for a universal cureall for real or imaginary ills will be unnecessary. Although the mutual obligations and responsibilities of nations, classes and individuals have largely been lost sight of in their immediate requirements and ambitions, a condition of stable equilibrium must sooner or later take place, for the biological law of the trend to the normal applies to groups no less than to individuals.

Inventive genius developed by the demands of war is further stimulated in many of the former belligerent countries by dire necessity and will help to counteract the discontent and disorganization which are now not conducive to logical thinking or orderly behavior. Optimism should be the prevailing note. It can be made real by individual and class cooperation. The medical profession must follow the lead of modern psychologists and endeavor to comprehend the fundamental reasons for the present social unrest and help to direct the public mind into normal instead of pathological

channels. If medical opinion is influenced by great political events, our era should be marked by a study of the individual reaction to present day problems.

From the student bodies in our institutions of today are trained and developed the teachers and leaders of public thought of tomorrow. Bodily ills are often less dangerous than the fancies and bizarre theories of minds distressed or diseased. The one affects the individual; the other may imperil the integrity of the nation.

Knowledge of the fundamental facts of science, correct economic ideas and logical methods of thinking, can do more to correct false theories of life than the delusions and quack remedies of so-called reformers. By reason of his intimate and confidential relations with all classes in a community the physician may administer not only to disease of the body, but often can direct his patients in matters of public policy and antidote mistaken social theories. Concerted efforts of medical men to achieve reform for the public good are often successful because they are unselfishly advocated and because professional politicians regard not only the individual but the group influence they can bring to bear both in and out of the profession.

The practitioner is not a mere dispenser of drugs nor a technician skilled in removing offending organs. He is an educated scientist whose advice is often invoked in questions of individual and public welfare. In addition to healing the sick, he should anticipate and endeavor to prevent disease. He should know the psychology of childhood as related to heredity, environment and proper feeding, and advise as to the best educational methods to be employed in the impressionable age of the young. He should be able to anticipate educational misfits, and limit the failures too often resulting therefrom. He can "minister to minds diseased" and learn from faith curists valuable lessons in psychotherapy. These are some of the qualifications necessary for the educated physician of today, in addition to the technical subjects which confront the entering student and the practical branches which complete his four years of work.

The education acquired by the medical student aside from its practical application is a useful and liberal one. Knowledge of the fundamental sciences preparatory to practical medicine is as well worth while as that acquired by the engineer, the lawyer, or the theologian. The structure and functions of

*Address delivered September 22, 1920, at the opening of the session 1920-21 of the College of Physicians and Surgeons of Columbia University.

the human machine and its living variabilities offer more intricate and interesting problems in chemistry and physics than those confronting the engineer in metallurgy, mining, or in the building of bridges.

Is it not worth while to know something of the organ which directs all intellectual and physical endeavor; which retains and coordinates the impressions of centuries; originates infinite combinations, and expresses them in works of art, immortal prose and poetry, and changes the crude materials of nature into magical shapes? The study of mental phenomena in health and disease opens the door to many obscure problems in the social relations of mankind and concerns not only the psychiatrist but the statesman and all who have to do with their fellowmen. A conception of the individual reaction to his surroundings means much to the teacher and his pupil. It develops in the one a more intimate and sympathetic attitude and a corresponding desire in the other to profit by the teacher's advice and instruction.

The study of medicine in its varied relations appeals to minds inclined to abstract and speculative reasoning, to the research worker, who is chiefly concerned in looking for causes and is constantly demanding the reason for things, as well as to men who are only interested in the concrete and obvious. In addition to the development of the power to observe and interpret it broadens one's viewpoint, awakens the logical sense, and stimulates the desire to penetrate further into the great mystery of life.

It is as much the duty of the instructor to teach the student to think clearly and reason logically as to convey facts or discuss theories. Inability to examine evidence in a critical manner, and to form independent judgments, leads too often to blind acceptance of the dictum of one who occupies a position which gives him the reputation of an authority. The written and unwritten history of medicine is replete with theories of disease, systems of cures, and operative procedures, based on immature knowledge, wrong interpretation of facts, and hasty generalizations. More accurate knowledge of the fundamental sciences and a wider grasp of pathological processes have revealed the limitations of our art, and should make us more conservative in accepting new methods of treatment.

The delightful paper by our colleague, Dr. Karl Vogel, on Oliver Wendell Holmes and the Medical Student, recalls to all of us one who was not only a great physician, a philosopher and a poet, but a logical thinker, and one honest enough to expose the humbugs, inconsistencies, and crudities of drug giving as practised in his day. The collateral reading of every student of medicine at some time during his early years should include his medical essays and especially his paper on the Contagiousness of Puerperal Fever, published in 1843, long before our knowledge of the bacterial cause of disease. It is a model of such careful collection and interpretation of facts, and clear and logical reasoning, that it now seems impossible to comprehend the bitterness, scepticism and opposition which it evoked among the obstetricians of that day. Refusal to accept demonstrated truths when opposed to preconceived ideas was not confined to days gone by. We see

it too often in minds guided only by precedent and tradition.

The motives which have led you to begin the study of medicine would perhaps be difficult for you to analyze. Inherited bent, love of science, the desire to be a member of a learned profession, dislike of the routine of a business life, may be some of the reasons why you are here today. The preliminary work required, and the crowded curriculum which awaits you, mean serious work, and it is reasonable to assume you desire the best instruction it is possible to obtain and are willing and desirous to cooperate with your teachers to secure it. Your work has a definite aim. You are striving to become practitioners. Some will doubtless acquire a love for research work, and will devote their lives to that. Others may find they have made a mistake in selecting an uncongenial profession, or for other reasons may not be able to complete the outlined course. No matter what the future may hold for you, an impression on your minds and characters will result from your work and associations.

Modern teaching methods correct some of the defects of medical instruction in the past, but we are yet in a state of evolution. Each year the public demands a higher type and better educated practitioners. They can only be supplied by public cooperation and support. The growth of the pure sciences with resulting multiplication of methods in diagnosis and treatment demands more laboratories, additional apparatus, and, above all, accurately trained instructors.

Individual gifts, endowments and liberal facilities in our public hospitals for clinical instruction and the study of autopsy material are needed to further the work of the student and to train the future instructor.

The student should be as familiar with the terminal stage of disease processes in death as with the more subtle chemical reactions which take place in life. The cycle of knowledge which should form our complete picture of disease is as imperfect without the one as the other.

Our present day means of imparting information is chiefly by experiments and concrete demonstrations and less by didactic lectures. The textbook sources from which lectures are usually compiled are at all times accessible to the student. Laboratory work, individual study and interpretation of problems of disease, and demonstration of autopsy material are more tangible than the finesse of rhetoric or the skilled oratory of the professor.

In speaking of the medical teaching today, it is difficult to avoid a certain amount of retrospection (a sure indication of old age). It may be worth while, however, to contrast briefly medical teaching as now conducted with conditions as they existed more than forty years ago.

Many subjects which have to do with medicine as a whole are in a state of flux. What is considered knowledge today is discarded tomorrow. Some theories have become established facts, others have been scrapped. All, however, have served a useful purpose, and have proved to be stepping stones on the road of progress.

Since the earliest days of medical instruction, I imagine, the prospective student has always been regarded as fortunate in beginning his work in a progressive age. He has been told by his teachers that had they been accorded the same facilities he now enjoys, their own careers would have been more successful and brilliant. These encouraging words will probably be made to the future pupils of our present undergraduates, and will be heard with the same polite scepticism. Many who practise medicine today are handicapped by lack of knowledge of the fundamental sciences, which have made such astonishing progress in the last fifty years. Medicine can now be placed among the exact sciences, but it is always progressive and will always present new problems to be solved. No matter how many cases of one type of disease are seen, variations in the picture are always present. Medicine will, therefore, never lose its interest to the mind which observes and asks the reason why.

Changes have taken place in the methods of teaching as well as in the subjects taught. Formerly the medical student was talked to by his teachers and told about all things in the curriculum. Now he is not only instructed by word of mouth, but does things with his hands. He conducts experiments and sees the relation of cause and effect. When only one sense is appealed to, the mental impression is not deep enough to be permanent. Modern methods develop the student, but afford less opportunity to develop the oratory of the teacher. Many of the spectacular and picturesque features of teaching have given way to more intimate, direct and effective ways.

During the forty odd years which have elapsed since my student days in medicine, the new sciences of bacteriology, serology and immunology have developed with their profound influences in all branches of our art. Organic chemistry, then only taught in the most elementary way, has been enormously elaborated and now supplies the key to many obscure problems in physiology and pathology. The manipulation of chemical substances made possible by a knowledge of their graphic formulæ has resulted in substitution products and many valuable therapeutic agents. It has made possible the new science of chemotherapy. If one seeks magic in medicine it can be found in the final achievement of the life work of Paul Ehrlich.

What is more remarkable in its benefit to the human race than the specific selective action of a chemical agent on a given type of disease producing organisms? The culmination of Ehrlich's work, the products of a scientific mind stimulated by scientific imagination, has given to the world a cure for syphilis, yaws, and relapsing fever. It is not alone the achievement in question, but the fundamental principle established, which opens the way for results equally as important and brilliant.

Scientific research has developed laboratory aids in diagnosis and treatment which have made the guesswork of former years the certainty of today. One procedure alone—the Wassermann reaction—has revealed the enormous importance of syphilis as an etiological factor in hitherto unsuspected conditions. It is an invaluable aid in the diagnosis of

all stages of this protean infection and is equally important as a criterion of cure.

In our zeal and enthusiasm for exact technical procedures we should never forget the prolonged clinical study, keen observation and ability to interpret symptoms of disease which formed so large a part of the attainments of the older practitioners. The clinical acquirements of centuries are an indispensable part of our present day knowledge.

If we were to eliminate from medicine the contributions of the clinician, our profession would be poor, indeed. The discoveries of the pure scientist were often anticipated by the clinician and furnished the former the incentive for his work. Tuberculosis was considered an infectious process and its clinical picture was almost complete before Koch's discovery. Fournier's clinical acumen enabled him to recognize the syphilitic factor in tabes and paresis. His observations have been fully confirmed by the laboratory worker. Examples along these lines might be multiplied indefinitely if we had the time or inclination to defend a useless thesis as to the relative superiority of the one or the other method. Both are needed. They supplement each other. The experienced teacher neglects neither clinical study nor laboratory aids. He emphasizes the relative value of each and reveals the pitfalls which await him who relies on one method at the expense of the other.

In practical medicine the transition from the older to the newer therapeutic procedures has been gradual and progressive. Serum, vaccine and chemotherapy have superseded many empirical drugs now discarded but formerly a part of the doctor's armamentarium. Empiricism has given us many valuable remedies from the animal, vegetable and mineral kingdoms and even Chinese medicine in employing dried snakes and lizards finds an explanation in the revelations of endocrinology.

With more exact knowledge of disease, we guide nature in her efforts to cure and rely less on polypharmacy. We have little sympathy for the practitioner who has a specific for every symptom and who always accepts personal credit for nature's work. It may be taken as an axiom that many remedies for one ailment mean that none is effective. At the beginning of practice young doctors have twenty remedies for one disease; the old doctor twenty diseases for one remedy. A single remedy spells specific therapy. An intimate friendship with one drug is better than a speaking acquaintance with many.

Our textbooks discuss in a learned way the possible causative factors in diseases of unknown origin, and in so doing cause the student as much confusion as in enumerating a long list of drugs which may be employed in affections for which we have no specific. As soon as the real agent is discovered the long list of possible immediate and remote factors becomes obsolete and meaningless.

The chief and perhaps the only reason for the existence and development of medicine as a profession is the prevention, control and cure of disease. In endeavoring to solve the many complicated problems which are concerned in abnormal bodily states, many collateral sciences are invoked

as aids. The preliminary work required of the prospective medical student is such that he is no longer confronted with subjects entirely new. He has learned something of the basic sciences that comprise his first and second years' work.

The teachers of anatomy, physiology, chemistry, bacteriology and other highly technical subjects, have devoted a lifetime to their mastery. The student is expected to acquire the essentials of these branches in a comparatively short time. The knowledge which is commonplace to the professor is almost a *terra incognita* to the entering student. He is confronted with a new nomenclature and a maze of details which he must master in a given time. When it is realized that a lifetime must be spent to become an expert in one science or in one special branch of our profession, the little that can be taught in the medical course and the yet smaller quantity that can be retained and assimilated is not surprising. The graduate is not a master of the science and the art of medicine. He has only begun to learn.

Each teacher is impressed with the relative importance of his own subject and perhaps exaggerates at times the value of minor technicalities that are only learned to be forgotten. If the main theme or purpose of medical education is kept in mind by the teacher and the student, the facts which have directly to do with the diagnosis and cure of disease will be emphasized by the one and acquired by the other.

A direct correlation of the work in the preliminary subjects with its relationship to the practical branches renders the subjects less abstract, prepares the student for advanced work, and avoids needless repetition. The efforts now being made to correlate and avoid overlapping of the work in the practical departments should include the preliminary and scientific subjects. If the teachers of the latter subjects were more fully informed of the requirements of the third and fourth year faculties, a closer cooperation would no doubt be secured.

A teacher who is the master of his subject can emphasize the essential facts which are of real importance and which can be applied in a practical manner. He can sift and select. The student is not yet sufficiently advanced to do it, and is often bewildered with details of little value. The more thoroughly a subject is grasped by the teacher, the more simply it can be conveyed to the pupil. Complicated and lengthy explanations usually mean superficial or poorly digested information. Lack of real knowledge of many subjects is too frequently concealed by a complicated and foolish nomenclature.

In his zeal to acquire names their real significance and the conditions they stand for are often lost sight of by the student. A book on almost any specialty in medicine expressing in a clear and concise manner our positive knowledge would be a small one. The majority of our textbooks contain too much irrelevant matter, and too much pedantic discussion regarding phases of subjects of which we are in complete ignorance. Our future developments will depend largely on recognizing our present limitations and on continuing to build our superstructure on the solid foundations of accurate knowledge.

Ideals in science and the pursuit of knowledge for its own sake are inspiring phrases, but in a school of medicine for undergraduates more will be accomplished by having in view a definite purpose. The arguments advanced to further cooperation between scientific and the so-called practical subjects apply with equal force to the various divisions of the latter.

It is not the purpose of an undergraduate medical school to make specialists. The student is, however, entitled to the special knowledge acquired by specialists. The viewpoint of the specialist, which is often limited, needs the perspective of medicine as a whole, as well as a fundamental grasp of the general principles of experimental pathology, bacteriology and other scientific branches, so that he may direct research work in his own department and add each year something of permanent value.

The routine work in most of our practical departments is carried on by voluntary assistants, hence frequent changes are inevitable unless something is done to stimulate their interest in research problems. A trained and permanent personnel in any department simplifies the teaching of students, the care of patients and eventually supplies men capable of occupying responsible positions in his own or other institutions.

A well equipped laboratory in each department which could make use of it would further research work by the staff, improve the teaching facilities and keep alive the scientific methods acquired early in the medical course by the student. Problems arise in every department which can only be solved by help from our colleagues.

The medical horizon of each of us would be widened by a more liberal give and take policy, and by more frequent conferences about conditions which touch at the borderlines of the various specialties. In speaking of the mutual obligations of the teaching and student bodies, it must not be taken for granted that all things are given by the former and received without return by the alert and intelligent young women and men who comprise the latter. The mental reactions benefit the one as much as the other. Contact with serious students having the desire to acquire knowledge does much to keep alive the scientific spirit in the teacher. As one grows older this necessity becomes more imperative.

The busy specialist may sacrifice something in teaching, but he is more than repaid by the opportunities to continue in touch with the younger men in his department as well as with the inquiring student he is instructing. These in turn he directs in lines of research and imparts to them his ripper acquirements.

In the strain and stress of modern life, the events of the past are pushed aside and eventually forgotten. We seldom stop to consider the work done by the masters who have preceded us and made our present secure position possible. We accept their gifts but forget even their names. It would be a graceful and well deserved tribute to the epoch making men in his own special work were each instructor to outline at the beginning of his course the important discoveries in his own field and their

influence on our present day knowledge. Were it not for the combined work of the many which leads to our gradual growth the great epochs which mark our progress would not stand out.

Years of work and careful observation are required to gather the necessary facts and prepare the way for some great generalization. The achievements of modern surgery would have been impossible had it not been for the bacteriological discoveries of Pasteur and their practical application by Lister. Every obstetrician and all women owe a debt of gratitude to Oliver Wendell Holmes and Semmelweiss. Our pathological superstructure is built on the solid foundation of Virchow's cellular pathology. Modern scientific medicine has been developed from so many sources that it is difficult to apprise them properly. Many fallacious doctrines were swept aside by Louis and new methods of investigation begun, which influenced in a marked degree the advancement of knowledge abroad as well as in our own country. The great clinician Laennec should always be recalled to the student of exact methods of chest examination.

At this time the currents of medical knowledge and inspiration had their sources in France. At the same time Great Britain was developing her school of great clinicians which included the names of Cheyne, Graves, Stokes, Bright, Addison, Hodgkin, Watson and many others. Austria and Germany in turn because of their scientific achievements and the personality of their great teachers turned the student tide. The depression of defeat, the overthrow of stable governments, and changed economic conditions have for the time retarded scientific development in the countries of Central Europe. We have no desire to profit by the misfortune of our professional colleagues. We do not forget their constructive scientific work and their stimulating teaching. Nothing good can result from keeping alive the war bitterness, but much mutual benefit will follow the restoration of international relations and help extended to the innocent sufferers of the great calamity. America's opportunity is not due to the misfortune of others, but to the impelling force of past and present achievements.

Have we not much to stimulate us in the work of Marion Sims, of McDowell, and in the deeds of our other dead and living pioneers and leaders? Compare the *Medical and Surgical History of the War of the Rebellion* with that of the World War. Read in the former accounts of wound infection, hospital gangrene, tetanus, typhoid fever, and you will see the graphic contrast of medical and surgical conditions then and now.

Can one estimate the millions of lives saved by vaccination against smallpox? Do you grasp the significance of preventive vaccines in typhoid fever and the millions of lives saved in war by this procedure? Is not the conquest of diphtheria by antitoxin a victory no less renowned than one of war? Do not forget that the elimination of yellow fever was made possible by the scientific work of Walter Reed and the personal sacrifices of Lazear and Carroll. Could the Panama Canal have been con-

structed had not Gorgas foreseen and applied the necessary measures of disease prevention?

We shall not dwell upon the slight recognition accorded by our government to the medical heroes who have sacrificed their lives in efforts to find the cause and control of epidemic and contagious diseases, but we may keep their memories fresh in our own hall of fame and convey to our students and the public something of which we and they may well be proud.

What has the present day student of medicine to anticipate? Not all drudgery, let us hope, but four years of interesting and delightful work in which new vistas of science are to reveal their mysteries and charm. Viewed in the right manner and approached in the proper spirit, one can well say, "The work that one delights in physics pain." Each month, each year offers new facts to learn and new problems to solve. Knowledge of the physiology of the wonderful and complicated human machine prepares one to grasp the abnormal functioning. A study of normal psychology affords us an insight into the mechanism of abnormal mental processes. The tissue changes caused by injuries, infections and new growths are made clearer by the study of gross and microscopic anatomy. Each science is a liberal education and a foundation stone in your future building.

A stimulating teacher directs your vision beyond his immediate demonstrations and embellishes his dry facts with concrete illustrations of their relation to your future work. As time goes on a mosaic will finally be completed in which a picture of the body in health and disease stands revealed. Work well done now makes the work to follow simpler and easier. The will to do, the desire to excel, already means the battle is half won. The psychology of achievement reveals latent possibilities of which perhaps you have never dreamed, and urges you to high ambitions.

Leave thy low-vaulted past,
Let each new temple nobler than the last
Shut thee from Heaven with a dome more vast.

8 WEST SEVENTY-SEVENTH STREET.

Coccygeal Neuralgia.—Chartier (*Presse médicale*, April 10, 1920) describes under the appellation "painful syndrome of the filum terminale" a definite form of coccygeal neuralgia characterized by continuous pain at the level of the second and third coccygeal vertebræ. The pain is of the drawing type and extends from the coccyx to the lumbar spine upon forward bending of the trunk, which causes elongation of the filum terminale. Neither pressure nor forcible motion of the coccyx cause pain—a feature differentiating the condition from the true coccygeal disorders. The condition is an expression of pathological change of or pressure upon the filum and the coccygeal nerves it embodies, either in its intradural portion—as in meningitis—or in the sacral canal—as in gouty accumulations, etc. In the treatment, x ray therapy or the high frequency effluve may be used with success according to the type of case.

POLYMORPHISM OF EPIDEMIC ENCEPHALITIS LETHARGICA.*

*Clinical and Pathological Types and Differential Diagnosis.*BY ALFRED GORDON, M. D.,
Philadelphia.

In the early months of 1919 the attention of the medical men in the United States was called to a relatively new disease whose chief anatomical localization was the midbrain. This affection, which is popularly known as sleeping sickness, but which must be distinctly separated from the African disease of the same name, which is due to a trypanosome, is, accurately speaking, not new. As far back as 1712 an outbreak of so-called sleeping sickness occurred in Germany and again in 1890 in Austria, Switzerland and Italy. Von Economo observed it in an epidemic form in 1917 in Vienna. Whether the disease under discussion was recognized formerly or not it is difficult to say. At present, since Netter's observation in France in 1917, the disease is known to exist in epidemic or sporadic form. The epidemicity or sporadicity suggested a microbic origin of the disease. Experiments have been conducted in various countries by inoculating with the nervous tissue from fatal cases (1 and 2), or with filtered extracts of the nasopharynx (3), apparently with positive results. Loewe, Hirshfeld and Strauss believe that they have succeeded in isolating a microorganism which is analogous to that of poliomyelitis but from which it nevertheless differs. All these investigations suggest that the disease probably belongs in the category of communicable diseases, hence the necessity of isolation in suspicious cases and therefore of prophylaxis. In view of this rôle of the nasopharyngeal secretions appropriate measures are indicated.

The clinical picture of lethargic encephalitis presents many varieties. The literature abounds with examples of its polymorphous character. In view of the latter, errors of diagnosis are likely to be made. A presentation of all possible occurrences, with emphasis on the differential diagnosis, may be warranted and this is the chief object of the present contribution. Three principal symptoms, rise in temperature, ocular palsies and somnolence, constitute the general characteristics of the malady. The onset is characteristic of an infectious process; the fever is accompanied by headache, backache, and sometimes vomiting. After the disease has reached the phase of full development it presents the above mentioned triad of symptoms. During this period the polymorphism of the principal manifestations and of additional phenomena sometimes presents diagnostic difficulties.

The ambulatory form.—There are various degrees of somnolence. In mild cases the patient has merely a frequent desire to sleep, although he may attend to his daily occupation. As soon as he sits down he goes to sleep. This is called the ambulatory form. The following brief history illustrates the fact that cases of this character may be overlooked and treated for different affections:

A young married man, who was a cashier in a bank, would frequently, while at work, close his eyes and go to sleep; at the same time he complained of exhaustion. Upon examination I could observe a paretic condition of the external rectus of the left eye. When, during the examination, his brother would engage me in a brief conversation, the patient would fall asleep. This condition lasted four weeks, after which complete recovery took place. This affection was formerly diagnosed as a very probable case of brain tumor for which the physician in charge was contemplating engaging a surgeon for operative procedures. The patient did not, however, present other symptoms of a neoplasm.

In another series of cases the somnolence may be somewhat more pronounced. The patient invariably falls asleep after meals or after the least amount of exercise. His eyelids have always a tendency to droop and he has to struggle against sleep. Although he can be aroused for food, and will answer questions correctly, he nevertheless rapidly resumes his sleep as soon as he has answered.

In some cases the sleep may be still more pronounced. The patient is in a state of absolute inertia, the features are immobile, the cutaneous folds are effaced, feeding by mouth is impossible and one has to have recourse to nutritive enemata. In one case, a girl of eighteen, during the deep sleep, Cheyne-Stokes's respiration was observed, which led her physicians to think of cerebral hemorrhage. The patient nevertheless made a complete recovery. The diagnostic error consisted in overlooking the absence of localizing symptoms, such as abnormal reflexes, etc. In another similar case in addition to the deep sleep, there was marked rigidity of the neck and the attending physician concluded that this was a case of tuberculous meningitis. Here also the patient recovered.

Palsy of ocular muscles is a common symptom in lethargic encephalitis. It is usually an early manifestation. The most frequent symptom is ptosis which is in the majority of cases bilateral. Here we observe various degrees, either complete drooping of the eyelids or merely a heavy feeling. Ptosis, strabismus and diplopia will also be observed. Here again various degrees of these disorders may be present and they may be unequally distributed in both eyes. For example, in three patients under the writer's observation, there was ptosis on one side and external strabismus on the other. The third cranial nerve is more frequently involved than the fourth and sixth. The various muscles supplied by the third nerve are usually unequally involved in the same eye or in both eyes.

The internal muscles of the eyes are less frequently involved. Inequality of the pupils, mydriasis and myosis, paralysis of accommodation, mild nystagmus, are the conditions observed. The intrinsic and extrinsic ocular palsies run an irregular course and their degree is variable.

In addition to the ocular nerves, other cranial nerves may be affected in the following order: facial, hypoglossus, motor branch of the trigeminal, glossopharyngeal and spinal. Facial paralysis, difficulty in swallowing, in masticating, in breathing, in speaking (dysarthria), are then observed.

*To be read before the Philadelphia County Medical Society, December 22, 1920.

In the latter case it may give the impression of pseudobulbar paralysis. Facial palsy may be bilateral. Not only paralysis of the cranial nerves but other paralyzes have been observed. In a case under my care, that of a colored man, there was a mild but distinct right hemiplegia with increased patellar tendon reflex and toe phenomenon. A similar case was reported by Halbron and Coudrain (4). Page (5) also reports a case with monoplegia in the upper extremity.

Sensory disturbances are usually rare. In one case in my series (6) there was a very marked tenderness of the left infraorbital nerve at its exit from the foramen and anesthesia of the left cheek. In Sainton's cases (7) there was a generalized cutaneous hyperesthesia so that the least touch produced pain. In a number of cases other disorders have been observed, such as excessive salivation, involvement of sphincters in grave cases, vasomotor display, gustatory disturbances, but these are all infrequent. Great variability has been observed in the course of the disease; its duration may be from several weeks to many months. The fever, the ocular palsies and the somnolence may present great oscillations in intensity and duration. One may say, however, that when the temperature remains high, the outlook is serious, and when myoclonic phenomena occur, that the prognosis is equally grave. A number of other manifestations of a motor or psychic character are met with at times either in the early course of or during phases of exacerbation of lethargic encephalitis.

The myoclonic type. This is one of the most striking clinical types. The following case is an example: A young man aged twenty-seven, a shoemaker, had a mild attack of lethargic encephalitis. There was somnolence, bilateral ptosis and a slight rise in temperature. The reflexes were increased. The disease ran a mild course and the patient began to improve. During convalescence his family physician observed slight twitchings in the muscles of his shoulder. Soon muscular contractions were seen in the face and in all four extremities. A few days later I found the patient affected with violent twitchings, brief and rapid, at irregular intervals but close to each other and involving every segment of the body. He was unable to eat, to rest, or to sleep. His respiration was rapid and his pulse could not be taken. He expired on the following day. In two cases the myoclonia was accompanied by severe hiccough, evidently due to violent contractions of the diaphragm.

Brouardel, Levaditi and Forestier (8) report a case (verified by autopsy) without ocular disturbances, but with abdominodiaphragmatic myoclonic contractions, which rapidly invaded all the four extremities. Sicard (9) observed five cases in which the initial symptoms were lancinating pain especially in the neck and arms, muscular twitchings in the arms, abdomen and diaphragm. The same author with Kudelski observed also hemimyoclonia confined to one side while on the other the seventh and sixth nerves were involved. It is evidently a mesocephalic condition of the Millard-Gübler variety.

Choreic type. In a girl thirteen years of age, the attack of encephalitis began with choreic move-

ments in the right arm and face. A few days later somnolence made its appearance and soon the involvement of the superior rectus and the external rectus on the left side became evident. Her temperature was 100.2°. The choreic movements lasted through the entire course of the encephalitis. Recovery took place at the end of three months. The lethargy and the muscular movements disappeared totally, the superior rectus recovered but the external rectus is still paretic. The concurrence of acute chorea with a febrile encephalitis supports the view of the infectious nature of the former (10). It is interesting to note a marked hypotonia of the limbs affected with choreic movement. Cases of electric chorea (Dubini) have been reported in conjunction with lethargic encephalitis.

Hemiplegic form. Cases with one sided paralysis are not frequently encountered. In addition to my case and Halbron and Coudrain's case, no record could be found in the literature. In my case the paralysis was mild. At the time of writing these notes the patient shows evidence of considerable improvement of all symptoms. The paralysis may be confined to one limb (monoplegia). Such a case was observed by Page (5).

Convulsive type. One such case came under my observation. It occurred in a middle aged man whose Wassermann test was positive, but who formerly was free from epilepsy. On the third day convulsions of a generalized character occurred. During the entire illness which lasted three months the patient had three attacks. Recovery was complete. He was treated with antiluetic remedies. In some cases the epileptiform convulsions were of Jacksonian type. In such cases a paretic condition or contractures on the same side have been observed. The prognosis in such instances is very grave (11). Aubry and Froment report two cases of trismus. One occurred in a pregnant woman who presented in addition to the characteristic symptoms, dysarthria, difficulty of swallowing, and trismus. The patient died. In the other case there were myoclonus and trismus. Trismus was probably due to an irritation of the motor nucleus of the fifth nerve.

Meningeal type. The triad of encephalitis lethargica symptoms developed in a girl, sixteen years of age. Her temperature rose to 102.4°. At that time her neck was rigid and Kernig's sign was present, facts which led the attending physician to reject the diagnosis of encephalitis. Within a week the two meningeal signs subsided and rapidly disappeared. The oculomotor palsies and somnolence remained. The patient died at the end of nine weeks after a period of Cheyne-Stokes respiration and difficulty in swallowing.

In this case the meningeal phenomena somewhat obscured the encephalitic manifestations. Nevertheless the disease began with the characteristic symptoms. It is to be borne in mind, therefore, that the same infectious agent which affects the nervous tissue of the mesencephalon or other portions of the brain tissue, may simultaneously involve the meninges and thus present a complex clinical picture. Rathery and Bonnard (12) report the case of a young girl in whom, in addition to ocular palsy, fever and somnolence, there were also Kernig's

sign and rigidity of the neck. The spinal fluid was under great pressure and distinctly hemorrhagic, containing 5.40 gr. glucose, with marked leucocytosis (50,000). Bassoe (13) also reports cases of meningeal type.

Sometimes encephalitis lethargica may present a condition suggesting strongly a basilar meningitis. In a young lady aged twenty-four years the disease began with vertigo and headache. The temperature rose to 101°. On the following day the patient noticed that she had great difficulty in keeping her eyes open. She was drowsy, could not keep up a conversation. Her neck was somewhat rigid. Kernig's sign was absent. There was a mild crossed paralysis. The facial nerve on the left was involved and right leg presented an increased knee jerk with ankle clonus and toe phenomenon. There was paresis of the left external rectus and also bilateral ptosis. The patient came of a tuberculous family and she was treated for suspected pulmonary tuberculosis. For three months her condition remained stationary with the exception of the temperature which fluctuated from 99.2° to 100°. Her lethargy became more and more pronounced. Finally she began to improve, the crossed paresis disappeared, the left external rectus became normal, the ptosis improved greatly. There was no more rigidity of the neck. For weeks thereafter, however, she felt drowsy. Eventually she recovered completely. A basilar tuberculous meningitis suggested itself very strongly, but the entire course of the illness, together with the spinal fluid findings, proved the case to be one of encephalitis.

Parkinsonian type. In two male patients, both of middle age, there was a typical picture of encephalitis. On the third week after the onset, passive tremor in the right hand with facies characteristic of paralysis agitans developed. On recovery from the encephalitis the tremor disappeared but for a long time the general attitude, the rigid and fixed position of the trunk and the mask like expression of the face remained typical. In a third case the tremor was absent but the facial expression was that observed in Parkinson's disease. After recovery from the original disease, the evidences of shaking palsy disappeared. Marie and Lévy (14) in describing their autopsied cases call attention to the lesions of the locus niger observed in paralysis agitans by some writers and to the predominance of encephalitis lesions in the mesencephalon. In a recent case of Trétiakoff and Bremer (15) paralysis agitans developed in the course of encephalitis lethargica. At autopsy a pronounced degeneration of locus niger was found in addition to other nuclear lesions.

Bulbar type. Four cases came under observation. In two of them (6) there was difficulty in swallowing and dysarthria because of a paretic condition of the lips and tongue. In the second case there was also unilateral facial paralysis and in the third involvement of the fifth nerve on one side. Both of these patients recovered. In two unpublished cases the initial symptoms were bulbar. One patient had difficulty in swallowing for several days, with temperature rise to 100°. On the fourth day the patient became somnolent, complained of

vertigo while in bed and, at the same time, bilateral ptosis and external strabismus on the right made their appearance. It is interesting to note that when improvement eventually set in, it was evident first in the symptom which developed first, viz., in the act of swallowing. The affection of the eye muscle persisted the longest. In the second case a difficulty in speaking was noticed in the course of the encephalitis, when the patient was aroused for food. He was unable to move his tongue and lips properly in speaking as well as in masticating, but there was no difficulty in swallowing. It was observed that this disorder appeared on the day when there was a rise of temperature (102°) as if an infectious element had penetrated the nucleus of the hypoglossal nerve. This particular disorder lasted a long time after the lethargy had disappeared. The patient made a complete recovery.

Neuralgic and neuritic types. Cases have been reported in which pain appeared in the face and in the extremities or was of a generalized character. In case number one of the first contribution (6) the encephalitis began with generalized pain which persisted as long as the temperature remained at 100° but subsided when the latter remained below that figure. In this case the pain was unusually severe and continuous in the neck more on one side than on the other. In Salmont's case (16) the patient, during four consecutive days, had violent pain in one arm. The radial reflex on the same side was altered, revealing the presence of a cervicobrachial radiculitis. On the fifth day lethargic encephalitis developed from which the patient subsequently died. Sicard (17) reports a case in which at the onset there was pronounced intercostal pain persisting during ten days and followed on the eleventh day by contractions of the diaphragm and somnolence and terminating in death. Similar cases were reported by Bassoe (13).

Mental type. In the apparently uncomplicated forms of encephalitis lethargica while there are no mental phenomena of a special character, nevertheless the sleep is not that of normal men. It is true that when the patient is aroused, he opens his eyes, answers questions more or less correctly and returns to his sleep, but back of the lethargy the psychic state is always more or less benumbed and functions defectively, i. e., the patient's orientation or appreciation of the condition is defective, he frequently makes mistakes, there is a certain sluggishness in associating ideas. Sometimes we observe what the French call *état crépusculaire*. This is analogous to the mental state observed in exhausted or inebriate individuals, the patient shows a very mild confusional appearance; his facial expression and his entire attitude exhibits surprise and astonishment when he is being observed or addressed.

In some cases, however, there is a genuine confusional state with delirium. With eyes closed the patient mutters unintelligible words and when he is awakened will look around as if bewildered and may not recognize surroundings. In another group of cases a genuine psychosis may make its appearance in the course of encephalitis lethargica and continue as such after the latter has recovered.

An interesting case of this type came under my

observation. A young man, aged twenty-three, had a mild attack of the disease from which he recovered completely. During the illness, when aroused for food he was disorientated in time and space, and had a tendency to get out of bed. This latter effort would last about five minutes, after which he would become somnolent again. Upon recovery from the somnolence and when eye conditions and fever had subsided, his mental state remained unimproved, even became more and more accentuated. When he was able to be about, he showed a hypomaniacal state, restlessness, talkativeness, voracious appetite, excessive desire for smoking, also puerilism. He talked like a child, laughed at the most insignificant remarks, acted in a silly manner, preferred to play with children. All the physical symptoms of the encephalitis had disappeared, but the mental condition was persisting five months after onset of the illness. The patient's personal previous history was negative, but the family history recorded mental disorders in several of its members.

In another case, that of a man thirty-nine years of age, there was marked depression at first. The hopelessness and despair expressed by the patient gradually led his physician to view possible melancholia, especially when the patient began to speak of suicide. Upon examination made ten days later, the writer noticed left sided ptosis, right sided internal strabismus and actual somnolence. The latter developed after the phase of depression. The patient was ill for nine weeks. As soon as the lethargy began to disappear, the former depressive state reasserted itself. Fifteen months after the recovery from encephalitis the patient was still in a state of depression with suicidal tendencies. Froment and Comte (18) report a case which started with epileptic seizures of Jacksonian type and delirium with visual hallucinations. Cortical involvement is here evident.

Cerebellar type. A man, aged thirty, after having recovered from somnolence in encephalitis showed the following symptoms in addition to oculomotor disturbances: ataxic gait with tendency to fall to the right, right hemiasynergia, adiachokinesia on the right, pastpointing on the right, and diminished patellar tendon reflex on the right. Eventually the man made a complete recovery. The examination of the patient's labyrinth was negative. A similar observation is reported by Achard and Leblanc (19).

Poliomyelitic type.—Tilney (20) reports the case of a child of four in whom prolonged somnolence was associated with acute anterior poliomyelitis. Such combinations are rare, nevertheless they show the possibility of simultaneous involvement of the spinal cord and brain.

Sensorial type.—Amaurosis and deafness have been observed in some cases as conspicuous symptoms. In Vincent's two cases and in Carnot's case day could not be distinguished from night. In the former's cases there were achromatopsia and deafness; in the latter case the amaurosis subsided a long time after the somnolence and at the same time the syndrome of bulbar palsy made its appearance (21).

Paraplegic type.—Sicard (22) gives the history of a woman who at first had an attack of flaccid paraplegia accompanied by retention of urine and

lethargy. During convalescence muscular twitching and rhythmic tremor in the upper extremities developed. I believe that there was simultaneous involvement of the mesencephalon and of the spinal cord with its roots in the lumbar region.

Incomplete forms.—In a certain number of cases the triad of symptoms has not been complete. Thus cases have been reported without ophthalmoplegia or without lethargy, or else with very slight somnolence, and finally in some cases there was little or no rise in temperature. Abortive forms have also been reported. In a case under the writer's observation the patient had a slight rise in temperature, general malaise, diplopia in looking toward the right; he felt drowsy and frequently would close his eyes. The entire condition lasted six days. Recovery was complete.

DIFFERENTIAL DIAGNOSIS.

In making a diagnosis of encephalitis lethargica one should bear in mind the three fundamental symptoms, ocular palsies, somnolence, and rise in temperature. It may be of interest to add a few data concerning the humors. The cerebrospinal fluid is usually clear, without undue pressure and without lymphocytosis, and these negative findings are uniform in all stages of the disease. Some observers, however, speak of a lymphocytosis in the early stages which gradually diminishes and disappears. This fact is important, for in meningitis the reverse is true (23). In a certain number of cases the spinal fluid contained an increased amount of sugar (24). In Netter's last six cases there were seventy, eighty-five, eighty-five, ninety-five, eighty-three and ninety-seven centigrams to the litre. According to Benard (25), a glucose content of 0.67 to 1.06 gram is a material aid in the diagnosis. It is possible that the richness in sugar is due to the irritative process in the medulla in which the centre discovered by Claude Bernard is situated. In meningitis, on the contrary, glucose is diminished. The blood, as a rule, presents no appreciable change in numerical count. However, in some cases a moderate leucocytosis was observed (26).

In view of the large number of associated symptoms and the multiplicity of varieties, the diagnosis of lethargic encephalitis is sometimes surrounded with difficulties. The protean character of the disease must be borne in mind, as grave errors of diagnosis have been reported and very serious maladies have been overlooked.

One of the diseases with which the affection under discussion may be confounded is meningitis. The above mentioned progressive increase of lymphocytes as the disease advances and the decreased amount of glucose in the spinal fluid are evidences of meningitis. In the tuberculous form of the latter somnolence is usually present but the abundant lymphocytosis and tubercle bacillus in the spinal fluid, the dissociation of temperature and pulse, also the irregularity of the latter, are all absent in lethargic encephalitis. In cases of doubt as to the possibility of syphilitic meningitis, Wassermann reaction, and treatment with antiluetic remedies will ascertain the nature of the condition. Meningitis of other forms will be recognized by rigidity of the neck, by the presence of Brudzinski's and

Kernig's signs, retraction of the abdomen, dissociation of pulse and temperature, and finally by the state of the spinal fluid (see above). Of course the observations recorded above demonstrate the fact that the meningeal manifestations should not be taken as absolutely final. Epidemic cerebrospinal meningitis is characterized by a cloudy spinal fluid, marked leucocytosis and meningococci.

The English writers considered the first cases observed in England as instances of botulism in view of the pronounced asthenia and paralysis of accommodation, but in this disease there is usually a dryness of the throat and mouth, with thirst, obstinate constipation, and extreme dilatation of the pupil, all symptoms which are wanting in encephalitis. Besides, fever is absent in botulism and there is not a true somnolence but a rapid coma.

Lethargic encephalitis may be confounded with hemorrhagic superior poliomyelitis, but the latter runs its course without rise in temperature and is accompanied by marked nervous manifestations in the motor and sensory spheres, such as ataxia, unilateral paralysis of the extremities, exaggeration or abolition of tendon reflexes, disturbances of speech, deglutition, and mastication. Finally, there are grave ocular lesions (optic neuritis, nystagmus, associated paralysis). Tumor of the brain may simulate an encephalitis, in view of the motor disturbances and the drowsiness, but severe headache, vomiting, optic neuritis, or atrophy, or papilledema, are encountered only in cerebral neoplasms.

Cerebral abscess may also simulate lethargic encephalitis because of the somnolence, but the eye ground changes, the condition of the blood, slowness of the pulse will enable one to recognize the former. Anterior poliomyelitis in its bulbar and pontine varieties may sometimes give the impression of encephalitis, but the predilection for early childhood, its occurrence chiefly in warm seasons, absence of meningeal reactions, paralysis, and atrophy of the affected extremities due to serious alterations of the cellular elements, are all characteristic of the former. Encephalitis attacks adults preferably, produces but slight cellular lesions, and is usually of a more favorable prognosis.

Intoxications may be accompanied by a state of stupor simulating lethargy. The mental state following the administration of opium and chloral is analogous to, if not identical with that in encephalitis. Uremia and diabetes may present the same picture.

Narcolepsy is a functional nervous disorder which may be confounded with the somnolence of encephalitis. It is to be borne in mind that narcolepsy is a manifestation of hysteria and may be removed by suggestion, psychotherapy, or psychoanalysis. Besides, it is totally free from organic symptoms characteristic of encephalitis.

Comatose states are differentiated from encephalitic lethargy by total loss of reaction to sensory stimulation, while the essential characteristic of somnolence in encephalitis consists of responsive reactions to stimulation; the patient can be aroused for partaking of food, and to answer questions asked. Besides, profound coma is associated frequently with conspicuous motor disorders due to profound

cerebral lesions. Neither do we find the ocular disorders characteristic of encephalitis.

Stupor due to cerebral syphilis may present great obstacles in formulating a diagnosis. In both conditions we find somnolence and palsies of ocular muscles. In such cases we must recall the character of the somnolence of encephalitis. In syphilis the stupor is continuous and if the patient is aroused the mental hebetude is pronounced, the patient is unable to understand fully what is spoken to him. In encephalitis the patient answers questions correctly and takes his food properly; in other words, there is comparative mental lucidity. Finally, the state of the cerebrospinal fluid with its lymphocytosis and positive Wassermann reaction will decide in favor of cerebral syphilis.

The modifications in the clinical picture of the disease, thus presenting special forms, correspond to the many variations in the pathological findings. The clinical polymorphism finds its explanation in the anatomical polymorphism. Let us now consider the varieties of lesions.

Grossly speaking, the pathology of lethargic encephalitis consists of inflammatory degenerative processes chiefly in the midbrain. Despite the variability and irregularity of localization, the lesion predominates in the cerebral peduncles. According to Marie and Trétiakoff the locus niger is most frequently involved (27). As to the lesions, there is essentially a perivascular inflammation with all its characteristics: dilatation of the blood vessels with cellular infiltration, occasional rupture of the vascular wall, and hemorrhagic inundation of the adventitia and the neighboring tissue. Transudation with localized edema, especially in the cortex, is sometimes seen. The cellular infiltration is not confined to the vascular wall and very frequently invades the gray matter. In addition to the inflammatory process there is also a secondary destruction of nerve cells and fibres. The cells present all degrees of chromatolysis. Neuroglia cells participate in the pathological process. The localization of all these lesions presents all degrees of chromatolysis. Neuroglia cells participate in the pathological process.

The maximum of involvement is found in the gray matter of the aqueduct of Sylvius and the fourth ventricle. The lesion radiates toward the gray substance of the pons and medulla. On the other hand, it may reach upward to the basal ganglia, viz., the optic thalamus and striate bodies. The nuclei of the fifth, sixth, and seventh nerves are sometimes involved, and Marinesco observed atrophy of the dorsal nucleus in the pneumogastric nerve. In the cases cited above the ninth, tenth and twelfth nerves were also involved. In Marie's and Trétiakoff's cases (27) not only the above mentioned structures were involved, but also the red nucleus, interpeduncular space, the tegmentum, the locus niger, the floor of the fourth ventricle, nuclei of the pons, the first two cervical segments, cerebral and cerebellar cortex, finally the meninges and ependyma of the ventricles.

We, therefore, see that the pathological condition is vast and concerns particularly the entire central nervous system. Of course, as such it is not met

with in all the cases, but the distribution of the lesions presents great irregularities. In pronounced or generalized cases, the entire cerebrospinal axis may become involved. In less pronounced cases the lesions are distributed in the pons and medulla, in mild cases only in the locus niger and its vicinity. There is also a large number of intermediary cases. The polymorphous character of the anatomical findings is, therefore, in keeping with the polymorphism in the clinical picture. The distribution of the lesions has a considerable bearing not only on the diagnosis but also on the prognosis. The knowledge of the state of reflexes is important from this viewpoint. It seems that abolition of the tendon reflexes (which is observed in some cases) with preservation of the cutaneous reflexes shows that the disease is not always confined to the bulbo-pontinepeduncular region, but it has a tendency to become diffuse eventually. Guillain makes an interesting prognostic observation in four cases: precocious abolition of tendon reflexes has a bad outlook, as all the patients died. In two cases in which the reflexes remained normal, the patients recovered.

Lethargic encephalitis is a protean disease with its histological characteristics of a definite type but with a great variety of localizations throughout the entire central nervous system. The infectious character which has been determined presents a promising field in the domain of treatment and therefore of prophylaxis. In view of continuously accumulating data the final word is approaching.

1812 SPRUCE STREET.

CUTANEOUS ANTHRAX.*

By JOHN RANDOLPH GRAHAM, M. D.,
New York,

Borough Diagnostician, Department of Health of the City of New York.

This paper will deal particularly with the manifestations of anthrax as I have observed them in the course of my work during the last few years, and let me say at the outset that my remarks will be confined to a discussion of that type of the disease known as cutaneous anthrax, or malignant pustule, for I have never seen a case of the internal variety, variously known as intestinal mycosis, woolsorters' disease, and splenic fever. Anthrax is of rare occurrence in this vicinity and heretofore the mortality has been very high, especially in cases involving the face or neck; but in spite of a decided increase in the number of reported cases during the last three or four years, methods of treatment adopted and perfected within this period have apparently resulted in a notable reduction in the percentage of deaths. It has been my unusual good fortune to inspect at some time during the duration of the attack, almost all the cases reported to the Health Department from the Borough of Manhattan since January, 1915; also occasional cases prior to that date. It seems probable that neglect to report cases, whether deliberate or as the result of failure to recognize the condition, is rare. And even though, now and then, one victim may die with the disease incorrectly diagnosed, and another may recover without his physician going through the formality of notifying the authorities, I believe that the total of cases on file at the department approximates very closely the actual number of infections that have been incurred here in the period mentioned.

I do not desire to burden you with figures, and my only offense of this character will be to quote statistics showing, 1, the incidence of known cases in the whole city and in Manhattan since January 1, 1915, and, 2, the recoveries and deaths from the disease during the same period.

	Whole City	Manhattan	Recoveries	Deaths
1915.....	9	4	0	9
1916.....	4	2	1	3
1917.....	17	8	8	9
1918.....	15	10	11	4
1919.....	17	10	8	9
1920.....	20	13	18	2

(To Nov. 1.)

My acquaintance with anthrax began in the autumn of 1911. A patient, who was a delivery wagon driver by occupation, and who, incidentally, took partial care of his horse, came to see me, looking ill and thoroughly exhausted. In reply to a question as to what ailed him, he said he had a "pimple" on his arm, which, by the way, is the usual description of the affection offered by the patient. The mental picture afforded by the subsequent examination is still most vivid. On the ulnar side of the left forearm, just above the wrist, was a black scab, the size of a dime, depressed, craterlike, in a brawny looking inflamed mass about four inches

*Read before the Riverside Practitioners' Society of New York, November 23, 1920.

in diameter. This eschar was bordered by a pustular rim and just outside its edge were numerous little vesicles dotting the red surface. From the finger tips to the shoulder there extended a huge edema, the limb appearing twice its normal size, and had it not been for the angry look of the centre of infection the whole affair would have resembled a dropsical edema. The man said that the first indication that there was anything wrong had appeared about three days before in the shape of a troublesome burning sensation on his wrist; that, although he noticed a pimple had formed and was steadily enlarging, it had not bothered him specially; in fact, in decided contrast to its very ominous look, it was not hurting him then. A head had developed, however, and he had pricked it, thinking it a small boil. Following this operation, the process had spread with such rapidity that he thought it ought to be treated. Suffice it to say that after a long and serious illness, this man got back to work, though with his health permanently impaired by a bad heart, a condition which developed during his attack.

I confess with some hesitation that I failed for some time to recognize the true nature of this infection, and you may rest assured that these details have not been recounted for the purpose of glorying in my ignorance. But in thinking over my experience in this particular case and in studying other attacks of a similar character, two things have impressed me and have influenced me very much in preparing this paper. First, that the lack of familiarity with the appearance of this lesion, due to its rarity, has probably resulted in others also having diagnostic difficulties, such as I have confessed, and second, that inasmuch as the infection is almost invariably far advanced when the patient first appears for treatment, it is, generally speaking, essential to a successful result that we identify the lesion promptly when we see it, and that with equal promptness we institute proper treatment. This last point is put forward with the proviso, of course, that we accept the fact that treatment is efficacious.

It will not be amiss to say that very few doctors ever see a case of this disease. An incident which in a way bears out the correctness of this assertion occurred in an Army camp in 1918. Two soldiers, of whom I shall have more to say later, were sent to the Base Hospital infected with anthrax, and of the threescore or more medical officers stationed there at the time, it appeared that but two had had

any previous experience with the malady; and this is probably a considerably higher proportion than would be found to exist among the profession as a whole. On the other hand, this lesion is so unique in appearance that, once it is identified, I believe it will remain fixed in the mind's eye for all time.

ETIOLOGY AND MODE OF TRANSMISSION.

The *Bacillus anthracis* is the causative organism. It uses as its portal of entry to the body any conveniently placed abrasion of the skin. Upon its entry, there promptly ensues the formidable inflammatory disturbance originating at and spreading from the point of inoculation, and, what is more serious, if the infection is not energetically attacked, there will develop later an overwhelming bacteremia. I am told that it is comparatively easy to find the bacillus in smears and to grow it in cultures taken from the pustule; positive blood cultures are, however, obtained only in cases approaching a fatal termination. The bacillus is not a pus producer and is itself easily killed, but its spores are very resistant to heat and germicidal agents. I should say possibly in this connection that the fatal attacks are generally those in which the face or neck is the site of the lesion, for there the tissue is loose and elastic and the blood supply plentiful. In each of the attacks which I have personally seen, where an extremity was the part involved, the patient has recovered.

The disease is most often found in those engaged in the handling of horses, sheep, and cattle, in fact, of all herbivorous animals; also, in those employed in the handling of the hair and hides of such animals. In late years, it has become a well recognized and established fact that shaving brushes, especially of the cheaper sort, may and frequently do carry the infection. The resistance of the spores to measures of sterilization already mentioned makes it very difficult to free hides and bristles from infection without at the same time ruining their texture; and this fact readily accounts for the brushes acting as carriers of the disease. An interesting etiological point is that while anthrax is quickly and easily transmitted under certain conditions from an infected animal or its hair or hide to a human being, there is very trifling danger, judging from our experience here, of this type of the disease passing from man to man. At best, human susceptibility to this infection appears very slight.

SYMPTOMATOLOGY.

The incubation period is short, probably less than three days. The primary lesion is practically always single and appears on an exposed portion of the body—the face, neck, wrists and hands—with the neighborhood of the angle of the jaw the most favored point of attack. Perhaps to be quite accurate, it should be said that on rare occasions there may be double lesions, though always in the same locality, and just as rarely the so-called pustule is located elsewhere than on the parts named. The patient will state that the first evidence of infection was a slight but persistent itching or burning sensation at the point of inoculation, which is probably an abrasion resulting from a scratch, a razor cut, or other minor injury. Very quickly there forms on this spot a tiny papule, no larger often than a mosquito

FIG. 1.—Striking drawing made at bedside of patient in Bellevue Hospital by Dr. Windom Blanton, of Richmond, Va.

bite or an acne lesion and causing just about as much discomfort as one would experience from such an affection. Little attention is paid to it, though in a few hours a chill or at least a chilly sensation may occur. Some time after this chill, the papule develops a head, the contents of which may be either hemorrhagic or vesicular in character. This head will shortly break down of itself, be opened by the patient, or be cut in the process of shaving. On its destruction, there regularly forms in its place a black necrotic eschar. From the time of its appearance, this eschar is a very intimate, prominent, and ever present part of the lesion and it adds to the clinical picture a diagnostic point of such importance, that we may well pause long enough to set forth the following facts regarding it:

1. It is purplish black in color.
2. It appears to be set into or framed in the papule.
3. Its size may vary from a coffee bean to a silver dollar.
4. Its border may be smooth and clean cut, or serrated.
5. Its contour may be round, oval or irregular.
6. It may have a pustular rim, which is not infrequently a delicate gray line, apparently inlaid between the scab and the deep red tissue outside its border.

I return to the consideration of the papule with the remark that, while in its early state it is certainly insignificant and harmless enough in its general appearance, this is no longer true after the formation of the pustule and its successor, the eschar. From that time it enlarges very rapidly until it becomes an irregular, though fairly circumscribed mass. This is sometimes tumor like and may attain the size of a hen's egg, but more often it is flat, much resembling a carbuncle in this respect, with its elevation above the surface scarcely appreciable owing to the adjacent edema. This mass is dark red in color, firm to touch, indurated and brawny; altogether a thoroughly vicious looking affair. When incised it offers almost as much resistance to the knife as would fibrous tissue and it may turn the point of a large hypodermic needle with ease. When the disease has existed three or four days, at which belated time the patient usually seeks the advice of a physician, the lesion will have lost most or all of its individuality, by having merged itself into the edematous tissue around it, and it then presents to the eye the appearance of a more or less diffuse cellulitis. The eschar sticks through thick and thin, and will be found embedded in this mass. With the continued advance of the disease, the induration becomes more widespread and the redness creeps further out until it finally covers the whole of the edematous area.

I believe that the most striking thing about anthrax is the edema. It starts early, very soon after the papule begins to assume form; it spreads rapidly and its extent is apparently unlimited, although it must depend to some degree on the laxity of the tissue in the region involved. The initial lesion is not always, in fact, I think not often, in the centre of the edematous area, and the edema may be noted spreading out from it somewhat in the same manner that erysipelas spreads from the point of inoculation. Perhaps I can emphasize how impressive this edema often is, by describing a case seen this year.

A truckman for a firm dealing in hides presented himself at one of the hospitals for treatment. He was a sorry looking spectacle. (Fig. 1.) The left side of his face was so swollen and distorted that he hardly looked human; the left eye was closed by great edematous eyelids; the right cheek and eyelids were also tremendously puffed up; the lines of his neck on the left side were almost obliterated and an enormous edematous collar ran most of the way around his neck, and made evident pressure on the trachea. The edema involved besides to some extent the soft tissue in the pharynx and larynx, though strangely enough in this case it hardly lapped over at all on the chest wall, as so often happens where there is a cervical lesion. Though he had been ill but three days, all semblance of the papule had disappeared. In its place, there was a good sized, angry looking area of inflammation below and behind the left ear, with the smallest eschar I have ever seen embedded at the point of inoculation. There were no difficulties of diagnosis offered by this patient, but in addition to illustrating the widespread area which can be covered by the edema, it showed too the rather startling rapidity with which the affection can develop. You may be interested

FIG. 2.—Case I. (Published by courtesy of Dr. Douglas Symmers, Director of Laboratories of Bellevue and Allied Hospitals.)

to hear that in spite of the critical condition and horrible appearance of this patient, he recovered in due time.

To complete the description of the cutaneous lesion, it remains only to mention the fact that an

indefinite number of vesicles, arranged singly or in groups, are generally, but not necessarily, scattered over the inflamed surface of the mass just outside the edge of the scab. They have no connection with the actual border of the eschar, which you will remember can be pustular in its makeup.

The lymphatic glands near the lesion are enlarged. There is a leucocytosis, sometimes marked. I have read of cases in which the count was 30,000 white cells. Anders and Boston in *Medical Diagnosis* give the average leucocytes in thirteen cases as 13,900. There is no special combination of constitutional symptoms which can be considered as regularly associated with anthrax, nor do such general symptoms as are found bear any direct relation to the virulence of the attack. The temperature may be moderate even in severe cases; or it may reach 106° or higher. The pulse is usually rapid, but I have seen wicked attacks in which the rate was slow. The patients may have a pasty pallor, but they rarely betray by their appearance the severe character of the infection which has gripped them. There is one characteristic feature which will generally be found, namely, marked physical weakness on exertion in surprising contrast to the appearance when at rest. The patients also exhibit mental apathy as a rule, are easily wearied by questioning and often act as if dazed, though even in fatal cases they retain consciousness to the end. A point which I think is significant and about which I invariably inquire, is the unanimity with which these patients declare they have little or no pain and I have no doubt that this feature of the disease accounts to a large extent for the long time which usually elapses before they come for treatment.

DIAGNOSIS.

With laboratory facilities available, the diagnosis can generally be confirmed in a short time, though once in a while the bacillus is not found. I believe that in view of the rather easily recognized earmarks shown by anthrax, one is justified in most cases in basing his opinion purely on clinical evidence. To wait for bacteriological proof is a doubtful expedient and may have serious consequences for the patient. By way of illustrating the futility of depending too much on the microscope, I am led to refer again and more in detail to the case of the two soldiers mentioned in passing a while ago. These boys were admitted to the hospital a few days apart and although from the same organization, indeed from the same tent, they were unacquainted with each other, the second man having been mustered into the service after the removal of the first man to the base. Both exhibited a typical papule at the angle of the jaw, and though in different stages of development, the lesion in each case was surrounded by considerable edema. They complained of practically the entire list of symptoms enumerated as characterizing anthrax. Furthermore, the first patient stated that he had purchased a cheap shaving brush in a railroad station on his way down to camp and that he had used it but twice when he began noticing symptoms. We could never actually verify it, but there was ground for rather more than a strong suspicion that the second patient had found this brush and had appropriated it for his own use.

The point which I wish to emphasize in this incident is that, notwithstanding the history and in spite of the thoroughly typical picture presented by these patients, the organism was not found in the smear or culture taken from the lesion in either case, and so they are not mentioned in the War Department records. But in the minds of the two physicians at hand who were familiar with the disease, the diagnosis was clear beyond the shadow of a doubt, and the fact that energetic measures of treatment were applied at once, despite negative findings, was I believe in a large way responsible for complete recovery in both cases.

Bearing in mind then that, if I am right in the opinion just expressed, the diagnosis of anthrax based on clinical evidence alone is not only feasible, but as a rule comparatively simple, let us review the salient points in the rapidly developed picture, which may have to be considered in arriving at our conclusion. It is essential as a preliminary step to ascertain if the patient was employed in caring for cattle or in the handling of their hides or hair; or if perchance he had recently used for the first time a new shaving brush. By a combination of questions and personal observation, we will learn that the first evidence of disease was a burning or itching sensation at the point of inoculation; that on and around this point there developed in rapid succession a small, insignificant papule, then a much larger papule, then a mass of intensely inflamed tissue, fairly circumscribed, sometimes tumor like in form but more often flat, resembling in a general way a carbuncle, and finally a diffuse, indurated cellulitis like area of inflammation, which merged itself into the encircling edema without showing any distinct line of demarcation. It is significant too that with all this objective display, we will probably be told that pain is negligible. We will learn further that quite early the papule developed a hemorrhagic or vesicular head; that this quickly ruptured and that its place was taken by the telltale black eschar. Just outside the border of the black crust, we will observe in most cases a number of vesicles scattered over the inflamed surface, singly or in groups. Finally we will note the edema, which in all likelihood will literally fill the eye, and we will be told that it began early and that it attained its present extensive proportions by steady and quick progress.

Having touched on these important diagnostic points, let me say that the early stage of the disease is likely to interest us only from the viewpoint of building up our history, for it is seldom that we see the patient until the disease has existed at least three or four days. At this period of the attack, I think we can regularly expect to find, 1, a large area of inflammation, perhaps circumscribed, perhaps diffuse, surrounding the point of inoculation; 2, a black eschar superimposed on that point; and 3, an edema which will probably be farreaching and entirely out of proportion to the cutaneous disturbance around the focus of infection. When we find this trio of signs associated, we can be certain that we are dealing with anthrax. Constitutional symptoms have not been dwelt upon here for they aid us not at all in making a decision.

The disease can be differentiated clinically from

carbuncle by the lack of an eschar, the absence of extensive edema, the less marked constitutional symptoms, and the presence of cribriform openings in the latter affection. To mistake it for a syphilitic chancre appears far fetched.

TREATMENT.

I shall mention briefly the various methods of treatment which have been used in the years covering my familiarity with the disease. I wish it to be remembered that practically all that is said in this paper is based on personal observation of this affection as it has occurred in New York city, and while an earnest effort has been put forth to portray accurately the results of this study, no claim is made that every case of anthrax must needs accord with the picture drawn here in all its details. In fact, in reading papers and reports by men who know the subject in other localities, one is impressed with the very material difference which often exists between figures given by them as to the incidence, results of treatment, and mortality of the disease, and similar data on record here. It is fair to say, too, that not a few good men scoff at the idea that the treatment of anthrax is of any avail, and, be it said, we now and then see a patient act in such a way as to make us think their opinion may be correct. However, after following up a considerable number of cases and after talking the matter over with physicians skilled in the handling of the disease, I for my part feel that it is hard to deny that treatment is efficacious in the face of the increasingly satisfactory results which follow the method now in vogue here.

Up until very recent years, there appeared to be no uniform opinion as to the proper method of attacking the lesion. It was cauterized, excised, incised, poulticed with various supposedly curative applications, or left alone, and truth to tell, one mode of procedure seemed about as potent as another and the mortality was rather appalling. Some time in 1916, I first heard of the use in the treatment of human anthrax of the serum prepared by the U. S. Agricultural Department and known as Eichhorn's serum. The method then followed was to combine as wide an excision of the lesion as was practicable, with the intramuscular or intravenous injection of the serum at certain intervals. This was undoubtedly a step forward and was signalized by an improvement in the mortality records. However, there was certainly a question about the propriety of making an extensive fresh incision in this dangerously infected area, and the method was inadequate, too, in that it offered no relief in those cases, frequently seen, where the inflammatory infiltration of the tissues was so widespread as to make an operation out of the question.

About two years ago, Dr. Joseph C. Regan of the Kingston Avenue Hospital, Brooklyn, evolved a scheme of treatment which meets effectively the difficulty in such cases, but which is applicable also to any surface anthrax lesion. He discards entirely the cutting and destructive operations, and introduces the antianthrax serum directly into the body of the lesion itself by means of several small injections around the periphery of the eschar. He uses seven to ten c. c. locally once daily and at the

same time administers twenty to forty c. c. intramuscularly, or intravenously, if the bacillus is found in the blood. At Bellevue Hospital, where this idea has been put into effect in a routine way, they have not been so conservative, for there they have used the serum intravenously in all cases, and have repeated the doses locally and in the vein every four hours for several days at a stretch, without, so far as my knowledge goes, any serious or even especially unpleasant consequences. The results, though, have been no better than at Kingston Avenue.

Let me say, in conclusion, that practically all the cases this year have been treated by this method; furthermore, they have been as serious as any I have ever seen. Then let me ask you to call to mind the figures on recoveries and deaths for the year, quoted at the beginning of this paper, and to compare them with the figures for the preceding years. When you have done this, I believe you will agree that if we have not attained actual perfection in treatment, we are at least making progress toward a happy solution of this serious problem.

X RAY TREATMENT OF EPITHELIOMA WITH THIN FILTER.

BY JOHN REMER, M. D.,
New York,

AND W. D. WITHERBEE, M. D.,
New York.

Filtered x ray, from the viewpoint of dosage, requires only twice the time for a given number of skin units at full distance as at half distance, whereas in unfiltered dosage four times the time would be required to produce the same effect. This was exemplified both biologically and by pastille in a recent article in the *NEW YORK MEDICAL JOURNAL* (1).

The results in the treatment of basal cell epithelioma are the most striking and encouraging of any of the cancerous lesions, the reason being that basal celled epitheliomata are localized lesions and not metastasizing until very late in the disease, if at all. However, cases that have been allowed to go without treatment until the disease is rather extensive, invading mucous membrane and showing marked induration, do not always do well with routine unfiltered treatment. This applies more particularly to the ulcerated type of epithelioma. It is in this class of cases, as well as in recurrent nodules, that we have used the thin filter. The lesion and from a half to three quarters of an inch of surrounding skin should be subjected to radiation. The rest of the surface must be protected by lead foil, a window being cut in the lead foil to conform to the conditions and shape of the growth.

A filter of one quarter of a millimetre of aluminum is used, the factors for treatment being a six inch spark gap, five milliamperes, ten inch distance, with a time varying from three to seven minutes (one and one half to two and one half skin units), depending on the severity of the case.

While our work has been done with one quarter of a millimetre of aluminum, we consider this

purely arbitrary, as from one quarter to three quarters of a millimetre of aluminum may be used, provided one and one half to two and one half skin units of filtered ray are obtained. Although the number of cases thus far treated with a thin filter have been somewhat limited, and the results obtained are not of long standing, we are using this method in those cases that do not do well with the routine unfiltered method.

The advantages of filtered x ray over the intensive dosage of unfiltered x ray are: 1. The filtered dose enables one to repeat the treatment in from three to four weeks, preferably three weeks, without causing any degree of local reaction. 2. These treatments at short intervals should produce more favorable results owing to the direct action of the ray on those cells which are undergoing mitosis. In other words, the action of the x ray on embryonic cells is dependent on the principle that the cells during certain phases of mitoses are easily destroyed by moderate amounts of x ray. Also, as the cells are constantly undergoing mitosis, it seems reasonable that more cells will be found in the sensitive phase and destroyed by the ray when applied at more frequent intervals. 3. The size of the dose in filtered x ray is correspondingly less than the unfiltered and would tend to produce less severe reactions, and consequently less danger to the eye or any other sensitive mucosa. 4. This method is applicable for use with the smaller (2 kw.) machine, which is commonly used in superficial or unfiltered treatment.

SUPERFICIAL AND DEEP ROENTGEN DOSE ESTIMATION.

Abstract of Several Lectures.

BY WILLIAM H. MEYER, M. D.,
New York,

Director, X Ray Department, New York Post-Graduate Medical School and Hospital.

Many methods of superficial röntgen dose estimation have been devised, lengthy descriptions of which exist in medical literature and will therefore be omitted here. However, three important facts, if not faults, common to the several radiometers are: First, that they indicate the local skin erythema reaction only, and give no clue to either the subcutaneous or true biological effect; second, that the erythema reaction is measurable with a reasonable degree of accuracy only when that particular ray quality (penetration) is employed for which the particular instrument was graded; third, that none of the meters indicate the erythema reaction when variable filter thicknesses are employed.

A table (Fig. 1) is here appended giving the approximate values of several of the most popular radiometers. However, at the risk of repetition, it is to be remembered that the higher the penetration, or the stronger the filtration, the greater is the necessary radiometer reading in order to produce an

erythema; and conversely, the lower the penetration (below that for which the particular instrument was devised), the lower the numerical reading.

For average radiographic purposes with unfiltered rays, the formula $\frac{A \times V^2 \times T}{D^2} = I$ is quite satis-

factory. To be sure, some variation will occur at the extremes of penetration, due to change in reaction of the silver salts with rays of varying wave length. On the other hand, this formula cannot be strictly applied when dealing with pastilles in relation to the erythema reaction. Experience has shown that employing the Sabouraud scale and varying the penetration, for example, with parallel spark backups of four, six, and nine inches, then an erythema would obtain at readings of .8,—1., and 1.2,—tint B Sabouraud respectively.

FIG. 1.—Four comparative radiometer values. In employing the various radiometers it is important to use that tube quality for which the instrument was graded. Only under these conditions are these relative values correct. An example of the variations that will otherwise occur is shown in the last column, where the various readings with a tube of high penetration are given.

A graphic illustration of these variations is shown in Fig. 2. The dose time for an erythema reaction has been calculated for the several backups ranging between two and ten inches, with a fixed skin focus distance of seven and one half inches and with the indicated M. A.

For an explanation of the aforementioned apparent empiricism, one would naturally turn to the various penetrometer measures.

A table of the better known penetrometers (Fig. 3) is herewith appended, arranged as closely as possible to their relative numerical values. In looking over these scales, one notes that the only one of the older methods that associates penetration and intensity is the half absorption rate of Christen. Here the factors are, a, incident intensity; b, one half of incident intensity or the transmitted intensity through; c, various thicknesses of a substance, water in various cm. depths (1), in order to show the thickness necessary to cut the intensity in half. In other words, the cm. depth of water necessary to absorb fifty per cent. of the incident beam.

I prefer and employ a fixed thickness of substance, usually one mm. aluminum, and determine the absorption percentage under varying conditions of penetration and filtration. This is accomplished with two rotating (or sliding) röntgen opaque discs revolving concentrically, one about one inch larger than the other. The larger is about three inches in diameter and has a half open section cut in the periphery; the smaller has only a quarter section removed. These are made to rotate (or slide) in such a way (the smaller at one half the time of the

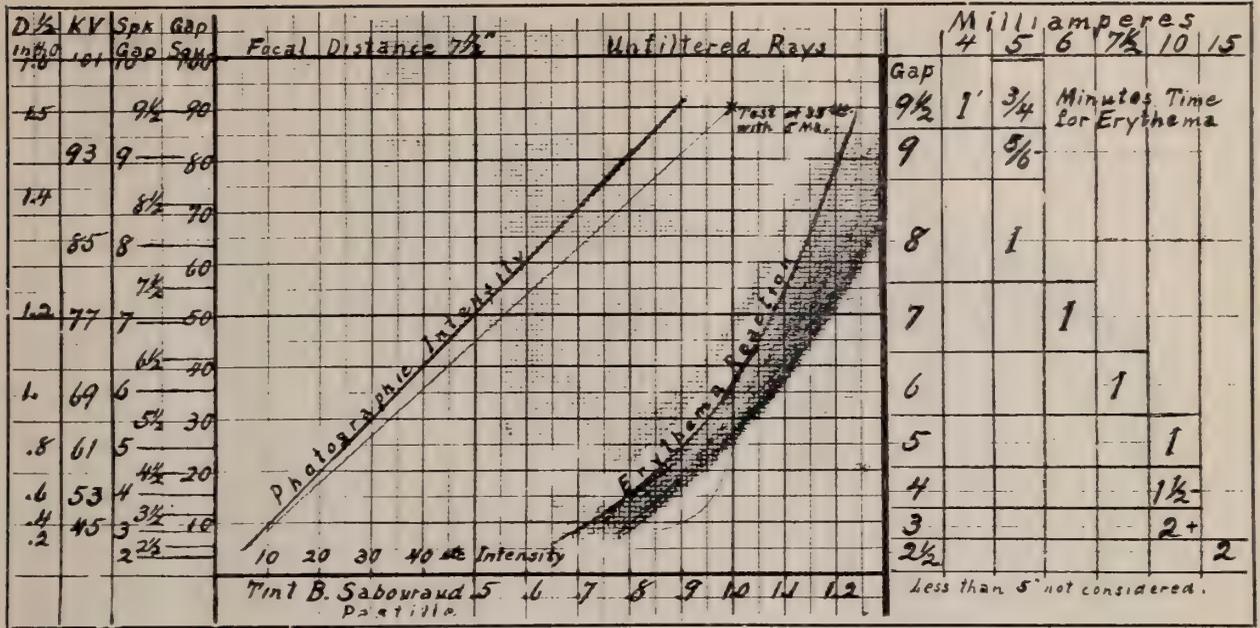

Fig. 2.—Photographic and pastille intensity vis erythema reaction. In the first vertical column will be found the half absorption rate of Christen as compared with the kilo volts in the second column, and the parallel gap in the third column; the square of the gap is shown next to the diagram. Along the bottom of the diagram the relative intensity values are given. The oblique line represents the variations in photographic intensity, according to the rule $\frac{A \times V^2 \times T}{D^2} = I$, in which A equals quantity expressed in milliamperes, V equals quality expressed in the square of the spark gap, T equals time, and D equals distance. The curved shaded area represents the zone of erythema reaction in relation to the penetration and intensity, but with the latter graded according to the Sabouraud scale. In the last columns, the milliamperes and minutes time for an erythema reaction with unfiltered rays and various backups are given calculated from the chart. These figures the author believes the maximum with which present day tubes should be taxed, and then only when good cooling conditions obtain.

larger) that during a full continuous exposure under the outer disc, a graded exposure from 0 to full time occurs under the inner disc. The percentage of absorption for any substance of a given thickness can thus be determined. Fig. 4 shows the author's penetrometer or absorption meter with a sketch of the result obtained with a tube of medium penetration. We can also gain a rough idea of the absorp-

equals the absorption for the given thickness of substance.

Notwithstanding that secondary ray effects play a part in the transmitted intensity, and though the character of the ray be altered by filtration, it still

Instrument	Spark Gap in Air Inches below points	Kilo-Volts secondary	Bauer mm sheet lead	Benoist mm Al. vis Ag.	Benoist-Walter mm Al.	Wehnelt	Walter mm Pt.	Christen d 1/2 in H2O	Absorption % in 1 mm Al.-Meyer

Fig. 3.—Comparative penetrometer values.

tion rate with the present day radiometers. If, for example, we place one Kienbock strip or Sabouraud pastille over a mm. thickness of aluminum, and another strip or pastille under the aluminum; after exposure at standard distance we would have the incident dose on the upper and the transmitted dose on the under strip or pastille. Thus we can say that the incident dose minus the transmitted dose

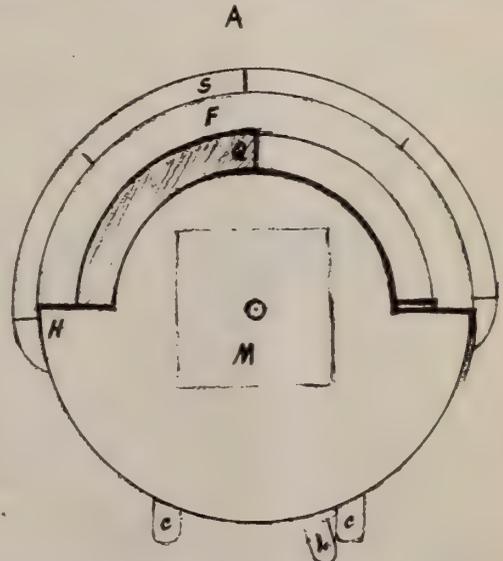

Fig. 4.—A.—Author's absorption penetrometer. A schematic illustration of absorption penetrometer: S, Graded sector, to read in absorption percent; F, fixed segment of one mm. aluminum; H, rotating disc with half section removed from periphery; Q, disc rotating at half time of H with quarter section removed from edge; M, operating mechanism; L, starting lever; c, clamps.

remains a fact that the absorption as indicated by a mm. thickness of aluminum, when taken in conjunction with the several radiometer readings, gives a close index of skin tolerance or the erythema dose.

Due to the difficulty of obtaining standardized

materials of continental origin during the war, the author constructed his own radiometer, using carbon velox paper. The standard tint was graded in one tenth erythema dose, using unfiltered rays with a tube backup of six inches, the maximum tint equivalent to three times an erythema reaction.

B

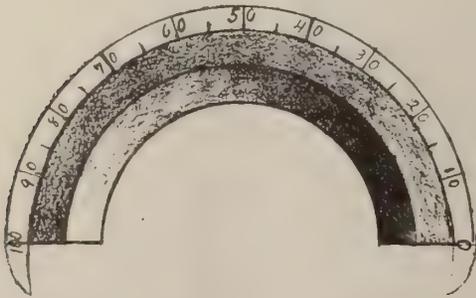

FIG. 4. B.—Author's absorption penetrometer, presenting a sketch of result of test with a tube showing 50 per cent. absorption in one mm. aluminum. The outer segment of even shade is the uniform exposure obtained under one mm. aluminum. The graded shaded inner segment has been produced by the revolving double discs allowing a graded exposure. Exposing from full time at 0—to nothing at 100. Where the shades of the two segments match a direct reading of the absorption percent can be obtained N. B. Any thickness of any desired substance can be substituted for the one mm. aluminum above used.

The double strip readings were used to determine the absorption percentage. The instrument was so constructed that a direct reading of the total cumulative absorption was possible.

The principle involved can be illustrated as follows: If we ray through a filter of three and one half mm. of aluminum with a tube backing up a nine and one half inch parallel gap, until a photographic strip shows the equivalent of $10\times$ Kienbock; then a second strip under a mm. of aluminum (both immediately under the first strip) would register $8\times$. (Fig. 5.) Further; if we accept the $10\times$ as standard for surface dose measure and call it an incident dose of one hundred per cent., then the

rate is still twenty per cent. However, if, as mentioned above, we accept the $10\times$ as standard representing one hundred per cent. surface intensity, then the difference between $16\times$ and $20\times$ in the second example will represent a total cumulative time absorption of 40.

It will be shown that an erythema reaction requires a total cumulative dose time absorption of over fifty per cent.; thus, in this particular example, the uppermost strip must record over $25\times$ and the lower strip over $20\times$, so that the total cumulative absorption in one mm. aluminum exceeds 50.

If we study the varying absorption with tubes of varying penetration, as illustrated in Fig. 5, and again the altered absorption, when using different filter thickness as illustrated in Fig. 11, then one will realize the futility of surface dose measurement and the advantage of the far more accurate dose estimation by total cumulative absorption.

It has been stated that the erythema reaction is indicated by one tint B Sabouraud only when unfiltered rays with about a six inch backup are used. Under these conditions, the absorption in one mm. aluminum approaches fifty per cent. of the incident beam. It will also be seen that with a softer tube, the absorption rate rises, and that less than a pastille dose is required to produce an erythema. Again with hard and, above all, with filtered rays, the absorption rate decreases, whereas the number of pastille doses necessary to produce a skin reaction increases markedly. The fact to which I wish to call attention here is that if one multiply the absorption in one mm. of aluminum by the number of unit pastille doses necessary to produce an erythema, the total cumulative absorption in the first mm. thickness of aluminum invariably approximates 50 .¹

To be sure, this percentage should be somewhat higher when strongly filtered rays are employed, since with such rays the transmission through a

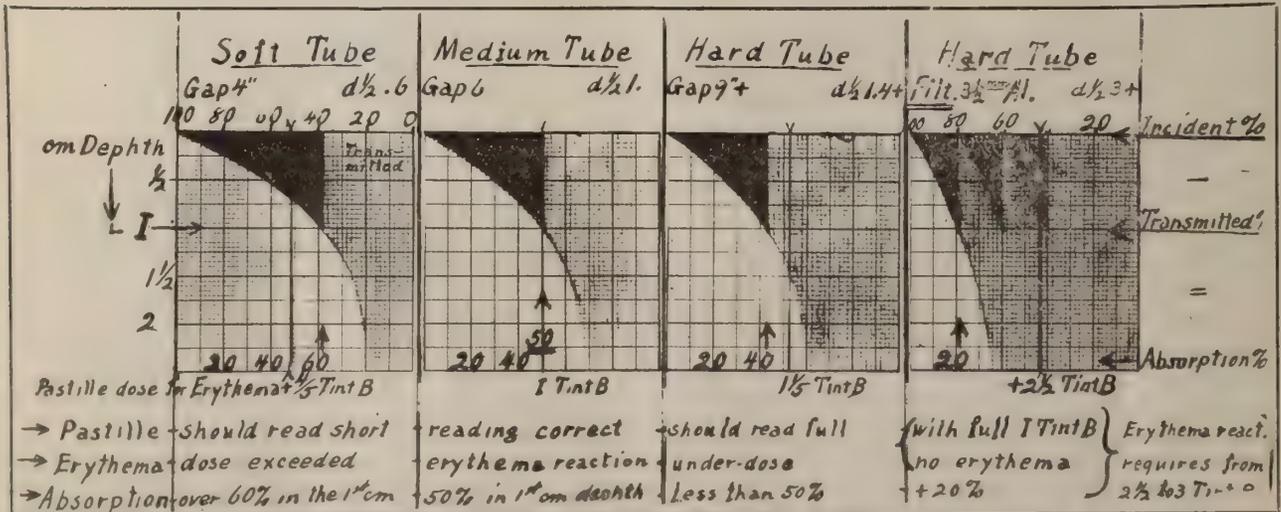

FIG. 5.—Schematic illustration of the absorption in the first cm. depth of tissue in relation to pastille dose and the actual erythema.

transmitted dose through one mm. aluminum equals eighty per cent. and the absorption equals the difference, or twenty per cent.

If we ray further until the strip over the one mm. aluminum shows $20\times$, then the strip under the mm. will register $16\times$. To be sure, the absorption

given thickness of substance is more uniform, whereas the maximum absorption in the superficial layers is most pronounced with soft unfiltered rays.

¹An indifferent skin surface is here suggested, that is, the skin of the back or an extensor surface. The skin of the face, neck, axilla, groin, and flexor surfaces generally being more sensitive.

A graphic illustration of the absorption rate with tubes of varying penetration, along with the pastille dose necessary to produce an erythema, will be seen in Fig. 5.

Experimentally and in practice, it is a fact that if to human skin we give the pastille doses with the backup and filtration indicated in Fig. 5, an erythema and epilation will invariably result.

The successive steps in the line of reasoning thus far are:

1. The assumption that the absorption of one mm. aluminum is practically equal to the absorption in one cm. of water, and this in turn is approximately equal to the absorption in one cm. of human flesh. Thus the absorption in one mm. aluminum is roughly equivalent to the absorption in one cm. of human flesh² (2).

2. With unfiltered rays and a medium tube, a pastille dose delivered to the skin will result in an erythema and temporary epilation (Fig. 1), as well as checking the function of the sebaceous and sweat glands.

3. The pastille dose achieved with a medium tube and unfiltered rays shows a half absorption of fifty per cent. in one cm. of water (3). This in turn is roughly equal to the same absorption in one mm. aluminum³ (Fig. 3).

4. An erythema will result, irrespective of penetration or filtration, providing the total cumulative absorption exceeds 50 in the first cm. of flesh as measured in one mm. of aluminum (Fig. 5).

5. Since, irrespective of penetration or filtration, a cumulative time absorption of over 50 in one cm. of human flesh produces an inhibitory action on cells of special function, then it is reasonable to assume that, irrespective of depth, the metabolic process of radiosensitive structures should be subject to inhibition when the total cumulative time absorption per cent. per cm. exceeds 50.⁴

²I do not wish to affirm that the absorption rate in the first cm. depth of tissue, as measured in one mm. aluminum, is an absolute measure of skin or biological reaction. As a matter of fact, the absorption in the half cm. is a better guide, and the absorption per mm. depth of tissue still more accurate. However, for average purposes, the method employed has proven sufficient.

³If one will study the ever changing absorption in the first cm. depth, as measured in one mm. aluminum, even with fixed backup, but employing various filter thicknesses (Fig. 12), one will realize that no such single rule as originally devised by Wetherbee and

Remer, i.e., $\frac{A \times \sqrt{x} \times T}{D}$ = I can apply, excepting in a single specific

instance. In their more recent communications, this has perhaps inadvertently been admitted by the injection of multiple exceptions with varying filter thicknesses.

That the dose time for an erythema reaction is shortened by supposed increased penetration with unfiltered rays, is due to the fact that the whole heterogeneous ray complex is increased with the surface intensity, varying roughly as the square of the parallel spark backup. However, as shown in Fig. 2, this cannot be unconditionally accepted as the measure of skin reaction, since the absorption rate varies with change of backup. Therefore, surface dosage is no more an index to erythema reaction than either of these is to the biological reaction, unless considered in relation to absorption.

⁴From some fifteen years' experience, I have arrived at the following conclusions: a. That with unfiltered rays, an erythema will result with a dose time absorption of fifty per cent. in the first cm. of flesh as measured in one mm. aluminum. b. That with filtered rays, the dose time will have to be continued until the cumulative absorption in the first cm. approximates sixty per cent. c. If a similar reaction is desired in the deeper seated structures, the cumulative absorption will have to be somewhat increased because of the increased filtration produced by the overlying tissue thickness.

With due respect for the opinion of such investigators as Belot (7), Spéder (8), and Régaud (9), there are others, myself included, who believe that with sufficient dosage, very similar skin reactions can be brought about, be the radiations soft or hard, filtered or unfiltered, röntgen ray, or radium.

In drawing conclusions from measured absorption, it must be remembered that the higher the penetration and the stronger the filtration, the less the superficial absorption. Therefore, when comparing reactions with soft and hard rays, the unit of measure will have to be exceedingly small, before offering too definite an opinion.

6. a. Experience has shown that less than a pastille dose with unfiltered rays to the skin is stimulative in action. (For mild stimulation, I employ one fourth to one third pastille dose, and for very strong stimulation from one half to two thirds pastille dose. These represent respectively a total cumulative absorption of fifteen to twenty, and twenty-five to thirty-five per cent. per cm. depth of tissue.)

b. The pastille dose with unfiltered rays (representing approximately fifty per cent. total cumulative absorption in the first cm.) is the erythema dose and generally recognized as of passing inhibitive action to cells of special function.

c. A double pastille dose with unfiltered rays has been found necessary to produce a more profound inhibitive action with retrogression (McKee and others); this in turn equals a total cumulative absorption of about 100.

d. Complete destruction with necrosis will occur with from two hundred to two hundred and fifty per cent. total cumulative absorption.

The lethal dose in malignancy has been variously estimated at from one and one half to four skin doses. I believe that the total destruction of malignant tissue should be the aim; not allowing some cell elements to remain to light up at a future date. The latter has all too frequently been the case where momentary brilliant results have been obtained.

To summarize röntgen dosage in relation to the total cumulative absorption per cm. depth:

Action.....	Stimulative		Inhibitive		Destructive Total
	Mild	Strong	Mod.	Prolonged	
Total cum. absorption per cent. per cm. depth.	10 to 20	25 to 35	50 to 60	100 to 120	200 to 250
Biological effect	Increased metabolism Passing		Anabolic Prolonged		Catabolic
Period.....	Repetition of dosage necessary for continuation of effect.		Possible recovery in from one to three years.		Ulceration and necrosis. Slow to heal with scar tissue formation.

Since under varying degrees of penetration and filtration and for deep therapy, the present day radiometers do not indicate the various reactions; and since the total cumulative absorption per cm. depth does, then this is the logical method of dosimetry.

Thus, whether the lesion be superficial or deep, the factors to be determined are: First, whether stimulation, inhibition, or destruction is indicated; second, what quantity and penetration, filtration, distance and time, and in deep cases what number of areas for crossfire are necessary to bring about the desired total cumulative absorption at the site of the lesion; third, protection of normal tissues as far as possible with special attention in deep cases to normal skin tolerance. Every means at our disposal should be employed to arrive at a correct diagnosis with a definite notion as to the location and extent of the lesion. It must also be remembered that along the path of a single beam of x rays, various reactions may occur. Thus we may have destruction with necrosis at the skin surface; immediately beneath this a strong inhibitive reaction may

occur, while but a little deeper we will have a stimulative action diminishing as the depth increases.

Again, at the same plane, all three reactions may occur, depending upon the radiosensitivity of the structures involved. From observations too numerous to mention here it can be said that organs of highly specialized function, tissues of embryonal type, young or rapidly growing structures, multiple small cells with large nuclei and rich in chromatine, are all highly radiosensitive.

These facts are so closely associated with high atomic weight and specific gravity, that a chart is herewith appended (Fig. 6), and it appears to indicate that the higher the atomic weight and specific gravity of a living structure, the greater is the radiosensitivity.

FIG. 6.—Chart showing the relation of radiosensitivity and specific weight. Tissues and organs in order of approximate radiosensitivity are: Testicle, ovary, choroid, thyroid, intima of blood vessels, lymph glands, epithelium of mucous membrane, hair follicle, glands, and epithelium of skin.

It remains then to determine with what penetration and filtration and with how many areas the desired total cumulative absorption can be brought to bear. As far as superficial conditions are concerned, the chart in Fig. 5 speaks for itself, in so far that in lesions so located, the unfiltered or weakly filtered ray is indicated. The more superficial the disease, the softer the ray quality. I always employ, however, one sixteenth inch of pressed fibre as a protection from heat, light, corpuscular and the extremely soft rays.

Our greatest difficulty has been with the estimation of deep dosage, and rather than accept mathematical conclusions relative to absorption at various depths, and with due respect for the elaborate studies of Guillemot (4) along the same line, I have preferred my own data drawn from experiments conducted on principles similar to those described by Gaus and Lembcke (6).

In measuring the half absorption rate by the photographic method, as illustrated in Fig. 4, the penetration appears almost double that shown when using either the pastilles or photographic test strips by means of the phantom, as illustrated in Figs. 7 and 8. There is a very close association between the half absorption rates of Christen (1 and 3) and those shown in the table of Guillemot (4). It is quite likely that secondary ray effects may be

responsible for the increased absorption shown in the upper strata in the method employed by me. The question is, Are not such secondary rays effective in the body as well? (5). Be that as it may, the area selection as practised here shows results, whereas a lesser number of areas of crossfire, as might be indicated by the half absorption rate, has in our hands failed.

The method of carrying out these experiments is illustrated in Figs. 7, 8, and 9. In Fig. 7 waterproofed photographic strips (or pastilles) are arranged vertically at cm. spacings, and the whole submerged in water. After exposure the intensity of each is determined, from which a transmission curve is constructed, such as those illustrated in Fig. 8. The result of such an experiment is illustrated in Fig. 9. Here the Kienbock strips used lend themselves well to photographic reproduction. The distance, depth, and transmission rate will be noted in the various columns. In this manner the best ray quality and filtration is determined, which gives the maximum absorption at the various cm.

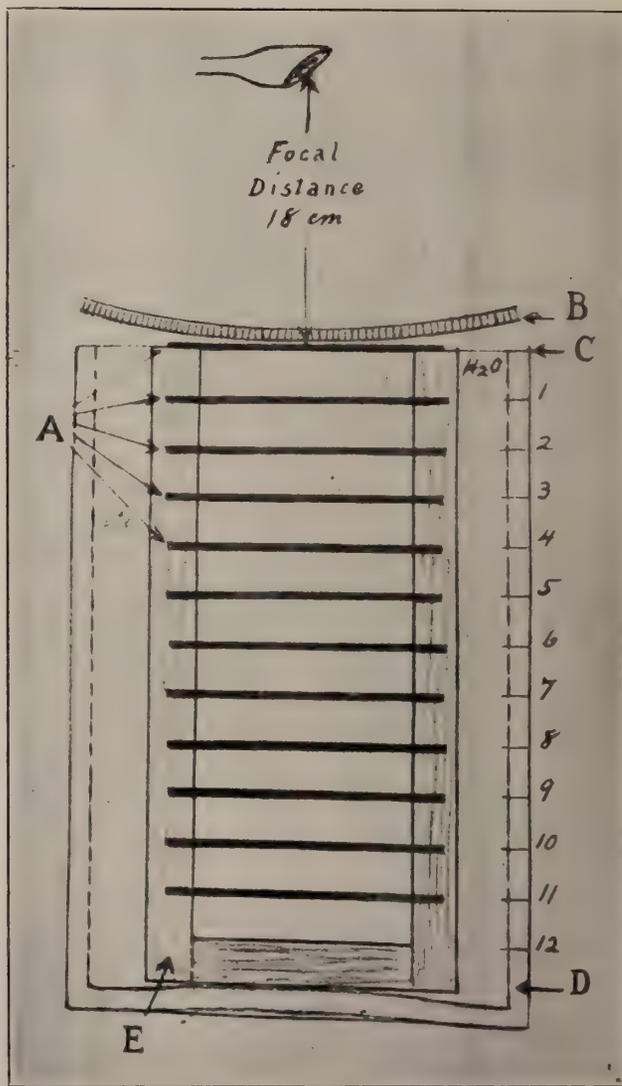

FIG. 7.—Measuring transmission (schematic). E represents a wooden frame so notched as to receive the Kienbock test strips, indicated by the letter A. Each strip is one centimetre lower than its immediate predecessor. This frame is submerged in water contained in the jar D; the water at a level with the uppermost strip and in close apposition with the filter B.

depths. From many such experiments, the composite results of which are shown in the charts in Figs. 10 and 11, the final chart in Fig. 12 has been compiled. On the surface the pastille may be used, though the absorption in the first cm. is the surest guide. Below the surface, be the depth the first or the tenth cm., the absorption is the dose measure.

I have taken as standard the strong inhibitive dose as represented by a total cumulative absorption of one hundred per cent. In the first two vertical columns of the chart in Fig. 12 will be found the skin focus distance and the depth below the skin surface in cm. and inches. In the third vertical column the most desirable filter thickness is given, with a tube of the indicated hardness; the absorption rate will be found in the fourth column, and in the last four columns, the number of areas for multiple crossfire will be found. (The oblique line roughly indicates the dividing line between, under and over skin reaction. Thus in the third column we expect an erythema.) Using a hypothetical example, if we had a lesion situated at about the

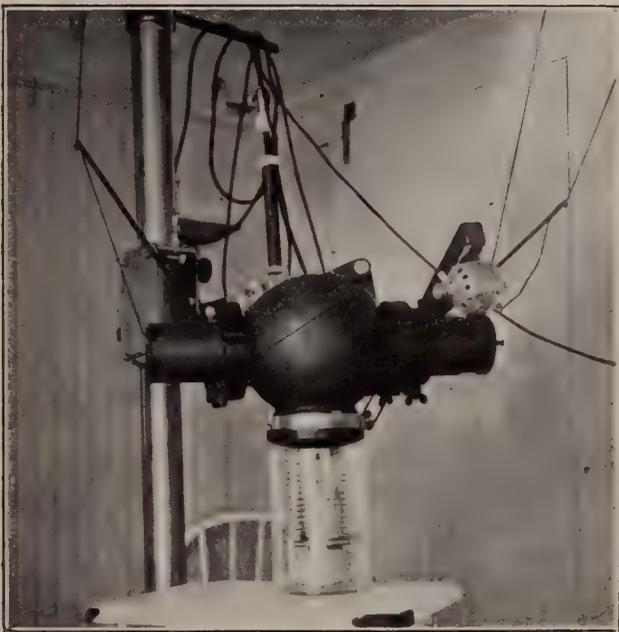

FIG. 8.—Measuring transmission (actual testing conditions).

fourth and fifth cm. depth in which a strong inhibitive action was desired, yet a skin reaction was not justifiable, then the most desirable filter thickness would be three to four mm. aluminum and the number of areas with maximum safe dosage would be five to six, found in the double pastille dose column.

It is evident that each area must be large enough to include the whole of the lesion, and the direction and depth reasonably correct. The most frequent causes of error with a technic as accurate as the foregoing, are incorrect diagnosis, and faulty posture; thus failure to obtain the proper total cumulative absorption. Fortunately, I have had the opportunity to put the foregoing to practical test and am ready to report numerous cases:

1. As illustration of superficial dose estimation by absorption, one hundred consecutive cases of

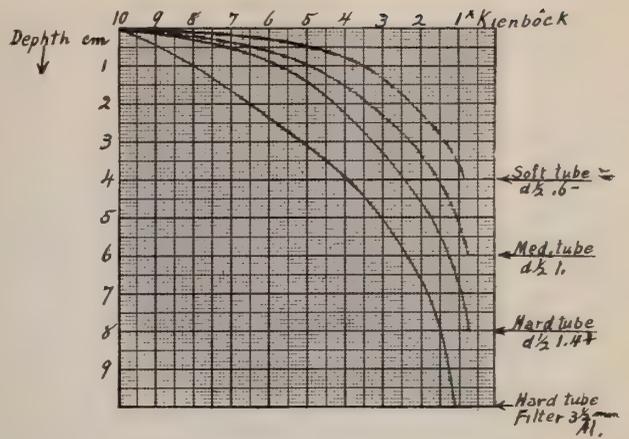

FIG. 9.—Transmission curves, with varying penetration and with filtration.

epithelioma and rodent ulcer and chronic ulcerating warts and moles (malignant) successfully removed within a period of one to two months following a single application, with but a single recurrence within a period of three years. 2. As illustration of deeper dosage estimation, one hundred consecutive cases of hyperthyroidism and thymic enlargement, with clinical cessation of symptoms in every case. 3. As illustration of deep seated conditions, twenty-five consecutive cases in which complete amenorrhea was produced in a single sitting. Also a similar number of cases of splenomegaly, lymphoma (Hodgkin's disease), etc., with disappearance of the mass in from one to three months.

Other conditions treated and the classification employed are as follows:

1. Mild stimulation: Superficial skin lesions—

FIG. 10.—Transmission rate without and with filtration (Kienböck test strips). The result of two experiments carried out as described and shown in Figs. 7 and 8. Experiment A, with no filter. Experiment B, with filter. The two central columns are the Kienböck strips; the columns on either side of the strips represent the approximate Kienböck readings; the column to the extreme left, the strip focus distance; the column to the extreme right, the centimetre depth of the strips in water. The comparative tints of the transmitted intensity of both tests is clearly shown; the marked improvement with the filter is quite evident.

FIG. 13.—Table of deep dosage estimation and area computation.

tion in one cm. of flesh as measured in one mm. aluminum with present day apparatus, the following conclusions are justifiable:

That a total cumulative absorption percentage of thirty-five or less is stimulative in action (increased metabolism).

That a total cumulative absorption of plus fifty is mildly inhibitive in action to radiosensitive structures.

That a total cumulative absorption of one hundred produces strong inhibition with retrogression.

That a total cumulative absorption of plus two hundred is catabolic in action with retrogression and necrosis.

That any of these effects may be produced at will within the first half cm. depth of tissue.

That as a rule only the first three reactions can be brought to bear below the first cm. depth, without producing, at the same time, total skin destruction. Therefore, with wide spread, deep seated lesions, besides stimulation, an inhibitive dose is frequently all that can be hoped for.

From these conclusions I wish to go on record as stating, without reservation, that any superficial malignancy can be destroyed; and that with the early

cases a far better cosmetic result can be obtained with radiant energy than with any other procedure, and this without pain or inconvenience and frequently within one month following a single treatment; and that, when properly applied, recurrence within three years is rare. Therefore, any case of

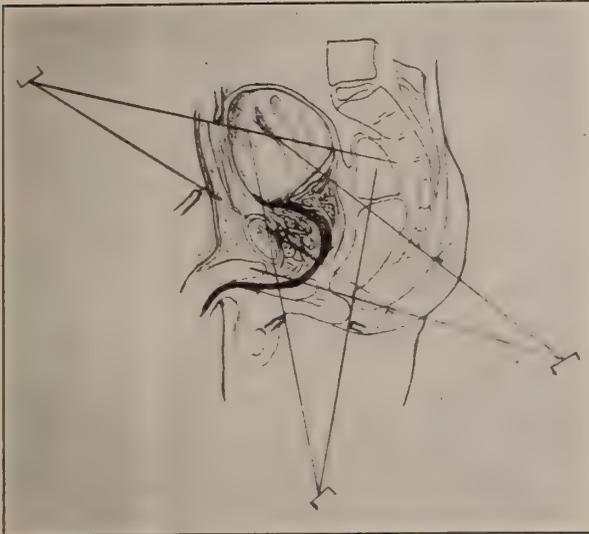

FIG. 14.—Three large and satisfactory areas for crossfire of the pelvic viscera. It will be noticed that each area is sufficiently large to include practically the whole of the true pelvis.

threatened superficial malignancy should receive the benefit of such procedure, and this in preference to the knife, caustics, freezing, or any other method, since our most difficult cases have been those subject to such previous interference.

On the other hand, as far as I am aware, in few *bona fide* cases of deep seated malignancy have the patients been reported as having been cured and remaining alive and well for a minimum period of three years. This may partly be explained by the fact that as a rule the radiologist does not see cases of malignancy until every possible surgical procedure has been attempted, and the patient is practically moribund when presented for treatment. There is not the least doubt that in many cases of malig-

nancy the patients have been improved (12). Hemorrhage can be controlled, foul discharge reduced, pain relieved, ulcers made to film over, and occasionally by shrinking and retrogression (13), an otherwise hopeless case may be brought within the pale of operative intervention. Again, experience has shown that both pre-operative and postoperative radiation are indicated.

Though the present outlook in these cases of deep seated malignancy is not over promising, yet I am far from giving up hope in regard to röntgen treatment. The road to complete success appears to lead along the lines above described—not in the excessively filtered, over penetrative and scanty gamma rays (10), for these lack both intensity in quantity (11) and absorption, and, as a matter of fact, excepting perhaps in the hollow organs, nothing has as yet been accomplished with radium that has not been done before with the x rays. Therefore, in apparatus of greater capacity and tubes to stand the output that we may have quantity (14) and penetration plus absorption, lie the future and hope of röntgen therapy.

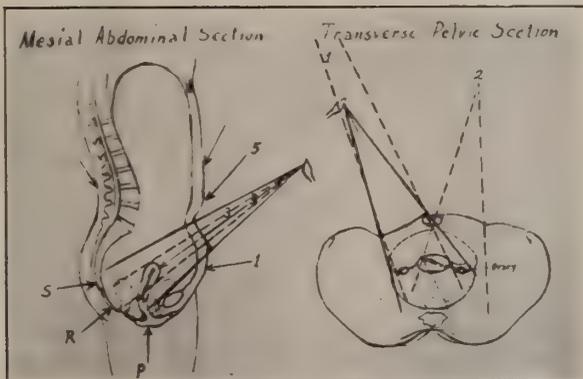

FIG. 15.—Correct and faulty technic. The usual errors that occur by using too small areas, or by incorrect focusing. In the mesial abdominal section the heavy lines from target to patient show the advantage of the large area as compared with the small cone of dotted lines representing a smaller diaphragm or area. The failure to include all the viscera one desires to affect is illustrated by the dotted lines in the transverse section. It will be seen that by incorrect focusing or too great a focal distance even with the same sized diaphragm, certain pelvic organs will not be included in the given exposure.

Duality of the Syphilitic Virus.—Milian (*Presse medicale*, June 19, 1920) believes in the duality of the germ of syphilis. In fact, he thinks distinction of tissues as regards the germ may be pushed still further, i. e., that some of the germs have an affinity for bones, others for the arterial system, etc. To induce tabes or general paralysis it is not sufficient, however, that the germ be neurotropic. In tabetics gummata are not ordinarily seen; leucoplasia, on the other hand, is frequent. Tabes and leucoplasia are affections of the same order, due to a germ of the same nature. Thus, it is not merely the factor of tissue tropism, but also that of special virulence, which make for resistance of the disease to treatment. Inoculation of leucoplasia tissue into the testicle of the rabbit produces lesions similar to those which Levaditi obtained with the blood of cases of general paralysis.

Hospital During the Clinical Congress.*

BY RALPH I. LLOYD, M. D., F. A. C. S.,
Brooklyn, N. Y.

If one gazes, without deviation, at a certain point, there is for each eye a surrounding area within which one is able to recognize colors and objects. Each color has a field of different size; white is the largest, extending 55° above the fixing point, 60° internal, 70° below and 90° external to this same point. Blue has a field somewhat smaller than white, red is smaller than the blue, and green is the smallest field of all. Visual acuity is not the same throughout the field, neither are the functions of the field the same in all parts. A diagram may be made to show how the visual acuity at the periphery is almost zero and increases as we approach the fixing area; so the diagram appears like a high mountain with steep slopes on either side. A formula has been offered to represent the rapid shading off of visual acuity as we pass from the centre toward the periphery. Representing perfect central visual acuity as one, the vision at any degree may be roughly estimated by dividing one by the distance from the centre multiplied by three, one divided by three n : (n equals distance from centre). The functions of the retina in different parts are also of interest and have a direct bearing upon the topic.

The central area is especially fitted for reading and noting fine detail and is practically vision, as it is usually understood. Vision of detail and a good part of color vision are located in the small central area. Without these, one is practically blind as we can easily understand if detail is eliminated from everything we look at and mass vision substituted. To be sure, the individual if afflicted in this way, would not bump into objects or persons as he walked along, even in strange places, but over the centre of the precise place where his vision was directed for obtaining an exact visual impression, would be a vacancy. He would know that large objects were round about him, would know just where to put his feet and where not to, would know whether the sun shone or not but could not read or obtain visual impressions except in mass form. His color vision would be defective also. But if there was a movement at the side, he would be instantly aware that something was going on there and would involuntarily turn his eyes as had been his habit and must be the habit of all mankind, to have the image of the area whence came the movement fall upon the central area, which would, if normal, give him all the detail of the small field upon which the fixing area was centred. Rapidly then, his busy eyes, for even the proverbial bee is no busier, would move around to allow the image of various parts of the part of the room or the floor which was now occupying his conscious effort, to fall in astoundingly rapid succession upon a small but central part of the retina (macular area or area of fixation). After these images have like a moving picture film been passing before the part of the

brain devoted to vision, he will add, as it were, these various pictures together like a mosaic to make a finished single picture or mental image.

The moving picture film is a succession of small but complete pictures; the successive visual impressions are small detailed bits of a large picture which must be added together to get a result, the adding is mental. In this important manner, the moving picture film and the visual impressions differ. Our patient without normal central vision comes now to the end of his day and as the sun goes down, there comes a change. In the dusk of the evening, he sees quite well because vision in dull lights or darkness is mass vision and no impressions of detail are possible. He is under these conditions as good as the next fellow. From the foregoing it is plainly seen that each of the eyes given us is a double organ; divided into a central eye upon which we depend for detail vision and color vision. This part of the eye works best in good light, daylight for instance, and it does not work well in the dark. We can prove that the central eye is normally night blind by a simple experiment. If one will step into a dark room or wait until nightfall for experimenting, and gaze upon a self illuminating watch dial, he will see it dimly. If he turns his eyes slightly to the side and permits this same image to fall upon a part of the retina just a little external to the macular area, the glowing image is clear and distinct. Astronomers know this and tell us that a star is best observed through the telescope by directing the gaze a little to one side of the star they wish to observe, moving the image of the star against the dark background from the night blind macular area over to the night seeing periphery.

The peripheral eye is particularly fitted for noting motion at the side and giving warning of location of things, a most valuable function which we use continually while walking through busy streets, keeping our eye upon the line we are reading, etc. This is called vision of discovery. It works well in daylight but in the dark this part of the eye functions also and does not become night blind. This function in the dark is called achromatic vision. Our patient who lost his central vision, was defective in his color perception and had lost his vision of detail. He got along quite well in the darkness or dull light. The patient who loses his peripheral eye is night blind, cannot protect himself against objects coming at him from the side, bumps into people, but can read, etc.

The retina is made up of rods and cones, the first predominate in the periphery and increase as we proceed from the centre to the outer limit, but the cones exist at the centre, or macular area, to the exclusion of the rods and decrease in number as we go externally. It is conceded that the cones are the organs which give the central eye its characteristics, just as the rods give the peripheral eye the power of vision in dull light and ability to detect motion in either kind of illumination.

Huey and others have studied the action of the human eye and mind in the act of reading and the preceding facts are plain in his conclusions as well as some others. He says the eye appreciates about four letters of average type if held absolutely still.

Another interesting fact is the demonstration that the eye jumps from letter group to letter group in the most amazing fashion and does not naturally remain long in one spot. Steady fixation is not habitual. Reading is done then by letter groups, the main groups being picked out by characteristic form and aid is given by the sense of the sentence already interpreted. Thus in the group of words "The act of reading," no time would be wasted upon the "ing" as the sense of the sentence would indicate that no other termination was reasonable. While the central eye fixes upon about four letters, the contiguous area of the field of vision would give some hint of the form of the letters standing next in line and the area still further out would act as a guide in keeping the jumping eye on the line as it goes rapidly along.

There is one other bit of eye physiology which is of importance to us in discussing or planning instruments for testing various functions of the eye and that is what is known as "phenomena of Troxler." If bright images are held steadily in fixation, some parts will fade and others become bright, and so on. In fact, prolonged fixation without change of field is sure to produce eventually this alternation of supremacy of one part of the image over another, even if the images are subdued.

Graefe was the first one to measure and study the size and shape of the field of vision. In 1855 he mapped out, upon a wall painted black, a series of concentric circles giving the five or ten degree zones from the centre out to 90°, although he used the rectangular method of obtaining these circles instead of the tangential. In spite of the fact that 90° was parallel to the wall and could not be measured thereon, some important facts were soon discovered. Atrophy of the optic nerve produced a narrowing of the field of vision by affecting first green, then red, and finally white, so that the early stages might have a normal sized field for white but a very small one for green.

Various other diseases and conditions affected the field in peculiar ways and were valuable in diagnosis and prognosis. Forster, in 1867, made an instrument with a semicircular arm along which the test object ran, equidistant at all times from the eye. This corrected the error of the Graefe plan. When the flat surface was used, the test object soon got farther and farther from the eye, as it passed laterally and subtending an ever diminishing visual angle, seriously affected the value of the test beyond twenty-five or thirty degrees, according to the distance of the eye under examination from the fixing point. Forster's invention was improved upon from time to time until with the added devices for recording the various points, changing size and color of test object, perfection seemed at hand. The recording surface of the modern perimeter is compressed, as much as twelve times in some, so it happens that the test object will travel on the arc about two inches for ten degrees and one sixth inch is allotted for this space on the recording surface. A ten degree scotoma is indeed a large defect especially near the central portion of the field and it is evident that outlining scotomas is not the function of a perimeter. The perimeter is also

inelastic and permits the approach of the test object from external or internal limit only. The flat surface with test object in the hand of the examiner permits outlining scotomas, especially those near the central area, because of the fact that the test object can approach the defect from any angle and the record made is not compressed but is recorded as large as it appears. Although this distinction in the function of the perimeter and the campimeter is evident, for years the perimeter was used for central field work, but it is now certain that many defects were overlooked.

We might say here, then, that the perimeter is an indispensable instrument for outlining fields of vision for color or white, but the campimeter in some form is indispensable for mapping out defects of the central portion of the field of vision. Bjerrum introduced his screen which is a modification, one might say, of the Graefe flat surface. Bjerrum was aware of the limit of usefulness of the flat surface to the central twenty-five or thirty or forty degrees, according to the distance of the patient from the screen. This screen was a black curtain with concentric five or ten degree circles upon it and was limited as suggested above. Dr. Duane, of New York, modified the screen so the distance from the patient was lessened, but the screen could be raised or lowered to bring the centre opposite the eye of the patient, and the degree markings are placed on one side and squares on the other, so the screen may be also used as a muscle screen. The pins marking the outline of the defect may be inserted from the side opposite to the patient, thus preventing any influence of recording where the patient might observe it.

Haitz in 1907 introduced his charts which were to be observed in an ordinary stereoscope. Other binocular methods had been tried but none so successful or simple as this. The stereoscope was familiar to all but was relegated by most to the position of an entertaining toy. Haitz saw the usefulness and possibilities which others overlooked. He utilized only a ten degree field but each eye could be examined independent of the other, binocular fixation was employed unless one eye was defective, in which case the good eye fixed and held the poor one in position. The perimeter and screen are monocular instruments and if the fixing power of an eye is bad, the eye is unsteady with the expected result upon the record. Haitz charts are made of paper and the recording of the defect necessitated the counting of squares in order to transfer the record to paper for permanency. This slowed up the process and with the unsteadiness inseparable from the hand stereoscope together with the limited field made three unpleasant features.

Dr. Peter, of Philadelphia, soon after this introduced his campimeter which is really a Bjerrum screen brought close to the eye. The available field is about forty degrees, the instrument is easily carried about and may be used with the patient in bed. The defect is recorded upon the campimeter as large as it appears to the patient, and there is no loss of time. It is of necessity somewhat unsteady, as it is held in the hand and is a monocular device.

The blind spot has been known since Mariotte

discovered it in the year 1668, but only in recent years has it entered into field study as an important factor. Coccius showed in 1859 that glaucoma enlarged the blind spot and Leber, 1869, proved its enlargement in tobacco poisoning. But in recent years, it has been thoroughly studied, and blind spot

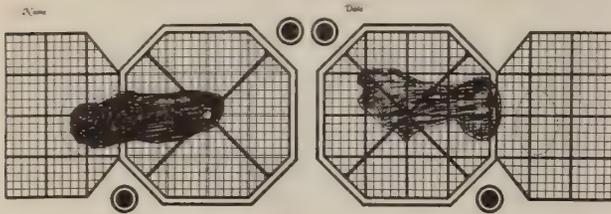

FIG. 1.—Case of old tobacco alcohol scotoma. Vision of O. S. much better than O. D. because fixing area of left eye retains its usefulness. Defect outlined is for red five mm. test object.

studies are now very important in many conditions, especially glaucoma.

It seemed to me that there was room for another instrument. The stereoscopic or binocular method appealed strongly because of steady fixation, indeed, it seemed the only way in the many important cases with impaired fixation in one eye. All kinds of central scotoma, amblyopia, exanopsia, cases of traumatic macular changes, and others, made a group of cases which any monocular method seemed not to fit. Mindful of evils of retinal fatigue (Troxler's phenomena), it seemed necessary to record the outline of the defect upon the surface of the instrument and save time and avoid weariness. The stereoscope should have a field large enough to permit blind spot studies as well as studies of the central area and it should stand upon a table and permit the patient to seat himself comfortably and eliminate all motion possible. Another idea was included to avoid retinal fatigue; the avoidance of strong contrasts and bright colors in laying out the diagram of the campimeter.

The negative fixation point of Haitz was incorporated because there is no doubt that this plan tends to encourage relaxation of accommodation and give true impressions of distance. Furthermore, the central circles were decentred outward so the image when fused is that of a large circle placed somewhat farther from the eye than the surface of the chart and a smaller circle yet farther off, but within the first circle. Thus a sort of psychic invitation to gaze into infinity is created. The degree marks are corrected for each degree as we pass from the fixation point to the periphery. It is true that the deviation from a fixed value is not great until we reach the vicinity of the blind spot, but there is no reason why we should not have accuracy when it is within reach. The location of the average blind spot is indicated upon the surface of the apparatus and the figures of Dr. H. S. Gradle of Chicago are used in locating the position and size of this standard normal field defect. His figures seem altogether the best at hand because of the excellent method used in obtaining them and the fact that his examinations were made in a larger number of cases than any other student of the blind spot.

The first efforts were made with an ordinary wide angle stereoscope and, while they were successful,

there were certain annoying features which were most appreciated when absent. To avoid color diffraction, unsteadiness, and to gain a larger field, I appealed to Mr. Max Poser for a wide angle stereoscope which would cover eleven degrees above, below, and internally, and twenty degrees externally. He responded with an instrument which was optically perfect, included correction for vertical and lateral muscular errors of the patient, and had a generous field of twenty-five degrees above and below the fixation; the usual eleven degrees internally, and thirty-five degrees externally. The instrument stood upon the table, allowing the patient and examiner to seat themselves, doing away with all motion possible. The name given to the instrument is self-explanatory, the stereoscopic campimeter slate. I am fully aware of the fact that so many instruments have been hurled at the physician that, in order to survive, it must overcome prejudice and pessimism. To speak of an instrument as "just another instrument" is usually sufficient to consign it to the limbo. For many years, oculists have endeavored to do what cannot reasonably be expected of the perimeter. This instrument has sharp and narrow limitations, and we are indebted chiefly to Dr. Luther Peter for calling attention to the fact that for years medical men have tried to do the impossible and map out central and paracentral defects on the perimeter.

There is no one instrument which will meet the demand of every case, but we ought to eliminate this ancient error. The stereoscopic campimeter slate is not adapted to work on peripheral fields. It is especially fitted for work in the central and paracentral areas, blind spots and fixation areas. As each field may be examined independently of the other

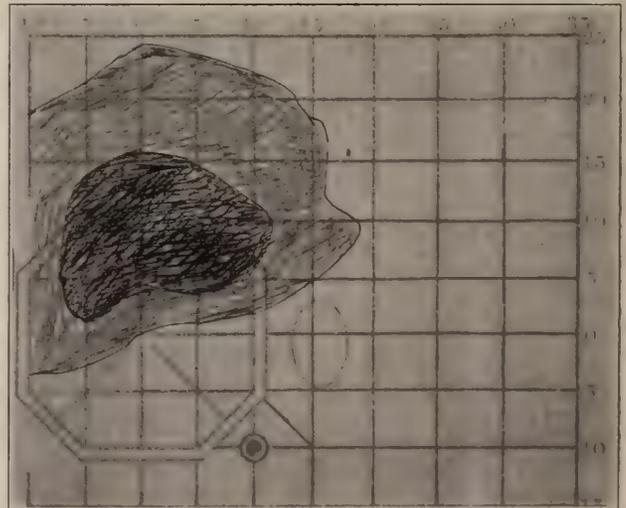

FIG. 2.—Central scotoma caused by wood alcohol. Dark central area is defect for three mm. white test object and lighter area surrounding is defect for three mm. red test object. Vision of this eye, right, 4/200. Apparently, the macular area has escaped but the fixation has been eccentric, thus accounting for the impression.

but with binocular fixation, steadiness and accuracy are evident. If one fixation area is affected, the good eye will fix and hold the one not able to fix by itself, and each field may be investigated. (Fig. 1.) The octagonal figure helps the poor eye to no small degree to cooperate with its fellow. This class of

case is probably the most common of the various kinds of field defects. A small lesion of the macular area of one eye is immediately noticed and the patient is examined by the usual methods and it is found that he cannot read 20/20 and a glass does not improve. The ophthalmoscope will not reveal

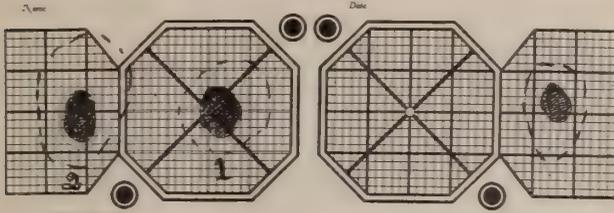

FIG. 3.—The difference between location of blind spot of 1-ft eye when the right eye fixes (marked 1), and the location of the same blind spot when the left eye fixes (marked 2) is the accurate measurement of the deviation, 15° which is about one half of the amount recorded by the perimetric method.

anything in cases in which the deeper layers of the retina, the nerve fibres or tracts or brain are involved. Are we to stop here with a diagnosis by exclusion? Too often we have done so. The lover of the concrete and absolute will deride any evidence which he cannot see himself or place his finger upon. (Fig. 2.)

We can outline these defects day after day and, if the outlines agree, we have evidence of great value. If the lesion is in the choroid or superficial layers of the retina, some will say there is no need of indirect evidence. But there are quite a number of cases of eye injuries in which the macular changes are slight, indeed—apparently negligible. But by the stereoscopic method, it is easy to show that a small central defect, even a degree, will have a serious effect upon the vision. Again, there are cases in which the diagnosis between glaucoma and optic nerve atrophy or arteriosclerosis is so close that every bit of evidence is of value. But of far greater value in glaucoma is the prognostic influence and suggestion for operative treatment in glaucoma cases, of the fingerlike scotomas which reach out from the blind spot, reaching with sinister effect upon the all important few central degrees. It would seem that too often we have felt that the vision will remain good as long as the field is of fair size. This is a delusion, for, independent of the peripheral field, to a great extent, a scotoma may develop from the blind spot and affect the macular area and, in some cases, the process may even be reversed and proceed from the macular area to the blind spot. In the early stages, these defects are relative and detectable only by small test objects and when the examination is most carefully done.

If we find our patient's poor vision is due to kidney disease or diabetes, we are likely to be satisfied without going further. It is not unusual to find a nephritic patient with white spots in both macular areas, but the vision of one eye much worse than the other. Examination will show a central scotoma in the one and not the other. Diabetic cases are similar. Acute changes in either type of case attended by edema of the retina is destructive of vision. Elderly patients often appeal to us, stating that a black spot is before one eye. If these patients are watched the usual history is that

the process goes on to marked change in the retina in the macular area with very poor vision. The blood vessels show the changes of arteriosclerosis and the finer arteries are particularly angular and tortuous. Usually the second eye becomes involved, but not infrequently the processes resulting from general vascular change abruptly end the patient's life. In the early stages, when ophthalmoscopic evidence is scant, we can obtain evidence of a relative scotoma near the fixing point. Later, ophthalmoscopic evidence may be more pronounced but the pigment migration to the superficial visible layers of the retina is not necessarily the place where the perceiving organs are affected. In other words, the lesion which produces loss of vision is not always the one which we can see. There is not always a correspondence between the objective symptom and the subjective symptom.

We are taught that scotoma is an islandlike defect in the field of vision, but if we could realize that defective vision means central scotoma and that our work was incomplete until we had investigated that scotoma, better diagnosis would result. The preceding remarks have been included to give some idea of the usefulness of the slate in field defects, but there are also other fields. Amblyopia exanopsia can be studied to advantage. Here there is one poor eye and in about ten per cent. of the cases will be found a central scotoma, small but absolute. In a larger number will be found a relative scotoma. Color vision is not to be confounded with visual acuity, though both are mainly to be found in the macular area. The patient cannot have good visual acuity and have a color scotoma, but he can have very low visual acuity and not

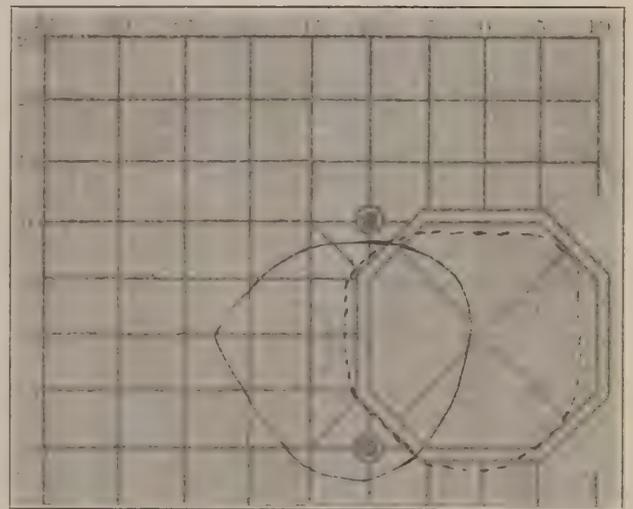

FIG. 4.—Set over obtained by Lancaster method in a case of divergent strabismus. Dotted outline is that obtained by three mm. red test object after operation and the continuous outline is the field obtained by the same test object before the operation. The perimeter registered 30° left exotropia but the campimeter slate shows about 12° and a single operation gave perfect result.

have a color scotoma. We should not forget that we are frequently using these terms one for the other. Another use of the stereoscopic campimeter slate is that of measuring deviations of squinting eyes. Sequential to this use is the proving up of the effects of muscle operations. (Fig. 3.)

For a long time the perimeter has been used to measure the degree of deviation in a case of squint. Does not the variation of the angle gamma influence our readings as much as twenty degrees? Why do some cases with thirty degrees of divergent squint seem so much harder to cure than other cases? If one will outline the blind spot of each eye in a case of squint, and also for greater accuracy, outline the field of vision of each eye for a red one millimetre test object, the patient will fix with the good eye. Then cover the good eye and have the patient fix with the poor eye and repeat the process for that eye only; the difference between the centre of the blind spot in trial one and trial two is the amount of deviation. The field for red one millimetre test object may be used as a check. Comparison with the result on the perimeter is enlightening. If one has operated in a case which has been measured as described above, the position of the deviating eye can be accurately located after the operation and the set over accurately measured (Fig. 4).

450 NINTH STREET.

A PLEA FOR PHYSICOTHERAPY.*

By JOSEPH RIVIÈRE, M. D.,
Paris, France.

The word physiotherapy, which in my opinion seems to be too extensive, too vague and ill defined, is far less suitable than physicotherapy, which is far more precise and the limits of which are much more definite. It may be that my fancy for the second word arises from its having been coined by me; but I indulge the hope that you will also appreciate, as I have done long ago, the scientific reasons which favor its adoption.

Physiotherapy (from *φύσις*, nature) simply means the natural cure, naturism, that is, the utilization, by the physician, of all the elements supplied to him by nature for the treatment of diseases.

Physicotherapy (from *φύσις*, physics) properly signifies the application to daily therapeutics of all apparatus, instruments and machines which physical science furnishes us. In other words, physiotherapy is accessible to all practitioners, whereas physicotherapy, to be practised appropriately, needs the combination of a good clinician, a learned physician and even a skilled mechanic. For the practice of physicotherapy utilizes physical science, clinicophysiological observation, and the experience gained in the handling of the countless instruments which it is likely to make use of. Without this threefold combination, nothing truly good can be obtained. The physiologist skilled in theory but lacking any clinical experience cannot be a good physicotherapist.

This failure in satisfying the proverbial condition of the right man in the right place has given insignificant curative results, and produced definite consequences disastrous to victims of the war.

The sphere of action of physical agents, how-

ever, has become so important and varied, that medical science, formerly so disdainful toward these methods, is no longer allowed to neglect the present resources of physicotherapy or to look down upon this important branch of the medical art as being menial or of an inferior quality.

When, some thirty years ago, I ventured to group under this heading of physicotherapy, in a single sanitary formation, the combined action of the various physical agents, I declared my desire of utilizing all instruments constructed according to the physical laws of gravity, heat, light, electricity and kinetics (together with vibrotherapy, atmiatry, hydriatry, etc.) adapted to the improvement or the correction of the most varied vital acts and of all our organic molecular exchanges; all in view of the perfect and normal regularization of physiological health.

I also added, that the more complete the scale of instruments made use of the more intense and decisive favorable antipathological reactions should prove to be. It is especially in the struggle against chronic diseases, which so deeply shatter the organism, that the abundance and the perfect condition of the curative instruments become attendant on our duty. If it becomes necessary to replace or at least to complete an inadequate chemicotherapy by our methods, while carefully sparing the refractory or already imperilled digestive organs, we shall obtain mild and truly beneficial reactions to correct the deviated nervous function, to hasten the peripheral circulation, to secure the required eliminations, to pick up the trophism of the tissues and to restore the humors to their normal condition.

All these methods, whether they remain isolated and specialized (as is most often the case) or whether they are collected together and combined, as I recommended in France in a debate dating thirty years back—all these curative methods belong to the province of physiotherapeutic science, an important branch of the legitimate practice of medicine, which require the diligent control of a practitioner conversant with clinical science quite as much as the pharmacological branch, and, in addition, a person well versed in physics and mechanics, straightforward, honest and disinterested according to the noble Hippocratic tradition.

In creating and vulgarizing the word physicotherapy, I was therefore working out a reasonable acceptation thereof, well defined in its determination. It by no means had to do with the utilizing of physical agents in their natural state; but it dealt with their precise domestication, in separate instruments and within a synergical group. Physiotherapy appeared to be, thirty years ago, and seems to be at present, an expression much too vague; without any paradox, the contention may be raised that the whole medical art is essentially physiotherapeutic. Do not medicines themselves form part of the domain and the province of nature? On the other hand, the physicotherapist, without despoising chemistry and its vast pharmacological vistas, takes his stand upon physical science, wherewith he controls and limits the scope of his operations rationally adapted to a method.

The progress attained by physicommechanical processes within the last quarter of a century has caused

*Read at the twenty-ninth annual meeting of the American Electrotherapeutics Association at Philadelphia, September 19, 1919.

excellent results to be obtained by our instruments, for altering the complex modalities of vital energy and the potential function of biodynamical phenomena. This is readily understood if one considers that the human body is the greatest transmuter of force and of matter. Reactional expedients are infinite, when one knows how to incorporate in a methodical manner the electrical, the thermodynamic, the hydriatic, the mechanokinetic energies duly adapted in our usual treatments. Electricity, heat, light, motion, these are the unerring causes of our physiological existence, these are the agents of our biodynamism and the equipoising principles of our nutritive economy. Chemical medication, on the other hand, has mainly disturbing effects.

A medicine acts only on the condition of its being a body foreign to the organism, of a taste generally unpleasant; it has never been in request, otherwise it would become a food without any healing effect. The fashion which prevails in pharmacological therapeutics is explained by custom. The property of transforming and utilizing ambient physical energies is increased by exercise, and such a training is highly profitable to us. When it is desired to obtain an equitable and judicious application of our treatments, it is indispensable to possess physical science and to be a practical mechanician able to supply the workmanship if required; also to appreciate the possible resources of human physiology allowing a cure to be hoped for, or, at any rate, an improvement and a change for the better in a countless number of chronic diseases which cause the despair and opprobrium of drug medication.

To repair the human motor, to unstiffen or strengthen its machinery, to stop lesions and restore the normal utilization of imperilled or disordered functions, it must be known how to administer, in a timely and adequate manner, the variable modalities of the physical cure, which is universally admitted to be the least fallacious for all functional restorations and recoveries. Physiotherapy gives the best results in diseases of the nervous system (neurosis, neuralgia, neuritis, paralysis, atony, ataxy, atrophy, tics, tremors, cramps, etc.); in nutritive slackenings and the pathological condition of sedentariness (obesity, migraine, gout, rheumatism, lithiasis, congestive state of the viscera, overworked brain, diabetes, albuminuria); in the diseases of women (pelvic congestions, metritis, fibroma, dysmenorrhœa, ovarian neuralgia); in the diseases of the senses, debility, ptosis, stricture, prostatic hypertrophy, impotency, incontinence of urine; dyspepsia and gastric dilatation; enteropathy, constitutional constipation, intestinal occlusion, cardiorespiratory disorders (asthma and emphysema, tuberculosis, arteriosclerosis, fatty heart); diseases of the blood (anemia, leucemia, various infectious toxemias); the various kinds of dermatopathy and the most malignant neoplasms. In surgery, all traumatic and trophic lesions, stiffness, impotence, atrophy, ankylosis, congenital and acquired malformations; all cases requiring the re-education of attitudes (scoliosis, deviation of the waist, growth disorders), or the mobilization of the articulations; the correction of old traumatic le-

sions and the timely resumption of a maximum useful amount of work, also fall in the sphere of physiotherapy, in its successive modalities and stages. We may add: the cicatrization of wounds and ulcers, the retrocession of certain tumors, the cure of varices and hemorrhoids. In a word, the restoration of physiological equilibrium and the maintenance for a long time of the good results achieved, are the usual rule in physiotherapy. Thanks to the perpetual improvements and to the easy doses of treatments, to the variety of the instruments and the machines employed, the practitioner may combine gentleness with energy and add to the curative precision and extent.

By regenerating the energies, by reinforcing the resistance and the means of defence of the organism, by improving cellular gymnastics, physiotherapy has revolutionized the art of healing. Thanks to the penetrating activity of the potential function infused by our various instruments, economical forces are restored, nutrition is spurred on, sleep is regained, nervous pains are allayed and circulatory disorders are regularized. Power for effort energy for work is kindled, with the joy of life and cerebrospinal equilibrium. These are all the happy results (obvious to the least attentive of observers), which have conquered for sure methods a most lasting and cheering popularity.

25, RUE DES MATHURINS.

Skin Lesions in Measles.—F. B. Mallory and E. M. Medlar (*Journal of Medical Research*, March, 1920) base this study on examinations made on 130 patients covering a period of over two years. Blood culture, smears, and the dark field illumination of fresh blood were negative for any organisms which might have an etiological relation to the disease. A study of the nasal, pharyngeal, laryngeal and conjunctival secretions also failed to reveal any significant facts about the cause of measles. The skin lesions are considered to be infectious in origin without much question, and due to the causal agent of the disease. The reasons for this belief are that the lesions are focal in character and discrete, not uniformly distributed like the rash in scarlet fever, but scattered irregularly, sometimes singly, often in smaller and larger groups, becoming confluent when sufficiently numerous. Tissue from thirty-five patients was studied, using small pieces of skin removed during life. The reaction is almost entirely on the part of the endothelial cells and leucocytes, as in certain other infectious processes. The endothelial cells lining the capillaries in the lesions have swollen, finely granular cytoplasm, which in the earliest lesions often contain one to four minute intensely staining spherical bodies, varying in size a little. These bodies are fewer in older lesions, and usually more evident at the periphery of the lesion, disappearing entirely later in the disease. It was impossible to determine the nature of these bodies, and no similar bodies have been found in the endothelial cells lining the blood vessels in other acute lesions examined as a control. The suggestion is offered that they may be the causal agent.

tation through the mail as second class matter.

NEW YORK, SATURDAY, DECEMBER 11, 1920.

THE MENACE OF TYPHUS IN EUROPE.

One of the most serious aftermaths of the war is the prevalence of the disease known as typhus fever, which is incubated and fostered by filthy conditions, for the cause, the louse, can only exist in such conditions. During the war it raged in Serbia, and is of peculiar interest to the American medical profession, because the discovery of its main means of development and dissemination was due to American investigation. At the present time the presence on a large scale of typhus in Russia and other parts of Central Europe is a distinct and growing menace to the health of the rest of Europe.

According to the report of the chief medical adviser to the British Ministry of Health, issued recently, during the past two winters almost the whole of what used to be the Russian Empire has experienced the ravages of typhus and relapsing fever in a very grave epidemic form. For Soviet Russia alone it has been stated officially that at least 1,600,000 cases of typhus were reported in 1919, while extensive and severe epidemics have occurred in the border countries of Rumania, Poland, Lithuania and Esthonia. The country of the Ukraine has also suffered most severely and conspicuously. In this connection it may be said that now refugees from Soviet Russia are crossing the Ukrainian frontier, as well as persons being repatriated, in a fearfully filthy condition, infested with lice and some of them stricken with typhus. Their disinfection and disinfection at the frontier towns are being done under American auspices, so that although the ques-

tion does not directly concern America, yet, at the same time, it is one of intimate interest. The report just referred to points out that the condition of Poland in this respect has called for special consideration on account of the geographical position of that country in relation, on the one side to Russia, and on the other to the exhausted and presumably susceptible Germanic countries, which up to now have, for the most part, escaped. Attention is drawn to the fact that in the first instance this distribution, which occurred both in 1918-19 and 1919-20, has been due to the importation of typhus infection from its permanent focus in Russia, under condition which would have put a most severe strain upon the sanitary service even of the best organized government of a settled and peaceful country.

Infection has again and again, during the past two years, been introduced in mass by the large number of prisoners of war and refugees reaching Polish territory; many actually suffering from typhus or carrying its infection. It seems practically certain that in Soviet Russia typhus will continue and increase again this winter, while in Poland further opportunities for constant introduction of infection will arise in consequence of the return to Poland, or through Poland, to other countries of large numbers of persons waiting to be repatriated, and of the influx of refugees and returning prisoners of war. Indeed, the menace of typhus to western Europe is so evident as to need little emphasis.

The outstanding question is how to prevent its gaining a foothold and devastating the population. It is fortunate that there are few diseases in which the necessary preventive measures are so well known or the principles of prevention so well established as typhus and relapsing fever. Furthermore, the experience of the war has taught that the work of disinfection can be effectively carried out by the observance of a few simple rules and with improved apparatus for the destruction of the insects and their eggs dependent on currents of steam, hot air, petrol and various other methods.

But in order to carry out measures for prevention on a large scale, as well as treatment and the observation of typhus contacts, a large quantity of raw material, a considerable and trained personnel, and a satisfactory organization of the whole of the anti-typhus work are required. In this campaign, American medical men and lay helpers have greatly assisted. There is yet much to be done, and it is to be hoped that American efforts will not be relaxed, and that Europe may be saved from the impending menace of typhus.

BLOOD TRANSFUSION IN OBSTETRICAL PRACTICE.

Direct transfusion of blood is certainly worthy of taking a foremost place among modern therapeutic measures. It is an operation that no longer presents any serious danger, and in obstetrical practice may render real service in certain circumstances. Animal experiments and the practical results in man leave no doubt of its superiority over injections of physiological salt solution in the treatment of simple hemorrhage with or without shock. Performed with Elsberg's or Bernheim's instruments the anastomosis of the vessels is rapidly and easily made, and the dangers of coagulation are avoided. Care should be taken, as far as possible, to ascertain the hemolysis of both the donor and the recipient, as well as the agglutination of the blood of each. If time is lacking to make these tests, the donor should be selected from the patient's near relatives.

In very serious puerperal hemorrhage, when the usual means of treatment by subcutaneous injections of ether, camphorated oil or caffeine, or the subcutaneous or intravenous injection of artificial serum, are insufficient to control the situation, blood transfusion should be resorted to without delay. Even if the source of the hemorrhage is not completely arrested the oozing will subside after a time on account of the increased coagulability of the blood resulting from the transfusion. This operation is also useful when the hemorrhage is combined with shock, as occurs in rupture or inversion of the uterus, as well as in premature detachment of the placenta. In ruptured tubal pregnancy transfusion will hardly ever be required, as in most cases rapid recovery will ensue by dealing directly with the source of the loss of blood. In puerperal eclampsia transfusion has given some good results, and although this question requires further study, transfusion of blood should be employed when other classical means of treatment have failed.

In serious hemorrhage in the newly born, transfusion has given unquestionably good results. Nevertheless, before resorting to it, injections of human or animal serum should be essayed. In case of failure or at the onset of the hemorrhage when unusually severe, in spite of the technical difficulties of the operation, direct transfusion of blood offers the only chance of saving the baby.

The only real accident to be feared is acute dilatation of the heart, which is due to a too large quantity or too great rapidity of the flow of blood from the donor. This accident is particularly to be feared when an organic disease of the heart exists in the recipient. Acute dilatation does not take place suddenly, and the onset is usually ushered in

by dyspnea, cough, cyanosis and precordial distress, and if the transfusion is not stopped at once, the condition of affairs will go from bad to worse. When hemolysis or agglutination of the blood occurs, it is usually when the recipient is afflicted by some serious affection of the blood.

The transmission of an infectious process must never be lost sight of, and not long since de Martel reported a case of transmission of syphilis. It was a case of transfusion from a mother to her offspring, and very shortly after the operation the baby presented a specific roseola without any primary sore.

The results obtained in hemorrhages in the newly born are so favorable that this would seem to disprove the infectious nature of these hemorrhages. It is likewise difficult to admit the vascular theory of hemorrhage in the newly born which supposes an anomaly in the structure of the capillary vessels, because the sudden change for the better following transfusion cannot be accounted for by a structural regeneration of these vessels nor to a cure of an infection. The only explanation for so rapid a recovery in these cases is some abnormal chemical condition of the blood of a congenital nature, more particularly of the serum, whose chemical makeup is not yet clearly understood.

PHYSICIAN-AUTHORS: ANTON PAVLOVITCH CHEKOV.

"The picturesque and pathetic pageant of Russian letters," writes Christian Brinton, "shows no figure comparable to Anton Pavlovitch Chekov"; and it might be added that, in recent times at least, there have been comparatively few literary figures of any other nationality that are comparable to him, especially in the field of the short story, on which his fame is primarily based. Chekov was one of the supreme masters of the short story, and even in this golden age of short story writing, his work is like manna to the reader of cultivated taste. We of America are not yet wholly familiar with the great procession of characters who march through Chekov's pages. With us, although he has been dead since 1904, he can still be regarded as a contemporary author, since new translations of him are still appearing. Thus far ten volumes of Chekov's stories have been published in English, and each succeeding volume has enhanced the author's reputation. A large section of the reading public has yet to learn that Chekov is not merely another of those gloomy Russian authors. He is much more of a genial philosopher than those compatriots of his who established in this country the grim tradition of perpetual Russian literary gloom. Like the

others, it is true, he paints the banal life of Russia, the prerevolutionary Russia that is gone, but unlike the others he has the saving grace of a sense of humor. "If his palette was gray, if the monotony of the steppe, the disillusion and disenchantment of the Russian soul covered his canvas," says one critic, "it is because they were factors in contemporary life and because Chekov always remained resolutely true to conditions around him." But Chekov's palette is not gray—that is, not solid gray. Satire and sadness, gaiety and grief, go hand in hand through his pages. His stories are full of well flavored humor. He is the true realist who sees all sides of life, and who does not forget that laughter and tears never are far apart.

Humor was a natural characteristic, an ingrained habit, with Chekov, and even life's bitterness could not turn him wholly from it. He began his writing career by contributing farcical *contes* (in 1879, under the pen name of Chekonte) to a Russian humorous paper called the *Dragon Fly*. It is true that in later years he became tinged with pessimism, but his humor simply took on a more significant form. Rollicking drollery became keen satire and subtle irony. In the English translations of his stories, the publishers have made each volume a judicious mixture of his earlier and his later work, and this disregard of chronological sequence is a happy idea, despite the inevitable violent contrasts, since it gives the reader of a single volume a more complete idea of Chekov's range and his supreme artistry within that range.

Although it is as a short story writer that we know Chekov best, he also "transgressed," as he himself puts it, in other directions. He wrote several longer stories, but they are hardly of novel length—at best they are but novelettes. These have not the charm of his shorter work, because of their lack of action and plot; but they reveal the same close observation of and insight into the human animal that marks the briefer tales. He also wrote eleven plays, five of which are serious dramas and six farces. These dramatic efforts achieved great success on the Russian stage, but they have hardly been successful elsewhere, probably because, as has been said, they are too indigenous to Russia and, like the novelettes, are too deficient in action and climax. They are said, however, to be admirable pictures of ordinary, everyday life, and are excellent reading. Five of them have been published in English.

Chekov's medical training undoubtedly was of great value to him in his literary work. Hospital scenes abound in his stories, and in nearly all there are physicians as characters. It was in the capacity of doctor that Chekov was able to familiarize him-

self with the moral frailties of the average man and woman, their banality and stupidity, their grossness of habit and lack of heart. "Chekov looks upon human nature with the charitable eye of the wise doctor who has learned from experience that people cannot be other than what they are," says Edward Garnett, the English critic. . . . "Of all modern masters of fiction, he is the most delicately responsive to the spectacle of life's ceaseless intricacy. . . . He strips the last rags of dignity from the human soul with pitiless assiduity and wanton ferocity."

Chekov was born on January 17, 1860, at Taganrog, in southern Russia. He was the son of liberated serfs and got his early education in a school at Taganrog, after which he entered the University of Moscow, where he was graduated as a physician in 1884. At the outset of his career he was pitifully poor and, to make his handicap all the greater, was afflicted with the white plague. He continued in the dual rôle of physician and writer for nearly a score of years, until at last his writings began to bring him such prosperity that he was able to retire to a villa on the Black Sea where the mild climate was favorable to his health. Even then, however, he continued to practise a little, and on the occasion of the twenty-fifth anniversary of his debut as a writer, in 1904, he said in a little autobiography which he wrote for the journal which had published many of his writings: "Medicine is my occupation, and to such a degree, in fact, that some time during the year I perform more forensic medical dissections than I once completed in two or three years." Chekov lived only a few months after this anniversary. He died of tuberculosis in the fall of that year, at Badenweiler, Germany.

LIVING BEYOND OUR MEANS.

Living beyond our means, psychologically. In lesser ways, too, accusations have been made in many directions. They will always be made until the day of wisdom comes, when psychological knowledge of ourselves is complete enough, serene enough to take ourselves for what we are. Wherever we strain on tiptoe to maintain a level not really ours, the larger background of psychological ignorance is at fault. The picture which decorates the walls is not there because it gives expression to something truly within or to some aspiration which would release that something into healthy freedom. Our clothes form the same oppressive mold, because we are trying to maintain something which is not ourselves. But much more serious is this state of things in moral attitudes and in the graver questions of life. Certain standards, ideas accepted

ready made, seem good in themselves, but there is no question if they represent inner truth—the truth of human life and individual human lives.

It was Freud chiefly who taught us how different this latter is from the external standards toward which we strain. He saw why we come away broken when the strain cannot endure. A rereading of his *Reflections on War and Death* revives for us his plea to nations as well as to individuals. We go on fooling ourselves as to our high standards, which then inexplicably collapse; our denial of death, which comes after all. He begs us to ask if we have not "again lived psychologically beyond our means."

Freud is being more and more widely accepted as the world's greatest physician, who heals because he turns his patients away from such placebos to the actual man and woman which these have sprung up to conceal. His searching reveals the weaknesses in individuals, in social institutions, in national and international character. But at least it strips away the lies that cover them. And beneath, if there is weakness, there is also the bedrock of actual material for more genuine and lasting construction.

Prostitution continues to prey upon infantile natures, while the veil of separate moral pride forbids the frank discovery of the undisciplined cravings which prostitution serves. Alcoholism is only covered over by a zealous repression which knows little of the forces it seeks to restrain. Religion, patriotism, fear to take the real measure of man, or to gage both preaching and science by man himself. Therefore, nations befuddle themselves and one another, until their need breaks out in greedy violence. Society wonders at the cankers which continue to gnaw. The individual flings himself into lawlessness or more often falls into helpless neurosis. Can medicine, politics, statesmanship, religion do better than to find out just what human means are, and educate themselves and their dependents down to them?

THE SORROWS OF TRAVEL.

The joys of travel have been much mentioned but its discomforts and dangers have been too much ignored. Even the fatigue of riding without a seat is accepted on some local lines of railway as a matter of almost daily necessity provided by Providence. There are certain features of travel that cannot be done away with until there are further developments in methods of conveyance. We refer to the noise and dirt, which in themselves are sufficient to take the joy out of railroad travel. Just why ugly sights should be added to the dirt and noise we must wonder. It would seem as if all the dwarfs and hunchback creatures in the land had been culled over for representative specimens to be exhibited in the aisles of railway coaches, and not merely presented to the eye of the traveler once,

but shown again and again, every day in the year. Now if these unfortunates could find no other employment so suitable to their capacity, or if they could be made to serve as an object lesson in public health—as a walking placard of the results of preventable disease—there might be less objection, but why a railroad coach should be turned into an objectless sideshow we are in doubt.

Railway toilets, in stations and on trains, are, as a rule, unspeakable examples of what they should not be, and are often sources of disease transmission. We have already, in these pages, gone more into detail with this unpleasant subject. But the mental wear and tear of travel is even worse than its physical discomforts, especially for the many who are not constant travelers. For most people traveling is, from the outset, a source of anxiety, and this anxiety is not always lessened by the kindness of agent, baggageman, or conductor. We know of no business in which kindness is more needed for the welfare of those in their charge. We see no reason why the hygiene of travel should be overlooked, in a day when health conditions are being developed elsewhere. If traveling can be made less wearisome, uncomfortable, and dangerous, the public deserves the benefit.

THE TOO POPULAR TREATMENT CLINIC.

In many of the clinics the child, where possible, is treated at home under supervision by the visiting nurse, or, if an ambulatory case, has to appear at the clinic during school hours. Two difficulties have arisen: many children are excluded from school dozens of times during the term for that which the mother, had she cared to note the nurse's treatment or to use it, could easily have prevented. The children also, in slight cases, enjoy being excused from school and the importance of being a patient.

What a terrible time these clinicians have! First the people will not come, then they abuse the opportunity. It has been resolved to teach the mothers and elder girls when domiciliary visits are made, and to let children attend the clinic after school hours. This latter has already had a good effect. As to payment, a small charge would cause the treatment to be valued accordingly. The overworked nurse is not supposed to replace the mother, but to teach hygiene, and the tired doctor should not have children returning again and again because the mother has been too indifferent to acquire a little knowledge.

A CORRECTION.

In Dr. Howard Fox's article on Standardized Röntgen Ray in the Treatment of Skin Diseases, which appeared in our November 27th issue, p. 837, an error occurred in the last sentence in the second paragraph of the first column. The word five should be changed to three, the sentence reading as follows:

"In cases of ringworm where short exposures were preferred the figures were as follows: six inch spark gap, three milliamperes, a minute and nineteen seconds and six and one half inch distance."

News Items.

Federal Permits to Prescribe Alcoholic Liquors.—It is reported that out of the 6,131 physicians in New York State who in 1920 had federal permits to prescribe alcoholic liquors for medicinal purposes, only 985, or less than one sixth, have applied for similar privileges in 1921.

The New Surgeon General of the Navy.—It is announced that Rear Admiral E. R. Stitt, Medical Corps, U. S. Navy, has been selected to succeed Surgeon General W. C. Braisted, who is to retire, in conformity with his own request, after more than thirty years' service in the Medical Department of the Navy.

Wellcome Prize Essay Medals.—Medals in the annual competition for prizes given by Henry Wellcome, of London, for the best essay on medico-military subjects, have been awarded to Assistant Surgeon W. C. Rucker, United States Public Health Service; Lieutenant Colonel E. B. Vedder, Colonel James L. Bevans, Captain Mahlon Ashford, and Captain Carl M. Bowman, Medical Corps, U. S. Army.

Associated Out Patient Clinics.—The annual meeting of this organization will be held at the New York Academy of Medicine, Wednesday evening, December 15th, in Du Bois Hall. The address of the evening will be delivered by Dr. W. Gilman Thompson on the Present Inadequate Dispensary Service for the Treatment of Industrial Accident Cases. All who are interested in the subject are invited to attend the meeting.

Prevalence of Venereal Diseases.—During the months of July, August, and September, 1920, there were reported to State Boards of Health 91,195 cases of venereal diseases, an increase over the preceding three months of 21,781 cases, or about thirty-one per cent. It is not considered that this indicates an increase in the prevalence of these diseases, but is a result of more complete reporting on the part of physicians.

Röntgenologists Wanted in the Public Health Service.—The United States Civil Service Commission announces examinations for the following positions in the United States Public Health Service: Röntgenologist, \$200 to \$250 a month; associate röntgenologist, \$130 to \$180 a month; assistant röntgenologist, \$90 to \$130 a month; junior röntgenologist, \$70 to \$90 a month. For full particulars regarding the requirements for eligibility, duties, etc., write to the Civil Service Commission, Washington, D. C.

James C. Farrell Memorial Hospital.—Mrs. James C. Farrell, daughter of the late Anthony N. Brady, is planning to build a million dollar hospital in Albany, as a memorial to her husband, who died about a year ago. It will be called the James C. Farrell Memorial Hospital and will take the place of St. Peter's Hospital, which is badly located and is in need of renovation. The new hospital will be erected on a large plot of ground in the Pine Hill residential section, and will be thoroughly equipped with all the most modern appliances.

Football Victims.—During the 1920 season there were eleven deaths due to football games, five more than in 1919 and one more than in 1918. Twelve lives were lost during the 1917 season, eighteen in 1916, and fifteen in 1915. The majority of deaths this year occurred among high school players, none among the big universities.

Annual Meeting of the New York Academy of Medicine.—Dr. George David Stewart was re-elected president of the New York Academy of Medicine, at the annual meeting held on November 18th. Dr. Edward L. Keyes, Jr., was elected vice-president, and Dr. D. Bryson Delavan and Dr. Seth M. Milliken were re-elected corresponding secretary and treasurer, respectively.

An Outbreak of Botulism in California.—During the month of October, 1920, there occurred in the St. Anthony's Hospital, Oakland, Cal., an outbreak of botulism. There was a total of six cases, two of which could be considered mild and four severe; of these latter, three were fatal. Unfortunately none of the cases was recognized as botulism until the third day of illness, and therefore they were not immediately reported.

Personal.—Dr. Edward J. Kempf, formerly clinical psychiatrist to the Government Hospital for the Insane, Washington, D. C., announces the opening of an office at 100 Central Park South, New York. His practice will be limited to psychopathology.

Dr. Haven Emerson, formerly health commissioner of New York city, has been appointed medical adviser and assistant director of the Bureau of War Risk Insurance.

Medical Association of the Southwest.—At the fifteenth annual meeting of this society, held in Wichita, Kan., November 22nd to 24th, Dr. Edward H. Skinner, of Kansas City, Mo., was elected president, to succeed Dr. Ernest F. Day, of Arkansas City, Kan. Other officers were elected as follows: Dr. William W. Rucks, of Oklahoma City, Dr. John T. Axtell, of Newton, Kan., and Dr. Herbert Moulton, of Fort Smith, Ark., vice-presidents; Dr. Fred H. Clark, of Oklahoma City, secretary-treasurer. The next meeting will be held in Kansas City, Mo., in October, 1921.

Brooklyn Cardiological Society.—This society, the only one of its kind in New York State, held its first meeting on Monday evening, November 29th, at the office of the president, Dr. William J. Cruikshank, 102 Fort Greene Place, Brooklyn. Other officers of the new society are: Dr. Glentworth R. Butler, vice-president; Dr. William W. Laing, secretary; Dr. Frank Bethel Cross, treasurer. The society has twelve members, all of whom are active in cardiological work, and the following honorary members: Dr. Thomas Lewis, of London; Sir James Mackenzie, of London; Dr. John Cowan, of Glasgow; Dr. Robert H. Halsey, of New York; Dr. William Thomas Ritchie, of Edinburgh, and Dr. W. S. Thayer, of Baltimore. Dr. Cruikshank made the opening address at the first meeting and other addresses were delivered by Emil Krading, Ph.D., Phil.D., the Hon. Andrew MacLean, and Mr. Henry Allan Price. The society will meet for scientific discussion every two months.

A Medical Regiment.—The new Army reorganization laws provide, it is said, for a complete medical regiment, consisting of ambulance, sanitary and hospital battalions, veterinary and administrative companies, medical supply division, and medical laboratory. All its members will be trained for the special technical services involved. Such a regiment is now being organized and will be attached to the Second Division at Camp Travis, Texas.

Infant Mortality Affected by Housing Situation.—The crowding caused by a shortage of houses has caused an increase of fifty per cent. in the infant death rate in some localities, according to the findings of the conference of health authorities held recently in Detroit for the purpose of considering housing conditions in relation to public health. It was also found that tuberculosis and other diseases were being spread by overcrowding.

Needs of the Charity Organizations Society.—At the thirty-eighth annual meeting of the Charity Organization Society, held recently, reports were made that during the last year it received \$590,450.97 and spent \$590,490.21 in its welfare work. The general work of the society caused a disbursement of \$230,218.40, while the income from special endowments amounted to \$97,183. Actual family relief was \$187,420.25 this year, against \$151,346.71 the year before. The relief budget for the coming year was set at \$190,000, while to cover all expenses the organization must raise \$511,500.

Quarantine for Venereal Diseases.—The First District Court of Appeals of California has upheld the right of a local health officer to detain and quarantine persons who are venereally infected. A woman was arrested on a charge of vagrancy. She voluntarily submitted to a physical examination, and tests were made which showed that she was infected with venereal disease. The health officer of the city and county of San Francisco ordered her detained and quarantined. Habeas corpus proceedings were instituted to secure the woman's release from quarantine, but the district court of appeals held that the health authorities had the power to isolate venereally infected persons.

Johns Hopkins Hospital to Be Remodeled.—It is reported that Johns Hopkins Hospital, Baltimore, is to be reconstructed on the most approved plan. The estimated cost of the proposed reconstruction of the hospital group, with provision for endowment, will amount to between \$11,000,000 and \$12,000,000. A new pathological building will be erected at a cost of \$600,000, to replace the old one which was burned last winter. The construction of a woman's clinic, to provide for obstetrical and gynecological patients, will be begun next year. The estimated cost is \$400,000. Other plans are:

Outpatient or dispensary building, \$1,714,000; endowment for dispensary, \$1,000,000; heating and power plant, \$100,000 to \$500,000; addition to nurse's home, \$500,000; teaching building for school of nurses, \$250,000; endowment for school of nurses, \$750,000; convalescent branch, \$250,000, endowment \$500,000; medical clinics for men and women suffering from general medical, nervous and skin diseases, \$500,000, endowment \$1,500,000; additions to service building, \$200,000.

League of Nations Discusses Typhus and Cholera in Poland.—According to cable dispatches from Geneva, the League of Nations devoted Tuesday, December 7th, to a discussion of typhus and cholera. The net results of this meeting were, first, the announcement that £200,000 only of the £2,000,000 asked for had been subscribed by the world in reply to the Council's appeal; second, it was decided that the Assembly should make a new appeal to nations and welfare societies, and, third, that the Assembly should appoint a committee of three to conduct the fight against typhus. Sir George E. Foster said that Canada withdrew the conditions attached to her offer of \$200,000. M. Hanotaux, of France, said that there were no strings to the French offer of 1,000,000 francs. A. J. Balfour said the same of England's £50,000. Wellington Koo pledged China's support. Palaccio, of Greece, said that his country would give £40,000.

Meetings of Local Medical Societies.—The following medical societies will meet in New York during the coming week:

MONDAY, December 13th.—Society of Medical Jurisprudence (annual); New York Ophthalmological Society; Yorkville Medical Society; Williamsburg Medical Society, Brooklyn.

TUESDAY, December 14th.—New York Academy of Medicine (Section in Neurology and Psychiatry); Manhattan Dermatological Society; New York Obstetrical Society; Clinical Society of the Hospital and Dispensary for Deformities and Joint Diseases.

WEDNESDAY, December 15th.—New York Academy of Medicine (Section in Genitourinary Diseases); Geriatric Society; Medicolegal Society (annual); Northwestern Medical and Surgical Society of New York (annual); Woman's Medical Association of New York City; Alumni Association of the City Hospital.

THURSDAY, December 16th.—New York Academy of Medicine (stated meeting); New York Celtic Medical Society.

FRIDAY, December 17th.—New York Academy of Medicine (Section in Orthopedic Surgery); Clinical Society of the New York Post-Graduate Medical School and Hospital (annual); New York Microscopical Society; Brooklyn Medical Society.

Died.

ABRAHAM.—In Appleton, Wis., on Monday, November 22nd, Dr. Henry W. Abraham, aged fifty-four years.

BOLEN.—In Brooklyn, N. Y., on Monday, September 20th, Dr. Nicholas Thomas Bolen, aged fifty-nine years.

BOYCE.—In Memphis, Tenn., on Friday, November 12th, Dr. James D. Boyce, aged sixty-five years.

BRECHT.—In Lebanon, Pa., on Saturday, November 27th, Dr. Samuel A. Brecht, aged sixty-one years.

CONROY.—In Everett, Mass., on Saturday, November 27th, Dr. Peter J. Conroy, aged sixty-five years.

HOGG.—In Richmond, Va., on Friday, November 19th, Dr. Moses D. Hogg, Jr., aged fifty-nine years.

HAMILTON.—In Holdenville, Okla., on Monday, November 15th, Dr. Charles M. Hamilton, aged sixty-four years.

LEIGHTON.—In New Haven, Conn., on Sunday, November 21st, Dr. Alton Winslow Leighton, aged fifty-two years.

MOORE.—In Birmingham, Ala., on Friday, November 19th, Dr. John A. Moore, aged fifty-nine years.

SHARPLES.—In Goshen, Ore., on Saturday, November 20th, Dr. Abraham Sharples, aged seventy-nine years.

SCHLITZ.—In Brooklyn, N. Y., on Friday, November 19th, Dr. Francis A. Schlitz, aged seventy-four years.

SCHUYLER.—In Utica, N. Y., on Saturday, November 20th, Dr. William J. Schuyler, aged fifty-nine years.

Book Reviews

ELECTRICITY IN MEDICINE.

Electric Ionization. A Practical Introduction to Its Use in Medicine and Surgery. By A. R. FRIEL, M. A., M. D. (Dub.), F. R. C. S. I., Aural Specialist, Ministry of Pensions, London District, etc. Illustrated. New York: William Wood & Co., 1920. Pp. ix-78.

Electrotherapy. Its Rationale and Indications. By J. CURTIS WEBB, M. A., M. B., B. C. (Cantab.), Hon. Associate of the Order of St. John of Jerusalem; Order of Merit of the Cruz Vermehla; Hon. Associate, King's College, London, etc., etc. With Six Diagrams. Philadelphia: P. Blakiston's Son & Co., 1920. Pp. 90.

Electrical Treatment. By WILFRED HARRIS, M. D., F. R. C. P., Senior Physician and Lecturer on Neurology, St. Mary's Hospital; Physician to the Hospital for Epilepsy and Paralysis, Maida Vale. Illustrated. Third Edition. New York: William Wood & Co., 1920. Pp. x-354.

Diathermy in Medical and Surgical Practice. By CLAUDE SABERTON, M. D., Hon. Radiologist to the Harrogate Infirmary and to the Royal Bath Hospital, Harrogate; Late Hon. Medical Officer to the X Ray and Electrical Department, Royal Victoria and West Hants Hospitals. With Thirty-three Illustrations. New York: Paul B. Hoeber, 1920. Pp. xii-138.

The war did much to bring the use of electricity as a therapeutic agent to the fore. In many instances the use of this important physical agent has been the most valuable at our command in the treatment of lesions caused mechanically. Healing has been hastened and function restored. A great deal that has been done during the war can be duplicated in civil practice. For this reason we feel the importance of presenting the findings of the men engaged in this field.

* * *

Vague theories and untried methods do not attract the too busy practitioner who wants sixty minutes in his hour. He will flutter the leaves of the book, and, if something novel does not catch his eye, he will put it aside until coaxed back to a reperusal by hearing it praised.

But Dr. Friel carries his credentials on the front page, and the B. E. F. certainly does mean real work, dwarfing even the M. D. He refers to Professor Leduc, of Nantes, who discovered the laws which regulate ionization, and defines that term as a form of treatment which means electrically introducing into the tissues one or other of the compounds known as salts. It also expresses the exchange of ions which takes place in the tissues following the continuous electric current.

What can it do? It promises speedy relief to a number of those complaints which are due to the inoculation of microorganisms into tissues or organs, where, owing to lowered vitality and mechanical conditions, they find a lodgment and set up irritation. It need not supersede other agencies; rather, it favors their successful use.

A clear description of what ionization really means, and the equipment necessary, leads the reader on to effects of different ions. One instance, when used in ankylosis, is worth quoting:

"An officer, early in the war, had a gunshot wound in the thigh and a compound fracture of the lower third of the femur. The fracture was excised; recovery followed, but with shortening and an ankylosed knee. He was discharged as unfit,

but he came to Professor Leduc and asked if he could be helped. The knee was treated by salicylate ionization twice a week for five weeks, each treatment lasting an hour, a current of 60, 80 or 100 ma. used. At the end of that time movement had been so restored that the minister of war had him reinstated and advanced to a captaincy, and he led his men to the attack on Chemin des Dames."

Even better are the results on cerebral affections. The bones of the skull conduct well enough to allow of action on the brain, and the brain tissue is an excellent conductor. The ionic changes, which take place between the brain cells and the fluids surrounding them, promote nutrition. That old enemy, suppuration, is dealt a deadly blow by ionization with zinc, also boils and abscesses, ulcer, ringworm, acne, pyorrhea. One's satisfaction grows with the list of diseases subdued; even eye affections are conquered.

Full details are given of the treatment for each case, but it is specially urged that the doctor should not send his patient for ionization to another doctor, losing sight of the invalid for some weeks, because, receiving him back and not knowing exactly what has been done, he is unable to go a step further and perhaps free the patient from an unhealed wound. Cooperation is becoming imperative in the medical as well as the labor world. The book is clearly written in good English and is not a heavy volume in any sense.

* * *

In reading Webb's book one is reminded that there are many doctors who send their patients to the electrotherapist because they know by results the advantages of his treatment, but cannot carry it out themselves. In the scanty leisure of a crowded life they have often picked up books giving technical details, because they honestly wanted to understand, but the inquiry was given up as one requiring too much time. Moreover, the cures wrought by an inappreciable dose or by a pretended one which were, in reality, due to psychotherapy, not electrotherapy, were puzzling and disconcerting. A case is recalled of a lady suffering from hysterical aphonia who frequently made a long journey to recover powers of speech by an electric cure, which was always successful, though the doctor declared he did not use enough to "worry a kitten."

Bearing all this in mind, Webb has confined himself to a little practical volume, nontechnical, giving the modern view as to the action on the human body of each form of electric current and how these currents may cure disease, with a list of the diseases most amenable to treatment, all of which he has treated himself. He gives a list of the larger works he has consulted in order that the readers may do the same when time is not limited.

Very carefully, never presuming anything to be known, the mysteries of currents, static electricity, radium, x rays, are simplified, and their action on the body described. Part II is devoted to general diseases, then to diseases in particular. His success in treating diseases of the nervous system and in gynecology has been encouraging, and equally so

in those commonplace bugbears, dyspepsia and constipation. Most doctors will be grateful to the author for giving them the cream of his own and other men's work and successes in one small volume.

* * *

Dr. Wilfred Harris gives us a third edition, necessitated by all that the war has taught. It might almost be imagined that the war epoch had been intended by Nature as a postgraduate school in which should be put to the test all that was new in the medical and surgical world, so many men have refurbished up their old editions, assuring us there is no doubt about their assertions because they have been converted into stern facts during the war. Harris has borne in mind that many men have only a faradic or a galvanic battery, that very few can get the use of radium, that the thorough knowledge of x ray treatment is rare, the theory of the various forms of current somewhat hazy, and has written for such, so that the wayfaring man need not err and the experienced traveler be gladdened to find old stumbling blocks cleared away.

Methods and apparatus fill the first chapter, the faradic current the second and third. Galvanism, with all its possibilities, is thoroughly worked out before the question of electric baths is dealt with or the electric light baths and x rays. Finally, a study of medical applications of sinusoidal currents, static electricity, and high frequency currents end this accumulation of garnered facts.

It will be a revelation to many to find how sure an aid electricity has been and still is in troubles small and great, from the neurasthenic with logorrhea and the woman who is "so ill as to think she is ill when she is not" to the despondent, mutilated, war spent soldier with increasing paralyses. It can soothe and banish all those everyday attacks of headache, tics, neuritis, and make all nerves approach the happy condition of the ninth one. Only those who have tested the restfulness of what is sometimes termed the fatigue couch can appreciate its consoling power.

The various diseases are not given a place in the index and only a few lines devoted to them in the text, as is the case in so many manuals. Harris has remembered that that which may seem insignificant is, to the seeking doctor, the one important thing demanding treatment by the worried radio-therapist.

* * *

Let not the amateur who doesn't think he can diathermatize but would rather like to know, think he can seriously practise without danger to patients until he has given some time and much study to it. Not everyone who possesses a dry battery may give electric treatment. First of all, high frequency currents are dealt with, then a description of the apparatus is given, and an account of physical properties and physiological effects, followed by methods of application.

Where it helps in diseases of the circulatory and nervous systems, in joint disease, in thoracic affections, forms Part II, and surgical diathermy the third. In these days, when old age finds people rebellious, not resigned, the hope given in their

misère physiologique is cheerful. Appetite, digestion, general health, are improved. The artificial, general pyrexia resulting from diathermy treatment differs from ordinary pyrexia in that it is not produced by toxins circulating in the blood. One of the evils which inexperience may bring about is an attempt to produce a raised blood pressure by means of high frequency currents in chronic auto-intoxication during constipation. An excessive absorption of enterotoxins from the intestines may be set up which will raise the blood pressure and produce an acute toxemia.

In brachial neuritis, so difficult to combat, particularly when there are trophic changes and atrophy, the author finds that diathermic application to the joints, followed by x ray treatment, often causes absorption of the periarticular adhesions. Insomnia, too, a dreaded foe, is defeated by faradization of the brain. All those diseases vaguely grouped under so-called rheumatism, especially osteoarthritis, have been much eased.

The author is quite frank about its disadvantages in surgery; the healthy structures may also be destroyed; the surgeon cannot see important vessels and nerves; secondary hemorrhage may result if operating near large blood vessels; cheloid may form when skin surfaces are involved. As exact references are given when other men are quoted, this handbook is the key to much valuable literature which will help the serious student and deter those inclined to practise with only a superficial knowledge.

HYDROTHERAPY.

An Epitome of Hydrotherapy. For Physicians, Architects, and Nurses. By SIMON BARUCH, M. D., LL. D., Consulting Physician to Knickerbocker and Montefiore Hospitals; Hydrotherapeutist to Sea View Hospital for Tuberculosis, etc. Illustrated. Philadelphia and London: W. B. Saunders Company, 1920. Pp. xi-205.

Curious, how obstinately we have fought our three benefactors, sun, air, and water. "I can't imagine how you can worship the sun," said a London lady to the Persian ambassador. "Oh, but Madam, if you could only see it," he answered. That was some years ago. Now stuffy curtains and ill lighted rooms are vanishing, bath rooms are in every house, the poisonous night air is admitted and everywhere extolled. There are still a few old people who never take a bath in case they should take cold, and some invalids, who would specially benefit, who content themselves with a foot bath for the same reason. In the largest lycée in Rheims it used to be put on the prospectus that the pupils had a footbath once a fortnight. In middle class houses the water for the children's Saturday tubbing had all to be carried from the kitchen to the nursery. At the end of each tubbing one pailful was emptied out, one of clean put in. An upstairs water supply was a luxury.

But hydro has now to carry the word therapy, and such is the charm of the unknown, many will go in for hydrotherapy who would despise the cold water cure. That it is not more appreciated and effectual Dr. Baruch ascribes to faulty instalment, conscientious but untrained directors in hospitals and sanatoria, and the ignorance of doctors concerning its theory and technic.

When in the chair of hydrotherapy at the College of Physicians and Surgeons, Columbia University, the author was able to train five hundred students without difficulty. Now he has sent out the printed word that it may be used in large institutions and in class teaching. There are special chapters on typhoid, influenza, sunstroke, tuberculosis, neurasthenia, and one on whirlpool baths, also a special one on correct instalment. Through this book hydrotherapy regains its lost status, for it is not a mere statement of what might be but a record of results gained by the author when on the staff of New York hospitals. Any mistrust of the cure now is akin to Naaman's contempt for Jordan and ours for simple fresh water as a curative agent. There is one rather odd sentence:

"In the management of chronic diseases, the espousal of the water cure by so-called empirics created bitter opposition, especially when eminent men like Sir Bulwer Lytton aided their cause by excessively lauding water in literary contributions." Here, at least, it was somewhat out of place.

A CORNER IN AMERICA.

Poor White. By SHERWOOD ANDERSON. New York: B. W. Huebsch, Inc., 1920. Pp. 371.

Too often the psychology of present day writers of fiction struggles with an oppressive self-consciousness. The unaffected telling of this tale is, therefore, strangely refreshing. It is like coming upon a fragrant, straight limbed growth of pine in a dry northern sand, after wading the dank growth of a tropical jungle. It has this simple fragrance of the earlier days in our northern central states—most of the story happens there. But into such an atmosphere creeps and hardens the merciless greed of capitalistic industrialism with its rasping worship of money power and steel made success.

The story is well told. The strokes are almost homely in their directness as this development is traced and those characters are drawn which so well typify the sons of this American age of "success." It is the true homeliness which lies close to the inner lives of the men and the few women of the book. It is not wanting even when they become encased in the mail which their greed for success has forged upon them. There is a sincerity to nature in the writing which maintains about and beneath the harshness the softness of the Ohio country, and finds its influence unmarred in certain truer souls.

Jim Priest, the farmhand, and Joe Wainworth, the harnessmaker, preserve their integrity in spite of the weakness of the former and the crazed tragedy of the latter. Chiefly does Hugh McVey, the "poor white" hero, keep his life clear from contamination. He, moreover, shows what dreams are for. He fought bravely against their slothful grip upon him, and then at last his long struggle brought him the knowledge that dreams are the background for creative achievement. So faithful was he further to the reality of dreaming that when the steel age had burned out the creative force from his inventions, he could drop a barren success and go back to the fountain of dreams for new creation. There the story leaves him.

Very often the author goes back to tell of some previous events, often rather far from the movement of his story. This is a somewhat disturbing device for providing the necessary settings for men and events. Yet even this is so straightforward, the sentences always so clearcut, that it can scarcely be complained of. The writer makes no lumbered pretense of an astute psychology. But whether only intuitively or with a specialist's knowledge he reveals many a clear gem of deep psychic fact. Is the cabbage patch chapter, for instance, one of those spontaneous revelations which writers make? The association of the crooked body, the crooked mind soured against progress, and the hunched position over the brown earth among the cabbage plants give a by no means unfamiliar psychic constellation.

Sex is handled with healthy freedom. The writer's mind is uncluttered and able to take the existence of sex in its psychic and bodily naturalness. Behind his hero's struggle into its reality, behind the various phases in which he treats the subject, the author maintains a clear understanding. One would look far to find a subtler or more genuine appreciation of its homopsychic phase than in the character of Kate Chancellor, a familiar type of woman.

New Publications Received.

[We publish full lists of books received, but we acknowledge no obligation to review them all. Nevertheless, so far as space permits, we review those in which we think our readers are likely to be interested.]

HELPING THE RICH. A Play in Four Acts. By JAMES BAY. New York: Brentano's, 1920. Pp. 107.

CAPTAIN MACEDOINE'S DAUGHTER. By WILLIAM McFEE. Garden City, N. Y.: Doubleday, Page & Co., 1920. Pp. xxii-326.

SEX AND LIFE. By W. F. ROBIE, M. D., Superintendent of Pine Terrace, Baldwinville, Mass. Boston: Richard G. Badger, 1920.

DOMNEI. A Comedy of Woman Worship. By JAMES BRANCH CABELL. New York: Robert M. McBride & Co., 1920. Pp. viii-218.

WARFARE IN THE HUMAN BODY. Essays on Method, Malignity, Repair and Allied Subjects. By MORLEY ROBERTS. With an Introduction by Professor ARTHUR KEITH, M. D., F. R. C. S., F. R. S., etc. London: Eveleigh Nash Company, Limited, 1920. Pp. xii-286.

VORLESUNGEN ÜBER BAKTERIOLOGIE, IMMUNITÄT, SPEZIFISCHE DIAGNOSTIK UND THERAPIE DER TUBERKULOSE. Für Aerzte und Tierärzte. Von Dr. ERNEST LOWENSTEIN, a. o. Professor an der Universität Wien. Mit 1 Abbildung in Text und 2 Kurventafeln. Jena: Verlag von Gustav Fischer, 1920. Seiten viii-476.

BACKWATERS OF LETHE (Some Anesthetic Notions). By G. A. H. BARTON, M. D., Anesthetist to the Hampstead General and Royal National Orthopedic Hospitals; Formerly Anesthetist to the Throat Hospital (Golden Square), etc. With Illustrations. New York: Paul B. Hoeber, 1920. Pp. vii-151.

A MANUAL OF PRACTICAL ANATOMY. A Guide to the Dissection of the Human Body. By THOMAS WALMLEY, Professor of Anatomy in the Queen's University of Belfast. With a Preface by THOMAS H. BRYCE, M. A., M. D., Professor of Anatomy in the University of Glasgow. In Three Parts. Part I: The Upper and Lower Limbs. New York and London: Longmans, Green & Co., 1920. Pp. viii-176.

Practical Therapeutics and Preventive Medicine

A Compendium of Treatment and Prophylaxis, Original and Adapted

A Therapeutic Study of Whooping Cough.—David I. Macht (*Bulletin of the Johns Hopkins Hospital*, July, 1920) studied 115 cases of whooping cough, a few of which were in adults, but the majority were in children from a few weeks to fourteen years old. All the cases were characterized by whooping and in many vomiting and small hemorrhages accompanied the paroxysm. Most of the patients before coming to Macht had been unsuccessfully treated by paregoric and other popular drugs; some had had no treatment, while others received vaccines, with no noteworthy results. The author discontinued all medication but a twenty per cent. solution of benzyl benzoate by mouth, the doses varying from five to forty drops in water, three or four times a day or oftener, according to the age of the patient and the severity of the disease. A little benzaldehyde added to a solution of benzyl benzoate in amounts varying from one per cent. to five per cent. seemed to act more effectively than the benzyl benzoate alone. The medicine can be given in sugar water or milk where the simple alcoholic solution of benzyl benzoate is distasteful. It was not found satisfactory to give benzyl benzoate in the form of a suspension in simple elixir, in syrup of yerba santa and other syrups or elixirs. Clinically, about ninety per cent. of the patients showed more or less beneficial results, and there was marked improvement in the symptoms in about fifty per cent. The drug exerts only a palliative effect on the violence and number of whooping cough paroxysms; it is not curative.

Radium in the Treatment of Diseases of the Eye and Adnexa.—G. B. New and W. L. Benedict (*American Journal of Ophthalmology*, April, 1920) state that their experience with radium in diseases of the eye has been in two groups of cases, first, those in which, in their judgment, treatment should be with radium alone, and second, those in which the radium treatment is employed in addition to surgery. The malignant cases were selected on a basis of the character of growth, chronicity, and extent of involvement of the tissues. Various types of epithelioma may be found about the lids and globe as well as within the eye. They may be situated on the margins of the lid, at the canthus, or at the limbus. The degree of malignancy will be determined by the type of cell most abundant, and by the location and direction in which the tumor extends. A basal cell epithelioma may extend over considerable area on the surface of the lids and do less permanent damage than a much smaller, similar epithelioma at the inner canthus, which is rapidly extending toward the apex of the orbit. Epitheliomatous nests that lie deep in the tissues are difficult to reach, and for several months, or even years, after treatment with radium, it is impossible to determine whether or not the growth has become inactive. A section of tissues which had been subjected to treatment with radium years before for epithelioma, was found to be undergoing epithelial

cell proliferation and infiltration without evidence on the surface. In some cases, therefore, it is better to remove the involved tissue with the knife or cautery and apply radium later. In other cases radium alone may be sufficient to effect a cure. The action of radium in infectious diseases of the eye is comparatively slow. Rapidly extending ulcers of the cornea should be treated locally by the remedies commonly employed in addition to the use of radium, if it is used. Vernal catarrh is probably benefited by radium treatment, but a report on this disease is withheld pending further study.

The Cure of Hookworm Infection.—John L. Kantor (*American Journal of the Medical Sciences*, April, 1920) says that an individual from a hookworm district should not be pronounced hookworm free until a series of at least five negative stools has been obtained, and then only if the last treatment took place six or more weeks previously. The latent period after treatment, that is, the period in which the egg laying function of the hookworm is depressed by the vermifuge so that the persistence of worms cannot be revealed by stool examination, may extend up to six weeks. However, the great majority, ninety-eight per cent., of cases become positive again within four weeks after treatment. The usual form of treating ankylostomiasis with drugs given by mouth has been shown to be unsatisfactory, even relatively mild infections resisting as many as seven or eight treatments. Much more efficient results can be obtained by the method of intractintestinal tube treatment, owing to the fact that the full, concentrated dose of vermifuge is delivered precisely at the point of infection. Instead of thirty-four per cent. of cures, as in the case of a first mouth treatment, fully eighty per cent. are cured by a first tube treatment. Only one repetition is necessary for relief in the majority of cases.

Cardiovascular Reaction to Epinephrin.—Paul W. Clough (*Bulletin of the Johns Hopkins Hospital*, August, 1920) records his observations of a group of patients in which the cardiovascular response to epinephrin was studied in detail, because of the increasing use as a diagnostic procedure of the response of a patient to a subcutaneous injection of epinephrin. Tests were carried out on ninety-five subjects, of which thirty-two were either normal controls or patients who were regarded as physically normal. Marked differences in the cardiovascular reaction to a subcutaneous injection of one mg. of epinephrin were noted. The reactions Clough classifies as negative, moderate, marked, and very marked. A moderate reaction consisted of a rise in systolic and a fall in diastolic blood pressure, an increased, often doubled, pulse rate, and slight tachycardia. With marked reactions there was also sometimes glycosuria, and often tachycardia, palpitation, pallor, mydriasis, tremor, nervousness, and anxiety. Two factors seem to be concerned in these reactions: a direct stimulation

of the heart with increase in the force of the beat, and in the volume output, as well as in the rate, and constriction of the peripheral vessels. Atropine often exaggerated the response to a subsequent injection of epinephrin. Eighty-two per cent. of the thirty-two normal individuals gave a slight or moderate response. Patients with hypertension often showed severe reactions, which occurred irrespective of the cause, the degree, or the duration of the hypertension. None of the patients gave evidence of significant endocrine disturbance. This epinephrin sensitiveness in hypertension may be only one manifestation of a general abnormal reactivity of the cardiovascular system to stimuli, and need not be attributed to a hyperactivity of the chromaffin system or the thyroid.

Jejunocolic Fistula After Gastrojejunostomy.

—C. Bolton and W. Trotter (*British Medical Journal*, June 5, 1920) report in detail four cases of this complication and summarize the literature on the subject. Twenty-seven cases, beside their own series, are quoted. The symptoms develop after the symptoms of jejunal ulcer have existed for some time. The onset is usually with diarrhea, intestinal colic, and finally fecal vomiting. Physical examination is not of much assistance in establishing a positive diagnosis, but the x ray may help. There are various tests of feeding or of rectal injections with the examination of rectal or gastric contents shortly afterward which may help considerably in the diagnosis. Prognosis in the condition is fair if an operation is performed, as in the thirty-one cases investigated, in twenty-seven operations were performed, with twenty-one recoveries. The four cases in which no operation was performed were fatal. Realizing the possibility of this complication of gastrojejunostomy, it is highly important that we use such prophylactic methods as are at hand. The aim must be to reduce the acidity of the gastric contents by a correct diet and by the use of alkalies.

The Effect of Arteriovenous Fistula upon the Heart and Bloodvessels.—Mont R. Reid (*Bulletin of the Johns Hopkins Hospital*, February, 1920) gives abstracts of experiments on twelve dogs in which fistulae were produced, in the femoral vessels in five instances, and in the remaining seven between the internal carotid artery and the jugular vein. Abstracts are also given of fourteen cases of arteriovenous fistula treated in the wards of Johns Hopkins Hospital. From this clinical observation and experimental study Reid concludes that an arteriovenous fistula of long standing usually causes dilatation of the artery proximal to the fistula, which dilatation may extend as far as the heart. An acquired arteriovenous fistula of long duration may produce cardiac hypertrophy and dilatation with eventual decompensation. The wall of the vein involved in an arteriovenous fistula becomes hypertrophied, and though the vein on the proximal side of the fistula does not increase greatly in size, its wall does show a greater increase of elastic tissue than the wall of the vein distal to the fistula. There is an increase in the venous blood pressure in the part of the body distal to an arteriovenous fistula, which returns to normal when the fistula is cured.

Treatment of Industrial and Traumatic Deformities.—Walter G. Stern (*Ohio State Medical Journal*, May, 1920), in discussing the treatment of these conditions, concludes that infection must be avoided at all costs by thorough asepsis, the avoidance of needless operations, and perfect fixation during the stage of first aid. Fractures must be thoroughly reduced and accurately fixed in appropriate positions. All fractures should be radiographed for study and record. After the danger of infection has passed corrective operations can be safely performed. Closed fractures are not to be unnecessarily opened up. End to end apposition is not always the best method to obtain a good functional result. Hydrotherapy, electrotherapy, mechanotherapy, massage, and active and passive exercises should be employed.

Treatment of Diphtheria.—Aurelio Ramos (*La Medicina Ibera*, June 5, 1920) divides the treatment into specific, local and general. As to specific treatment he emphasizes the importance of the administration of a sufficient dose of serum at the outset, preferably by the intravenous route, and he does not repeat the dose until the second or third day. He disregards the dangers of anaphylaxis as being very rare. Locally he has had the greatest success with Dakin's solution and pyocyanase which is an enzyme obtained from cultures of the pyocyanus bacillus. This enzyme was found by Emmerich and Loew to inhibit the growth of the diphtheria bacillus and to fix its toxins, at the same time dissolving the membrane. General treatment consists of rest in bed with attention to tachycardia, high temperature, and albuminuria.

Intermittent Hydrops of the Parotid Due to Artificial Dentures.—Jardet (*Bulletin de l'Académie de médecine*, April 13, 1920) observed in four healthy persons a sudden painful but temporary swelling of the parotid gland, which he ascribes to the wearing of new artificial dentures. The condition generally appeared within a few days after initial use of the dentures, and set in suddenly, as a rule at breakfast time. The gland enlarged rapidly during mastication, and soon reached the size of a mandarin or even an orange. The initial sharp pain passed into a dull pain, suggesting mumps. The gland gradually subsided in the afternoon, but the swelling recurred on the next day. Suppression or modification of the denture was always followed by recovery in two or three days. Where the denture was not removed, the acute manifestations subsided after four or five days, but recurrence took place frequently within three or four weeks, continuing in one case as long as eighteen months. In such instances the gland showed slight induration and sometimes slight enlargement in the intervals between attacks. In each of the author's cases the prosthetic apparatus used was a plate of hard rubber bearing upper molars on the affected side and with a markedly prominent outer border, impinging on the tissues between the gums and cheek with each movement of mastication. Abrasions of the mucous membrane in this situation were noted. In no case was a gold plate in use; such plates are considered to have antiseptic properties and are lighter than the hard rubber plates.

Proceedings of National and Local Societies

NEW YORK NEUROLOGICAL SOCIETY.

Regular Meeting, Held April 20, 1920.

The President, DR. WALTER TIMME, in the Chair.

(Concluded from page 920.)

Acute Descending Radiculitis—A Spinal Type of Epidemic Encephalitis.—DR. IRVING H. PARDEE in this paper offered a survey of the literature on the subject, notably in its connection with herpes zoster and syphilis. During the influenza epidemic he had had occasion to study a number of cases of radiculitis all of which invaded the cord in a descending fashion, and presented characteristic symptoms of sharp lancinating root pains, paresthesia, muscular spasms, hyperesthesia, delirium, and fever. Several days after the onset of the pains, involuntary muscular spasms appeared, causing coarse twitching movements of head, shoulder and neck, like the spasmodic contractions sometimes observed in spinal cord tumors. About a week later when the symptoms had become much less severe a mild delirium usually appeared. A confusional state persisting for three or four days was noted, followed by a two week period of dulness and general apathy.

The clinical course of the disease was peculiar. The symptoms were at first confined to the arm and neck, then progressed downward in orderly fashion. Radiating pain was first felt in the upper chest, then girdle sensations around the waist. While the symptoms were at their height in the intercostal and abdominal region there was delirium, but the pain was usually less severe. The symptoms then descended to the legs, the pain increasing greatly in intensity. A slight increase in fever preceded the invasion in the lumbosacral region, which diminished again in about four or five days. Thereafter a slow convalescence of many weeks' duration began. During this convalescence there was a coarse tremor of the arms and legs. No other vasomotor, trophic, or sensory changes were to be noted. There was no anesthesia to touch, pain or temperature, no disturbance of deep sensibility, and no herpes. The reflexes were not profoundly altered, though at the onset slight exaggeration of the deep reflexes was noted with a diminution in their activity several days after the invasion in each region. There was no alteration in pupillary reaction, no blurring of vision, nor oculomotor weakness. Control of the bladder and rectum was retained. One symptom of interest observed in all the cases was an involuntary flexion of the head. It was not necessary for comfort, and resembled the attitude seen in cervical spinal cord tumor, syringomyelia, and sometimes in amyotrophic lateral sclerosis. The results of laboratory analysis showed a leucocytosis in the blood—and in the spinal fluid an increase in globulin and a pleocytosis.

Dr. Pardee gave the history of one case that presented all the characteristics outlined. Clinical evidence from this and numerous other cases studied showed that there was frequently an involvement of the posterior spinal roots, appearing either

alone or in conjunction with signs of an encephalitis. All Dr. Pardee's patients recovered, so other reports had to be resorted to for autopsy findings. Round cell infiltration in the posterior root ganglia was noted by Strauss and Loewe, and a like involvement with some small hemorrhages and perivascular infiltration by Flexner and Amoss.

In summarizing the points brought out by his study, Dr. Pardee stressed the frequency with which epidemic encephalitis might invade almost any portion of the nervous system. It seemed to show a predilection for the basal ganglia, nuclei of cranial nerves, and posterior roots, as evidenced in the cases that he studied. Acute descending radiculitis was an infection of the posterior spinal roots which might appear as a separate clinical entity and pursued a stereotyped course, ending in recovery. It might also antecede in a more or less typical but usually attenuated course, the cerebral form of epidemic encephalitis. If a posterior root syndrome might be considered a prominent complication of epidemic encephalitis, Dr. Pardee believed that myoclonic twitchings, hyperesthesia, and radicular pains might be considered as much a part of the picture of the disease as diplopia, somnolence, and cranial nerve palsies. The concomitance of radicular pains and influenza offered another suggestion on the obscure etiology of this disease manifestation.

An Analysis of the Cases Admitted to the Neuropsychiatric Services of the U. S. A. General Hospital Number 1.—DR. SYLVESTER R. LEAHY, of Brooklyn, described the opening of the ward for neuropsychiatric patients from overseas and such cases as developed in hospitals under the jurisdiction of the Port of New York. The hospital was opened on November 22, 1918, in the former Messiah Home. It contained five wards, two of which were devoted to the psychoses, one for disturbed patients, and one for quiet depressed ones. The remaining space was allotted to mild mental states, epilepsies, psychoneurotics, constitutional psychopaths. The bed capacity was 220. During the time that the hospital was in operation, nine months and twenty-two days, 2,750 patients were admitted, 2,126 patients came from overseas, and 624 were local cases. Since the hospital was an evacuation unit, urgent conditions only were treated, but its facilities were very complete, and detailed reports and recommendations for treatment were forwarded to each patient's final destination.

Of the total number of cases, twenty-four per cent. were psychoneurotics, twenty per cent. were of the dementia præcox type, twelve per cent. were of the manic depressive group, ten per cent. were mental defectives, five per cent. were organic nervous disease, principally of the syphilitic type, four per cent. were definitely epileptic, and four per cent. were constitutional psychopaths. Doctor Leahy made a comparison between the group percentages of the hospital with the group percentages of the New York State Hospital service male admissions; twenty per cent. army and twenty-seven per cent. civilian was the result for dementia præ-

cox, and twelve per cent. army and nine per cent. civilian for manic depressive psychoses. The dementia præcox was predominant in both groups. A certain number of psychoses were left ungrouped because of lack of data sufficient to make a differentiation possible. Some of the patients refused to answer questions. They appeared confused and in a dreamlike perplexed state. At times they were very depressed.

Dr. Sanger Brown, II, in discussing this paper offered some statistics regarding the Hospital Centre at Savenay, France. From this centre nearly all the disabled of the A. E. F. were returned to America and it was at this point that neuropsychiatric cases were evacuated. The census of the centre was about ten thousand patients, and of this number about one thousand were in the neuropsychiatric service; in other words, one tenth of the cases. From a survey of all cases in the centre made later, it was found that about twelve per cent. of all the injuries involved the central or peripheral nervous system; and it was thought that in the general wards were other patients suffering from neurotic symptoms of sufficient number to bring the total percentage of cases coming under the care of the neuropsychiatrists to about thirty in that centre.

Of the patients returned to the United States from the neuropsychiatric service about thirty per cent. were suffering from psychoses, thirty-three per cent. suffered from psychoneuroses, ten per cent. were mental defectives, eight per cent. were epileptics, ten per cent. were psychopaths, and five per cent. suffered from organic diseases with mental manifestations; the remaining four per cent. were undetermined types.

The staff was conservative in rendering a positive diagnosis of dementia præcox since the symptoms were acute and the unusual circumstances were taken into consideration. A number of mental conditions were encountered, with which the staff was not familiar in civil life—the so-called war psychoses, physical exhaustion, delirium, and fear, with disorientation, were especially common. A second unusual condition was the combination of hysterical states, such as palsies, contractures or tremors with a psychosis, or with epilepsy or mental defect. Lethargic encephalitis, new at that time, was encountered to a considerable extent, and as no literature was available, these cases were very puzzling when they first began to appear.

A Study of Pubertas Præcox.—Dr. J. H. LEINER reviewed the historical references to cases of pubertas præcox. In this syndrome it would seem that the child passed through several stages of life *in utero*. The endocrines seemed to be a primary factor in the causation of this condition. Secondary factors were climate, race, and heredity. As was well known, menstruation appeared normally at a somewhat earlier age among women in southern countries, while the inhabitants of the north normally did not begin to menstruate until from fourteen to sixteen. Marriage in Oriental races took place very early, and the precocity of the southern races might be due to this inbreeding.

Doctor Leiner described two cases in which there had apparently been direct hereditary transmission.

One subject, a girl, at birth gave the impression of a twelve year old child; menstruation began at six weeks, and was regular thereafter. A second case, that of a boy, at four years of age looked as though he were at least ten, and had the physical development of a young man of twenty-one. The parents in both cases reported marked virility, or there was actual pubertas præcox in the parent.

Precocious puberty is caused by a hypersecretion of either the gonads, pineal, or corticoadrenal glands. A secondary involvement of the pituitary and thyroid is also unquestionable. Clinicopathological evidence showed that the first three glands were involved in this syndrome, either in the form of hyperplasia affecting them, or neoplasms.

Rogers collected 101 cases of pubertas præcox, eighty-one in the female and twenty in the male; out of the eighty-one cases in the female, seventy-three pointed to the hyperovarian type. Other writers had recorded cases of this type, among them Lenz, who described the case of a girl in whom menstruation began at sixteen weeks. The secondary sex characteristics were those of a mature woman. As she grew up she became a good scholar, but preferred the society of children of her own age. At twelve she was very shy and childish in behavior.

Lucas reported neoplasm of the ovary as a cause of pubertas præcox. At seven his patient showed all the signs of genitosomatic maturity, with early menses. After removal of a tumor of the ovary, all signs of adolescence, and menstruation, disappeared. Eleven cases of sexual precocity associated with ovarian neoplasms were collected by Roger Williams. This did not necessarily indicate that tumors of the ovary lead to sexual precocity, since other factors entered into the causation. The mentality in the ovarian cases never seemed to be very great; in fact, the patients spoke and acted their true age. Early menstruation in hyperovarianism produced excess calcium elimination, which resulted in short stature.

In the corticoadrenal types of cases the clinical picture differed according to whether the involvement was in the male or the female. Hyperplasia of the adrenals in the male tended to accentuate male precocity; in the female, the tendency was to change the female into the male type with all the secondary sexual characteristics of the male. The mentality in these cases was low.

In cases of hypergonadal condition in the male, mentality was usually retarded. In one case of precocious sexuality the removal of a malignant tumor of the testicle caused the disappearance of the adult characteristics. Tumors of the pineal and their effect upon sexual precocity had been extensively studied, but as yet no direct connection seemed to have been demonstrated, aside from the statistical fact that pineal tumors occurred predominantly in the male while those of the adrenals were most frequent in the female. There was little or no real mental precocity in all these types, the patients were usually shy and reserved on account of their appreciation of their differences from the normal type. Early diagnosis in the hyperplastic types might result in improvement by proper endocrine therapy.

Meeting Held on May 4, 1920.

Presentation of a Case of Epileptic Seizures, Transient Hemiplegias, and Temporary Papilledema of Doubtful Etiology.—Dr. THOMAS K. DAVIS showed a patient who had had typical epileptic seizures since her eleventh year. There was usually temporary weakness of the right side after an attack. She was brought to Bellevue after an especially severe attack, where her condition was diagnosed as a straight case of epilepsy. On the tenth day, however, she awoke with a severe hemiplegic condition on the right side with a partial motor aphasia. The fundi were considered normal on the day that the hemiplegic symptoms developed, but forty-eight hours afterward a papilledema was found on the right and a blurring of the disc on the left. The papilledema did not continue, so the theory of a neoplasm with a hemorrhage into it had to be abandoned. A month after the onset of the hemiplegia the patient had recovered the motor function of the right side, and was able to walk without support.

In reviewing the possible causes for this papilledema, ethmoid sinus infection was ruled out by absence of fever and by negative findings of the nose and throat. No edema or other signs of acute nephritis had been observed in the patient and the high tension cardiac changes were also lacking. Epidemic encephalitis did not seem probable, since there was no somnolence, no ocular palsies occurred, and the patient had no fever. Finally, Dr. Davis called attention to the glandular makeup of the patient, pigmentation and evidence of suprarenal deficiency, with gonadal deficiencies also, and suggested a possible etiology in focal compensatory changes in the pituitary gland causing temporary pressure on the third ventricle with resultant swelling of the optic nerve heads.

An Unusual Case of Epidemic Encephalomyelitis.—Dr. WALTER M. KARUS presented the case of a riveter, aged thirty-two, who was admitted to Bellevue Hospital on February 23, 1920, complaining of pains and weakness in the shoulders and arms. These pains he had had in the shoulders and arms for three to four weeks prior to admission. They were increased by movement. Soon after the onset, weakness of the upper extremities became noticeable and finally compelled the patient to stop work on February 10th. He noticed diplopia one week before admission.

On admission there was weakness and tenderness of the muscles of both arms from the deltoids down. There were fibrillary twitchings (paralysis of the long respiratory nerve of Bell to the serratus magnus). Some winging of the left scapula was also present. The weakness was generally greater on the right than on the left. This may have been due to the fact that for twenty years the patient had been accustomed to carry heavy pieces of iron on the right shoulder. The pectoral muscles were strong. There was a slight weakness of the muscles supplied by the left seventh cranial nerve, and a masklike expression. There were nystagmoid movements of both eyes to right and left. Tremor of the eyelids, tongue and hands was present. The triceps jerks were absent; supinator jerks present;

other reflexes normal; no sensory changes beyond the pain noted, and no incoordination. On April 26th the diplopia was still present; March 1st, sleepiness very marked and hard to control; March 4th, atrophy and tenderness of both infraspinati noted; W.B.C. 10,400, polymorphonuclears sixty per cent.; March 13th, tenderness in the shoulders had gradually disappeared and there was tenderness in the hands; March 17th, pill rolling type of tremor noticed in both hands; March 18th, gait was shuffling, conjugate movement of both eyes downward poorly done. Laboratory findings showed the spinal fluid, on admission, forty cells; globulin, colloidal gold 0000121000, Wassermann negative. There existed slight left facial weakness; complete paralysis of the right serratus magnus and partial paralysis of the left serratus magnus (winging); electrical reaction, complete R.D. in the right serratus magnus. All the other muscles of both arms, forearms and hands showed a partial R.D. There were fibrillary tremors, atrophy and weakness of all the muscles of both upper and lower extremities. In brief, a case of acute epidemic encephalomyelitis showing among other signs the results of involvement of the anterior horn cells of the lower cervical (5, 6, 7, 8) and first thoracic spinal segments.

Myotonia Accusata.—Dr. I. ABRAHAMSON presented a patient who had been shown two years before by him as an interesting example of myotonia accusata. The condition was of six years' duration, no illness preceded the onset, the patient was simply unable to move as quickly as before, and found that he could not swallow. The initial movement was always difficult, and at the present time this was one of the few symptoms retained. The patient could clench his fist, but an additional effort was required to unclench it. The Erb sign still continued. When the tongue was pressed a distinct ridge lasting for several seconds could be evinced. The treatment had been three fourths grain of thyroid daily, and forty-five grains of calcium lactate. Under this treatment the patient had recovered from his clumsiness and was able to work.

Doctor Abrahamson called attention to the fact that the left sternomastoid was beginning to waste, and remarked that certain myotonias of Thomsen merge into myotonia atrophica.

The Motofacient and Nonmotofacient Cycles in Elevation of the Humerus.—Dr. BYRON STOOKEY read a paper in which the results of his investigations on the muscles which act in the elevation of the humerus were set forth. Heretofore it had been generally accepted that the deltoid raised the arm approximately to a right angle and the elevation was completed by scapular rotation. His study made by means of radiographic plates proved that the deltoid without rotation of the scapula was unable to raise the humerus beyond 60°. From this height to about 115° scapular rotation was called into play, and finally the elevation from 115° to an approximate straight angle was completed by the deltoid. The deltoid accordingly acted first as abductor, then after the scapular rotation had raised the arm over the intervening 55° from 60° to 115°, the deltoid acted as abductor for the rest of the distance.

The elevation of the humerus was accordingly effected by alternating cycles. In the first cycle the deltoid and supraspinatus were motofacient while the scapular muscles were nonmotofacient. In the second cycle it was the scapular muscles that were motofacient, while the deltoid, supraspinatus teres major, pectoralis major and latissimus dorsi were nonmotofacient. The completing cycle again called into play the deltoid and supraspinatus. Supplementary factors, hitherto ignored, that played an important part in this last stage of elevation, were two muscles, the clavicular head of the pectoralis major, and the coracobrachialis. These muscles participated in elevation especially when great force was required, or when there was impairment of the normal function of the deltoid.

Medical and Social Problems of Childhood Delinquency.—Dr. SANGER BROWN, II, in reviewing the question of the medical and social aspects of childhood delinquency, spoke of a survey which was being made in one of the probationary schools in New York city, under the auspices of the National Committee for Mental Hygiene, and upon the invitation of the public school authorities. This survey consisted of a thorough physical examination of the child, a mental examination, psychological test, and a social survey of his home and environment. To carry on this work a physician, a psychologist and a social service worker had been appointed. In their inquiry as to the causes of delinquency, an attempt had been made to determine to what extent this condition arose from physical causes, mental defect, inherent personality, disorder, and environmental influences. In describing the cases so far examined, certain groups of children were found. There were the nervous children, not designated as neurotic in the way adults are generally described, but children who showed increased motor activity, decreased motor activity, lack of emotional control, such as explosive, irritable or sensitive states, and disorders of sleep. These nervous symptoms were considered benign in character and amenable to treatment. The causes were considered both physical and mental. In the physical, they might be malnutrition, overstimulation from unsuitable food and physical exhaustion. In the mental sphere a child might become neurotic and emotional for many reasons. A child was particularly sensitive to faulty home influences—a nervous mother, friction between parents, all of which caused social misunderstanding. The child might be unfavorably compared with another in the family and might feel a sense of failure or inferiority. Such maladjustments might, of course, arise in school and they might arise from sources within the child itself—from his instinctive life. Nervous children became delinquent because they could not conform to the ordinary school discipline. Reasons for their irritability and emotional state were not understood, and when they were disciplined they did not improve and were likely to become truant. They associated with bad companions, and delinquency was engrafted upon a nervous state.

Doctor Brown did not consider mental deficiency as important a factor in childhood delinquency as had been often stated. The real problem of delin-

quency was not one primarily of mental defect, but was one of maladjustment. About twenty per cent. of this particular group were mentally defective, and with them the delinquency was a secondary feature.

The question of personality and delinquency was considered by Doctor Brown. Although in the adult delinquent one felt that the personality was primarily at fault, one did not seem warranted in assuming that delinquent children had any special personality disorders or tendencies toward delinquency because of inherent mental traits. So many causative factors were found in their environment or in their physical condition that one did not seem justified in considering the symptoms which they showed as inherent. One did find in delinquent children many with special aptitudes and interests who did not get along well in the regular classes, and also children of rather dull intellect who did not like school; but they were delinquent secondarily, and not because of their mental traits. If, however, ill conduct continued over a period of some years there was reason to believe that these traits of character became established and were very difficult to eradicate in the adult.

In the management of childhood delinquency, the need of individual study as to the needs of each case was urged from a physical, mental and social viewpoint. The social attitude of the community toward delinquency was, as a rule, an unfavorable setting for the child because he received unfavorable judgment before his case was thoroughly understood. Doubtless the main way of dealing with delinquency was by preventive treatment, and much could be accomplished by separate classes for children with special aptitudes, neurotic symptoms, and for those who could not do the regular class work for any reason. This would tend to improve the delinquency which eventually developed in these cases, and there was reason to believe that it would also prevent considerable adult delinquency, since maladjusted children tended to drift to permanent conduct disorders unless corrected.

An Emotional Crisis.—Dr. EDITH R. SPAULDING told of the opening of the Psychopathic Hospital of the Laboratory of Social Hygiene at Bedford Hills. The attempt had been made to treat the patients as though they were in a psychopathic hospital that had no connection with a reformatory institution. Sources of irritation were removed and the patients were helped to make the necessary adjustments to make it possible for them to live in a social group. The various known methods of treatment and training were installed. None of the punitive measures usually practised in reformatories were used unless it was necessary to segregate an individual patient who would disturb the equilibrium of the group. The final solution, Doctor Spaulding stated, of this very intricate problem, would never be found in therapy alone, in educational or in self-government alone, or in discipline alone, but in the utilization of all these resources by those who had made a close study of the problem. It was urged that all neurologists and psychiatrists contribute their findings in an effort to solve this, one of the most difficult of all social problems.

AN UNUSUAL CASE OF ALKALOSIS AND IMPAIRMENT OF THE EXCRETORY POWER OF THE KIDNEYS.

By JOHN LOVETT MORSE, A. M., M. D.,
Boston, Mass.

Professor of Pediatrics, Harvard Medical School.

Clara G. was admitted to the Children's Hospital May 3, 1920, when ten and a half years old. Her parents and two other children were alive and well. There had been no deaths or miscarriages. There was no tuberculosis in the family and there had been no known exposure to it.

She was born at full term after a normal delivery, was normal at birth, and weighed eight and three quarter pounds. She was nursed for eighteen months, but took cereals also at nine months. She had had what was called meningitis at two years, whooping cough at four years, diphtheria at five years, measles at six years and chickenpox at nine years. She had never been very strong. She had wet the bed since she was two years old, having stopped previously. Her urine had been examined in 1916 and the slightest possible trace of albumin and "quite a large amount of pus" found. It is presumable that the pyelitis had persisted since that time. She was said to drink much water and to pass large amounts of urine. She had had pain in her feet for three months and in her knees for a week.

Physical examination.—She was poorly developed and nourished. Her complexion was pale and sallow. Her teeth were poorly cared for and there were several cavities and old roots. There was very little tonsillar tissue. Her tongue was coated and her breath was foul. D'Espine's sign was absent. There was a slight systolic murmur at the base of the heart and a venous hum in the neck. The heart was otherwise normal. The lungs were normal. The abdomen was somewhat sunken. The liver, spleen and kidneys were not palpable. There was no tenderness in the region of the kidneys. The external genitals showed nothing abnormal. The extremities were normal. There was no spasm or paralysis. The knee jerks were equal and rather active. There was no clonus. Babinski's and Kernig's signs were absent. There was no edema or enlargement of the peripheral lymph nodes.

The examination of the blood showed: Hemoglobin (Tallqvist), sixty to sixty-five per cent., red cells, 2,932,000, white cells, 5,300, small mononu-

clears, thirty-two per cent., large mononuclears and transitionals, three per cent., polynuclear neutrophils, sixty-four per cent., and mast cells, one per cent. The red cells showed slight variation in size, but none in shape. There was very little achromia. No nucleated cells were seen. The blood platelets were apparently somewhat decreased.

The urine was pale, very cloudy, slightly acid in reaction and of a specific gravity of 1005. It showed a slight trace of albumin, but no sugar, acetone or diacetic acid. There were five mm. of sediment after centrifugalization. This contained a great many pus cells, singly and in clumps, and a few small, round cells, but no red cells or casts. It also contained many motile bacilli. The tuberculin test was negative.

She was started at once on thirty grains of bicarbonate of soda every four hours. On the morning of May 5th the dose was increased to sixty grains every four hours. That afternoon her hands and fingers began to be stiff and in the evening were in the typical position of tetany. The next morning her legs and feet also assumed the position of tetany. There was a marked facial phenomenon on both sides. At that time she had had two hundred and seventy grains of bicarbonate of soda and the urine was alkaline in reaction for the first time. The diagnosis of spasmophilia was made, but the importance and the possible gravity of the condition were not appreciated and the bicarbonate of soda was continued. She was drowsy that day, was very thirsty and passed much urine.

Edema of the face appeared the morning of May 7th. The signs of tetany continued. There were also attacks of slight spasm of the larynx. The urine contained the slightest possible trace of acetone but no diacetic acid. The carbon dioxide tension of the alveolar air was forty-five. During the morning she began to vomit continuously.

She began to have convulsions the morning of May 8th and soon became unconscious. The cerebrospinal fluid obtained by lumbar puncture was clear and under normal pressure. It contained two cells to the cubic millimetre. There was no globulin present and Fehling's solution was reduced. The fundi showed no signs of increased cerebral pressure. The bicarbonate of soda was then stopped, after she had had a total of 750 grains in five days.

The diagnosis of spasmophilia was made and it seemed reasonable to suppose that it was due to the bicarbonate of soda which had been given for the

pyelitis. It was difficult, however, to understand why the bicarbonate of soda had brought on the spasmophilia, because doses of this size are given very frequently in the treatment of pyelitis with no untoward results. A plausible explanation seemed to be that offered by Dr. Aub, that the sodium had driven out the calcium and that on account of the disturbance of the normal balance between sodium and potassium on the one side and calcium and magnesium on the other side, the spasmophilia had developed. Dr. Aub tested the alkali reserve of the blood and found it to be thirty-one volumes per cent. carbon dioxide for one c. c. of plasma, that is, diminished. It is very difficult to understand this finding, because it would seem as if the alkali reserve could not be reduced under the circumstances. It is possible, but not probable, that there was an error in the observation. It is more reasonable to suppose that the observation was correct and that we are unable to interpret it because of lack of knowledge.

Under active treatment with glucose and water by mouth and by rectum and with water subcutaneously, she gradually improved and by the end of a week all signs of spasmophilia were gone and she was in good condition. The urine still showed evidences of pyelitis.

As the urine continued to show all the signs of pyelitis, on June 3rd she was started on fifteen grains of urotropin and twenty grains of acid sodium phosphate three times a day. As the urine was not very acid and Burnham's test was negative, the acid sodium phosphate was increased June 9th to twenty grains every four hours. The next morning she complained of being tired, went to bed and was more or less drowsy all day. In the afternoon she complained of headache and began to vomit. The facial phenomenon and peroneal reflexes were present. She was very thirsty and edema of the face developed.

The carbon dioxide tension of the alveolar air was between ten and fifteen on June 10th and again on June 12th. The urine, however, did not contain either acetone or diacetic acid. Here again it is difficult to explain the low carbon dioxide tension, when the spasmophilia was presumably due to the intake of sodium. It is probable that there may have been some error in the observations, as when there is an error in estimating the carbon dioxide tension in the alveolar air, the mistake is always in getting it too low. It is possible, however, that the estimations may have been correct and that the low tension was due to some action of the acid portion of the acid sodium phosphate on the blood. The acid sodium phosphate and urotropin were stopped the next morning. She had had during the week 660 grains of acid sodium phosphate, which is equivalent to 110 grains of sodium by weight. The evidences of spasmophilia began to diminish as soon as the drugs were stopped and on June 14th she was well again. The carbon dioxide tension had then risen to between fifteen and twenty.

Dr. Lewis W. Hill then called attention to the fact that the specific gravity of the urine had been extremely low from the beginning, running 1005, 9, 8, 8, 10, 7, 8, 5, 6, 5, 4, 6, 4, 4, 2, 1, 4, 1, 4,

4, 4, 5, 2, 5, 3, 0, 3, 2, 3. He suggested that the trouble might be that the kidneys were unable to eliminate salts and that that was the explanation of the retention of the sodium and the development of the spasmophilia. The patient was then studied with this idea in mind. The investigations which were made from June 15th to 21st gave the following results: Phthalein test, first hour, seventy-five c. c., no color, second hour, seventy c. c., less than five per cent. The gravity fixation test which was done by giving the child three meals of practically the usual house diet to which two grains of caffeine sodium benzoate and fifteen grains of sodium chloride were added at each meal, the fluid being limited to ten ounces at each meal, with nothing between meals, showed:

6:00 a. m.	220 c. c.	1004
8:00 a. m.	125 c. c.	1005
10:00 a. m.	120 c. c.	1005
12:00 m.	180 c. c.	1004
2:00 p. m.	160 c. c.	1005
4:00 p. m.	155 c. c.	1009
4:00 p. m. to 6:00 a. m.	625 c. c.	1007
		1585 c. c.

The blood showed sixty-seven milligrams of urea nitrogen to the 100 c. c. of blood. A few days later the urea nitrogen rose to eighty-five and seven tenths milligrams. These figures show, of course, that the excretory powers of the kidney were very much diminished and there was nitrogen retention. The facts that she was very thirsty and that the output of the urine was about the same as the intake of fluid corroborates the conclusions drawn from the examinations detailed above. It would be expected that under these conditions the urine would show the evidences of an interstitial process in the kidneys and that the blood pressure would be raised. Such, however, was not the case. The urine, although examined daily, had never shown casts or red cells.

The systolic blood pressure was 110 and the diastolic, 90.

The electrical reactions done at this time were as follows: C. C. C. 4.50, A. C. C. 2.00, A. O. C. 5.00, C. O. C. 3.50. That is to say, the low C. O. C. shows that she was still electrically oversensitive, although there were no clinical evidences of spasmophilia.

She was put on a low protein diet without salt and directed to drink large amounts of water. She was kept under observation in the outpatient department. On August 9th one of the outpatient physicians, who was not well acquainted with her story, ordered small amounts of bicarbonate of soda three times a day. The amount was not specified. Five days later she had tetanic manifestations lasting a few minutes. She was brought to the hospital the next day, August 15th, and admitted. The facial phenomenon and peroneal reflexes were present. The urine still showed the evidences of pyelitis and was of a low specific gravity, running along the next few days 1003, 4, 2, 4, 4, 5, 7, 6. The bicarbonate of soda was stopped at once. The peroneal reflex was gone August 19th and the facial phenomenon was barely obtainable. As it was thought that there might have been something spe-

cific in the action of soda, she was then given fifteen grains of citrate of potash every four hours, this being increased to thirty grains every four hours on August 23rd. Three days later the facial phenomenon was increased and the peroneal reflexes reappeared. The urine, however, was still acid. The citrate of potash was then stopped because of vomiting and a large number of loose, watery stools. It is presumable that the reason the citrate of potash did not cause more marked nervous symptoms is that much of the salt was carried away in the intestinal discharges. She was discharged from the hospital soon after, on her former diet with the low protein and forced fluids.

She was readmitted to the hospital for further study October 26, 1920, having been well since her discharge two months before. She had gained in weight and strength and symptomatically was well. The physical examination showed no evidences of spasmophilia. The examination of the blood resulted as follows: hemoglobin, eighty per cent. (Tallqvist), red corpuscles, 4,380,000, white corpuscles, 6,400, mononuclears, forty-four per cent., polynuclear neutrophiles, fifty-four per cent., and basophiles, two per cent. The red cells showed no abnormalities and the platelets were apparently normal in number.

The urine was pale, cloudy, acid in reaction, and of a specific gravity of 1006. It contained no albumin and only one millimetre of sediment after centrifugalization. This sediment showed leucocytes, but no bacteria. The phtalein test showed: First hour, 110 c. c. 1006, less than five per cent.; second hour, 84 c. c. 1007, less than five per cent.

The gravity fixation test showed:

	8:00 a. m.	115 c. c.	1006
	10:00 a. m.	145 c. c.	1004
	12:00 m.	105 c. c.	1006
	2:00 p. m.	45 c. c.	1004
	4:00 p. m.	70 c. c.	1006
	6:00 p. m.	60 c. c.	1005
6:00 p. m. to	6:00 a. m.	880 c. c.	1006

1420

The urea nitrogen unfortunately could not be done, as the chemist was ill at the time. The carbon dioxide tension in the alveolar air was thirty-five. The electrical reactions were: A. C. C. 6.00, A. O. C. 5.00, C. C. C. 2.50, and C. O. C. 6.00. The systolic blood pressure was 140 and the diastolic 110.

It is very hard to understand or explain the marked impairment of the excretory powers of the kidneys, there never having been at any time any evidence in the urine of disease of the kidneys themselves. It is hard to understand how a low grade inflammatory process in the pelves of the kidneys, which is the condition in pyelitis, could interfere with the excretory powers of the kidneys. Furthermore, there were no evidences of disease of the circulatory system, except the slight rise in blood pressure at the last examination. It is hard to believe that the pyelitis could by reflex action through the nervous system have had any such action. The tuberculin test was negative and there were no evidences of syphilis. Neither of these conditions would, moreover, be likely to cause the manifestations present in this instance. Neither

does it seem reasonable to suppose that such conditions as stone in the kidney, twisting or kinking of the ureters or displacement of the kidneys, even if it was possible for them to exist for so long a time without symptoms pointing definitely to them, would cause such a peculiar impairment of the functions of the kidneys.

The development of the spasmophilia is easier to explain. On account of the impairment of their functions the kidneys were unable to excrete the salts given for the treatment of the pyelitis. If spasmophilia is due, as it seems reasonable to suppose, to a disturbance of the balance between sodium and potassium on the one side and calcium and magnesium on the other, all the conditions necessary for the development of the disease were present. Practically, it makes no difference whether the balance was disturbed by a simple retention of sodium or potassium without any driving out of calcium and magnesium or by a combination of the two.

The prognosis seems absolutely bad. Even if it was possible to cure the pyelitis, that would presumably not improve the excretory powers of the kidneys, in fact, there is nothing which can be done to accomplish this. The only treatment seems to be to spare the kidneys as much as possible by limiting the proteins in the diet to minimum needs and to favor the elimination of excretory products through the kidneys by the administration of large amounts of water. Furthermore, the alkaline salts should be eliminated from the diet as far as possible and certainly none of them should be given for the treatment of the pyelitis.

70 BAY STATE ROAD.

SOME INTERESTING PEDIATRIC CASES

*With a New Method of Bacteriological Study and Treatment.**

BY MYER SOLIS-COHEN, A. B., M. D.,
Philadelphia,

Pediatricist to the Jewish Hospital, Philadelphia, and to the Eagleville Sanatorium for Consumptives; Director of the Jules E. Mastbaum Research Laboratory of the Jewish Hospital, Philadelphia.

The bacteriological studies made in the four cases reported are based on a test for immunity and susceptibility described by the writer in conjunction with George D. Heist and Solomon Solis-Cohen (1). We found that the whole, fresh, uncoagulated blood of animals immune to pneumococcal infection, such as the pigeon and the chicken, killed the pneumococcus; while the whole blood of animals highly susceptible to pneumococcal infection, such as the mouse and the rabbit, served as an excellent culture medium for the pneumococcus. Similarly we found (1) that the globoid bodies grew vigorously in the whole blood of human beings, who are susceptible to acute anterior poliomyelitis, but were killed by the whole blood of rabbits, which are immune; and that diphtheria bacilli (2) multiplied rapidly in the whole blood of the susceptible guineapig and are destroyed by

*Read before the Philadelphia Pediatric Society, November 9, 1920. The bacteriological studies recorded in this paper were made in the Jules E. Mastbaum Research Laboratory of the Jewish Hospital.

the whole blood of the immune rat. Matsunami and Kolmer (3), using our method, demonstrated similarly that little or no growth of meningococci takes place in the fresh, whole blood of the immune rabbit, while in the susceptible mouse growth is vigorous. Incidental to our work we found that contaminating organisms usually failed to grow in whole uncoagulated blood.

These facts make us think that animals possess in their blood a bactericidal power against all organisms that are not pathogenic for them or for their species and lack bactericidal power against those organisms that are pathogenic for them or their species.

The question then arose in my mind whether infection in man might not be due to or associated with absent bactericidal power in the infected individual against the infecting organism. In such an event it might be possible from a number of organisms present in a discharge to separate those that are etiological or infecting from those that are merely saprophytic or accidental contaminations. At least, if the patient's blood were bactericidal to an organism present, it would be reasonable to infer that the patient was immune at the time to that organism, which consequently could hardly have any part in the infection. On the other hand, if the patient's blood had little or no bactericidal power against an organism present, it would indicate susceptibility on the part of the patient to that organism, which therefore might be regarded as possibly being an infecting organism. The late George D. Heist studied a number of cases with me at the Jules E. Mastbaum Research Laboratory of the Jewish Hospital and Louis S. Borow has studied others with me in the same laboratory. Our studies (4) demonstrate that the blood of human beings possesses bactericidal power against large numbers of organisms; that the blood of an individual differs in its bactericidal power against different organisms; that bactericidal power against a particular organism varies in different individuals; that in the discharge of an infected area organisms can usually be found against which the blood of the infected person has little or no bactericidal power; that frequently in such discharge or on such area other organisms are found against which the patient's blood has good bactericidal power; that organisms that are supposed to grow well in human blood fail to grow, at all in the blood of some individuals; and that organisms that are supposed to grow poorly or not at all in human blood may grow with the greatest vigor in the blood of some individuals.

The practical object of these studies was to make vaccine treatment more specific. It was thought that failure of autogenous vaccine treatment might be due sometimes to failure to include the etiological organisms in the autogenous vaccine and that certain harmful effects might be due to the injection of unnecessary foreign protein in the form of organisms that have no part in the infection. We regard the object of vaccine treatment to increase the bactericidal power of the blood against the infecting organism.

This view was based on observation made in

association with George D. Heist, and Solomon Solis-Cohen (1), that recovery from an attack of lobar pneumonia is paralleled by an increase in the power of the patient's blood to kill the type of pneumococcus causing the infection, and that the intravenous injection of dead pneumococci into rabbits produces bactericidal activity in the rabbit's blood which is specific to type. A similar rise in the bactericidal power of the blood was observed by Black, Fowler and Pierce (5) in rabbits following their intravenous, subcutaneous or intraperitoneal inoculation with dead typhoid bacilli and *Bacillus dysenteriae* of Shiga. We consequently regard it as at least unnecessary, if not harmful, to introduce into the system dead organisms against which the patient already has high bactericidal power.

In each of the four cases here reported an attempt had been made to discover the infecting organism; three received vaccines containing only those of the organisms present against which the patient's blood lacked bactericidal power; to the fourth serum was given. The cases are reported because of a number of interesting features they present. No assertion is made that the organisms obtained were actually etiological or that the improvement was due to the treatment. It is felt, however, that the results warrant further investigation and study of the method employed.

CASE I.—A. M. J., a baby girl, fourteen months old, was brought to my office on October 10, 1919. She had been a full term child, delivered normally. When four weeks old she had had diarrhea, which was cured after three months. When the child was nine months of age fever developed, the cause of which was obscure. The condition was regarded as acute double otitis media. Incision of both tympanic membranes had no effect on the high temperature, which persisted for two weeks. There was never any discharge from the ears, although a few particles were washed out. During the summer preceding her visit the baby had several attacks of fever accompanied by a whining cry of discomfort and evidences of pain. Apparently there had been no pain on urination, but there had occasionally been pain on defecation. During the last week in August the temperature had been 104° to 105°. Pus had been found in the urine in September and a diagnosis of pyelitis was made. Since then the pus had appeared and disappeared and the attacks had returned at intervals. Between the attacks the child was peevish and awakened at night. She had been in the best hands medically and had received the ordinary treatment.

Examination of the child was negative, except for a furunculosis, present chiefly on the buttocks. A culture on blood agar was made from the child's urine and from a papule on the buttocks. *Staphylococcus albus* and *Staphylococcus citreus* were isolated from both. A broth culture of each organism was diluted 1:10, 1:100, 1:1000 and 1:10,000 and each dilution was allowed to run in and out of a separate capillary tube, which was then filled with the baby's blood and sealed. After twenty-four hours' incubation the tubes were broken and a drop of each stained and examined under the microscope

to see if any organisms were present. *Staphylococcus citreus* had grown well in most of the tubes, but *Staphylococcus albus* had practically disappeared. A vaccine was prepared from *Staphylococcus citreus*.

TABLE I.

— Indicates no growth.
± Indicates doubtful growth.
+ Indicates growth.
++ Indicates vigorous growth.

Thirteen doses of a vaccine prepared from *Staphylococcus citreus* were administered at five day intervals, the dose being one hundred million, two hundred million, four hundred million, eight hundred million, and thereafter a thousand million. The baby improved in general health and appearance after the first dose. The crying spells with fever, etc., gradually diminished. The furunculosis cleared up. The urine showed some pus cells, on December 10, 1919, but none on February 26, 1920, or on October 25, 1920.

CASE II.—R. H., a little girl six years of age, came to my office on August 10, 1917, with a story that she had been subject since three years of age to attacks of high fever lasting two weeks, occurring chiefly in the spring and fall and preceded, accompanied and followed by weakness. These attacks had been diagnosed as malaria. For a year previous she had complained of frequent and urgent urination but had not wet her clothes. For the previous six months she had been irritable and easily upset, screaming and crying. She had lost weight. Physical examination was negative. The case at the time was regarded as one of enuresis and treated with tonic and belladonna, with some improvement. At this time the child was under observation for only three weeks.

Three years later, on August 16, 1920, the child returned with a history that the attacks with fever had continued, the last having been five days prior to the visit and the previous one two weeks before. Pain in the right lower abdomen had accompanied the last attack. The heart frequently became irregular during the attack. Between the attacks the child seemed well but had never been strong. She had lost weight, was always nervous and cried easily and frequently. Her appetite was poor. She had complained of palpitation and dyspnea on exertion for the past year and a half. For several years past she had suffered great distress when the bladder was full, which distress was somewhat relieved by doubling up. The urgency when the impulse to urinate came was so acute that she would wet herself if unable to relieve her bladder naturally.

The child was pale and poorly nourished. The heart was enlarged in all dimensions, its muscle was poor, and its action slightly irregular. There were some signs of infiltration of the upper lobe

of the right lung, without activity. The hemoglobin was sixty per cent. The urine showed pus cells in large numbers. A diagnosis was made of pyelocystitis. A blood agar culture of a catheterized specimen of urine contained *Bacillus coli* and *Bacillus lactis aerogenes*, both of which grew in the child's blood, the former very vigorously. This is the more remarkable as colon bacilli do not as a rule grow in human blood. Of fifteen men tested by George D. Heist and Solomon Solis-Cohen (6), *Bacillus coli* failed to grow in the blood of all.

<i>Bacillus coli</i> + Defibrinated blood	++	++	++	++	++
<i>Bacillus lactis aerog.</i> + Case 2	++	++	++	++	++
<i>Bacillus lactis aerog.</i> + Human control	++	+	—	—	—
<i>Bacillus lactis aerog.</i> + Defibrinated blood	++	++	++	++	++

As a control, one set of tubes was loaded with defibrinated blood. When growth takes place in the defibrinated blood and not in the whole blood, it indicates the presence in the whole blood of an antibacterial factor which is lacking in the defibrinated blood.

A vaccine was made of both organisms. A first injection of twenty-five million on September 20, 1920, was not followed by any general reaction, but the arm was sore for two days. The arm was slightly sore for one day following the injection of fifty million on September 27th. Injection of seventy-five million a week later was followed by the development of a large areola with swelling and induration, lasting two days, and by the child becoming irritable and nervous. Two subsequent doses of fifty million each and two of sixty million and seventy-five million respectively, produced no reaction. Hexamethylenamine and liquor potassii citratis have also been administered. There has been distinct general improvement with a gain of five pounds and three quarters in seven weeks until the severe reaction. For the past six weeks the child has not experienced pain or urgency when the bladder is full and has not wet herself. Examination of the urine on November 9, 1920, showed only a few leucocytes.

CASE III.—L. W., a little girl, four years of age, was admitted to my service at the Jewish Hospital on July 20th, 1920. No history was obtainable. The child was well developed but rather poorly nourished and lay somewhat listless, suffering from orthopnea. The pupils were equal and reacted normally to light and accommodation. The tongue had a curious geographical appearance, the epithelium being apparently denuded in places, where the papilla were prominent, the normal epithelium about their margins forming linear ridges which described circinate designs. The pulse was regular, weak, and of low tension. The left chest was slightly fuller than the right. A double thrill was present over the precordia. The apex beat was in the fifth interspace, a quarter of an inch outside of the nipple. There was a diffuse, undulating pulsa-

tion from one inch to the right of the sternum to the left axilla and episternal notch. The heart extended upward to the upper border of the third rib, on the left to one inch to the left of the nipple, and on the right to half an inch to the right of the sternum. The heart sounds were obscured by murmurs which at first could not be well made out. Later a double murmur, crescendo in character, was heard definitely over the entire chest, and transmitted toward the axilla (2) and scapula. The lungs and abdomen were negative. The systolic blood pressure was 75 and the diastolic 50. The temperature curve was septic in type, reaching 100° every afternoon, being unaffected by sodium salicylate in doses of seven grains and a half every three hours, or by quinine and urea hydrochloride in three grain doses three times daily.

The rhinopharynx was cultured on August 12th and from the blood agar plate three organisms were isolated, gram diplococcus, diphtheroid and Micrococcus catarrhalis. When incubated in the child's blood, the first grew up well, the last irregularly and the other only in undiluted culture.

A vaccine was made of the gram diplococcus. Twenty-five million were administered on September 6th, and again six days later. A week later fifty million were given and ten days later a hundred million. There was never any reaction. The temperature had been practically below 99° since the second dose, most of the time being practically normal, until October 14th when it went up to 98.8°, going to 99° on October 18 and 99.4° on October 22d. I went off the service on October 1st and my successor failed to administer any more of the vaccine, which probably accounts for the subsequent rise in temperature. In my opinion the vaccine treatment should have been continued for several months.

CASE IV.—R. D. Upon coming on duty in the pediatric ward of the Jewish Hospital on July 1st of this year, I found a girl of ten years who had been admitted a week before with violent nose-bleed. The only points of interest in the family history were that a maternal uncle had been subject to severe hemorrhages, her mother was subject to urticaria, and her father used to perspire freely. The patient was said to have been a full term baby, with normal delivery, but to have weighed only three pounds at birth. She had never been ill until her third year, when she contracted pneumonia, followed by empyema, for which rib resection was performed. Convalescence was protracted for nine

months and the child had never been robust since, but had always been pale and had experienced dizziness. She never had had tonsilitis. A year previously she had had a vulvar abscess. She had had no cardiac symptoms prior to a year before, when the first epistaxis occurred upon stooping after running. Other nasal hemorrhages had occurred since, a very serious one four months before admission and another, also severe, one week before admission. She complained of excessive perspiration at night, on exertion and on excitement, but not of weakness, dyspnea or palpitation.

The child was poorly developed, poorly nourished, and very pale, her lips, gums and conjunctiva being extremely pale. The pupils were equal and reacted well to light and accommodation. The tongue was slightly coated. The pulse was 160, regular, weak, and of low tension. The apex beat was in the fifth interspace, anterior axillary line. There was a pulsation over the lower precordia. The cardiac boundaries were the upper border of the second rib, the left anterior axillary line and an inch and a half to the right of the sternum, the transverse diameter measuring six inches and a quarter and the vertical diameter four inches. At the mitral area a blowing systolic murmur, with probably a presystolic element, was heard, which was also heard all over the precordia and in the axilla. A soft systolic murmur was also heard at the base of the heart, more pronouncedly to the left of the sternum. In the sixth interspace in the left axilla was a scar two inches in length. There were no depressions above or below the clavicle.

The veins were slightly prominent over the chest. Expansion was slightly diminished. There was moderate dullness on the right anteriorly on, above and below on the clavicle and slight dullness below this down to the lower border of the second rib. There was dullness over the whole left chest anteriorly. The percussion note, though resonant, was somewhat impaired. Posteriorly there was dullness on the left above the third rib and on the right above the first rib and below the fourth rib, becoming flatness below the eighth rib. Fremitus was increased anteriorly on the right and diminished on the left. It was increased posteriorly on the right above the fifth rib and absent below the seventh rib, and on the left it was increased above the eighth rib. Vocal resonance anteriorly was increased on the right above the second rib with slight whispering pectoriloquy on the left above the second rib. Posteriorly it was increased on the right above the fourth rib and absent below the seventh rib, and increased slightly on the left between the fourth and eighth ribs, more markedly above. There was slight whispering pectoriloquy posteriorly above the third rib on the left. The breath sounds were faint anteriorly and negative posteriorly. The x ray demonstrated both lungs somewhat infiltrated, the right hilus showing many enlarged glands. The heart was seen to be greatly enlarged, mostly upwards and to the left. Stereoscopic examination with the tube thirty inches from the plate showed the greatest width of the heart to be six inches and the greatest height of the heart shadow four inches and a half. The urine con-

tained a faint trace of albumin, a few light granular casts and many leucocytes. The blood had a hemoglobin content of fifty per cent.; the leucocytic count was 7000 and the differential count, polymorphonuclear neutrophils sixty-nine per cent., large lymphocytes nine per cent., small lymphocytes twenty per cent., eosinophiles one per cent., basophiles one per cent. The clotting time of the blood taken with my modification of Milian's method (7) was ten minutes. The systolic blood pressure was 124 and the diastolic 55. The sputum contained pneumococci, streptococci, *Micrococcus catarrhalis*, pus cells and blood, but no tubercle bacilli. The vaginal smear was negative. No reaction followed the intracutaneous injection of old tuberculin (O. T.) in doses of 0.000,0001 mg., 0.000,01 mg., and 0.000,1 mg. The temperature was of the septic type.

My feeling was that an organism that had participated in the pneumonic process seven years before had caused the empyema and was probably responsible for the cardiac complication and possibly also for the vulvar abscess of a year previously. There was also a possibility that the pulmonary infiltration was a chronic process dating from and consequent to the pneumonia. It was thought that the etiological organism might be found on blood culture, but a culture of the blood on broth proved sterile. It was then thought that if the same organism was the infecting agent of both the heart and the lungs it would be found in the rhinopharynx and might be recognized by the absence of bactericidal power against it in the patient's blood. We employed a different method of culture and test than we used in the other cases, one that permits a rapid isolation and identification of the organisms against which the blood is lacking in bactericidal action, but which does not measure the degree of bactericidal power present. It is best applicable in adults and older children. A swab from the rhinopharynx was lightly rubbed on the bottom of a sterile test tube, into which five cubic centimetres of blood from the child's vein was then introduced. A culture was also made on a blood agar plate, upon which grew *Staphylococcus albus*, streptococcus and a diphtheroid bacillus. The culture in the child's blood was incubated for twenty-four hours and then a blood agar plate was inoculated with a drop of the blood.

A pure culture of many hemolytic streptococci grew up. We deemed it unwise to administer a vaccine and instead injected antistreptococcal serum. One dose of ten c. c., two doses of twenty c. c. and four doses of forty c. c. were given at intervals of from one to four days. After the third dose the temperature curve began to drop, reaching normal two days after the fourth dose and remaining normal two days later. It rose again and did not begin to fall again until two days after the last dose. A gradual decline then occurred, no rise over 99° occurring after the eighteenth day following the last dose, and there being little rise at all a month later and thereafter. The child improved clinically, being allowed to sit up in bed on August 14th, to sit on a chair a week later and to begin walking ten days subsequently.

She gained two pounds and three quarters in twelve days. Quinine and urea hydrochloride in five grain doses was given three times a day from August 5th to 10th and four times a day from August 10th to September 9th, without producing tinnitus. She was discharged from the hospital on October 8th, at which time she was walking about all day.

THE USE OF ATROPINE IN THE TREATMENT OF THE HYPERTONIC INFANT.*

BY ALBERT D. KAISER, M. D.,
Rochester, N. Y.

There exists in the hypertonic infant a definite physical and psychic syndrome which is characterized by hypertonicity of all the skeletal muscles. The symptoms presented by this class of infants are those of vagotonia. The occurrence of hypertonicity among infants is not rare. It is found in breast as well as bottle fed babies. The most common picture is that of the unhappy and restless baby, crying a great deal, sleeping for short periods only, and subject to frequent attacks of colic, accompanied by vomiting. Constipation is common. In spite of these symptoms the infant may be taking food regularly and show a satisfactory growth and increase in weight. Attempts to alter the food seem to have little or no effect in eradicating these symptoms. These mild manifestations generally go uncorrected until the infant takes solid food. In other cases malnutrition results from the vomiting and lack of sleep, presenting a serious picture.

The symptoms of hypertonia can be grouped under physical and psychic as outlined by Haas in his description of this condition. The physical symptoms are chiefly expressed by muscular irrita-

*Read before the Seventh District Branch of the New York State Medical Society, October 7, 1920, at Rochester, N. Y.

bility, visible peristalsis, vomiting which begins in early infancy, mild at first but later becoming projectile in type, leading to a diagnosis of pylorospasm, constipation, and malnutrition. The psychic symptoms are general restlessness, crying, and insomnia. In studying these infants it becomes apparent that the fault is not with the food or environment, but with the infant itself. There is some mechanism in the hypertonic infant which is unstable and causes these manifestations.

In order to make clear the reason for using atropine in the treatment of this condition, it is important to review what is meant by the symptoms of vagotonia. The nervous system is made up of the sensorimotor and the vegetative systems. The vegetative is composed of the sympathetic and autonomic. Under normal conditions a sort of balance exists between the innervations in the two antagonistic systems, this balance being kept up probably by chemical action of hormones upon the nerve cells. Any disturbance in equilibrium may cause a temporary upset in the exercise of physiological function. In vagotonia there are various clinical symptoms indicating heightened tonus throughout the craniosacral autonomic system. This heightened tonus may cause stimulation of the vagus, which would lead to turbulent gastric peristalsis which readily changes into retrograde peristalsis and may manifest itself in vomiting. As atropine paralyzes the vagus and causes a relaxation of the intestines, its use can readily be seen in this condition. Inasmuch as there is a close relationship between the autonomic nervous system and the glands of internal secretion it must have an influence upon the mechanism of digestion.

If the assumption that the disorder is due to impaired action of the vegetative nervous system is correct, the use of atropine as a therapeutic agent is sound. Atropine is the drug of choice of those paralyzing the vagus endings, inasmuch as it is well tolerated by infants and particularly by the hypertonic baby. To procure desired results it must be administered accurately, bearing in mind that an active preparation is essential and that the drug deteriorates. The method of treatment as outlined by Haas has given the best results and has been followed in these cases. A one in a thousand solution is used. The usual dose to begin with is one drop or one thousandth of a grain in each feeding, or in a small amount of water before breast feedings. The mother or nurse is informed of the toxic symptoms. The dose is increased to two drops for the next twenty-four hours if no untoward symptoms develop. In order to procure the desired relief of symptoms three or four drops six or seven times a day may be necessary. The average hypertonic infant will tolerate from one fiftieth to one twenty-fifth of a grain of atropine a day. It is rare to find an infant in whom a thousandth of a grain will cause flushing of the face. The toxic symptoms that develop, in the order of their frequency, are: Flushing or reddening of the face and body (this may simulate a scarlet fever rash); dilated pupils and absence of reaction to light; dryness of the lips and mouth and inability to secrete tears; irritability with evidences of jerky

movements. The symptoms are not serious as in most instances the flushing is first observed, which disappears in a short time after discontinuing the use of the drug.

The hypertonic infants treated presented different pictures, but the treatment was the same as far as the use of atropine was concerned. In most cases there was no change in diet, although it was necessary to make additions to the dietary as soon as the irritability was lessened. A description of a few type cases representing the different groups of symptoms manifested in the hypertonic infant will give a better picture of the results of the treatment.

REPORT OF CASES.

CASE I.—Raymond B., normal, full term baby; birth weight seven and one half pounds. He was breast fed for two months; did poorly on breast, vomited frequently, had colic, and was restless. The baby was put on a whole milk mixture, but no improvement was noted. When first seen the baby was three months of age and presented the following symptoms: Vomiting with no relation to feedings, marked irritability, restlessness, crying, and insomnia. The weight was eight pounds. The stools were well digested and the formula seemed to be a rational one, so was not changed. Two drops of a one thousandth solution of atropine were given in each feeding. A definite improvement was noted in forty-eight hours. The vomiting ceased, there was less crying, and the infant slept better. There was a gain in weight the first week, which continued. In the next six weeks the baby gained two and a half pounds and seemed to be normal in every respect.

CASE II.—Lena G. was sixteen months old when she was sent into the hospital. She had always been an irritable baby and no food seemed to agree with her. For some months she had been taking cow's milk, but made no appreciable gain. On entrance her weight was fourteen and a half pounds. Crying was the outstanding symptom; this was so severe that it was feared the child would go into convulsions. The crying spells occurred frequently at night. There was a mild diarrhea, but no vomiting. It was estimated that the baby was getting sufficient food, though apparently not assimilating enough. Assured there was nothing else at fault but the hypertonicity, atropine was administered.

There was a rapid movement in the general condition of the child. The child became happy and contented, crying little and sleeping all night. With increased food the weight went from fourteen and a half to nineteen pounds and three quarters in seven weeks. The atropine was discontinued after six weeks.

CASE III.—John S. was a full term baby. He had breast milk for only two weeks. Cow's milk and a prepared food were given. The birth weight was seven and a quarter pounds. At the end of the third week vomiting began, which became more and more severe and eventually projectile in type. Little food was retained and it became difficult to secure a bowel movement. At the end of the fifth week, when the baby was first seen, it presented the picture of a starved baby. The least little sound would startle it. There was visible peristalsis and pro-

jectile vomiting, but no tumor mass felt. The weight was seven pounds. A diagnosis of hypertonia and pylorospasm was made. The color was poor and on the whole the prognosis did not seem good. The baby was first given a thick gruel feeding but even this could not be retained until atropine had been given. No results were obtained until three drops were given before each feeding. The intestinal activity became less marked and the food was retained. When the vomiting ceased the old formula of milk and the prepared food was again given. The irritability subsided and the baby began to gain. From June 5th to September 2nd the baby gained five and a quarter pounds and seemed normal in every way. Twice the atropine was discontinued and promptly the vomiting returned. Now the mother does not dare leave out the atropine.

In the last six months ten babies classified as hypertonic infants have been treated in this way. A marked improvement followed in all with the use of atropine, without any change in diet. It must be remembered that not all cases of vomiting, constipation and malnutrition are due to hypertonia, so unless the use of atropine is restricted to undoubted cases of hypertonicity, failure will result. Corrections in diet and habits should be made, but if in spite of this the infant presents symptoms of irritability atropine should be tried. The use of atropine will soon demonstrate the correctness of the diagnosis, for the relief of symptoms is evident in a few days and improvement continues as long as the drug is maintained. Atropine must be continued for a variable time.

SUMMARY.

The hypertonic infant presents a definite clinical picture, due to a disturbance of the autonomic nervous system which gives rise to physical and psychic disturbances.

The usual manifestations are irregular vomiting often with visible peristalsis, constipation, malnutrition, muscular irritability, representing the physical defects, and with insomnia and crying as psychic disturbances.

The diet usually needs no change in the hypertonic infant and the food is well digested.

A solution of atropine gives early relief of symptoms in these cases and thereby metabolism is increased, bringing about the desired gain in weight.

The use of the atropine is not dangerous if given in guarded doses and the early toxic symptoms are noted.

29 BUCKINGHAM STREET.

Case of Lethargic Encephalitis with Post-mortem Examination.—Ducamp, Blouquier de Claret, and Tzélépoglou (*Bulletin de l'Académie de médecine*, May 11, 1920) report a typical fatal case of lethargic encephalitis with pathological study of the brain. The lesions at present considered characteristic of the disorder were found, namely, acute perivascularitis with diapedesis and cellular degeneration, the process as a whole being situated particularly in the gray matter of the mid-brain. The cause of certain ocular disturbances witnessed during life was accounted for by degenerative changes in the corresponding centres.

THE CLASS METHOD OF TREATING MALNUTRITION IN CHILDREN.*

BY WILLIAM HENRY DONNELLY, M. D.,
Brooklyn, N. Y.,

Instructor in Pediatrics in the New York Post-Graduate Medical School and Hospital; Chief of Nutrition Clinic in the Brooklyn Hospital.

At the outset in a paper on malnutrition in children it might be well to make clear what shall be understood by malnutrition, subnutrition, or undernourishment. Emerson, of Boston, at first classed as undernourished any child ten per cent. under weight for his height, but later he made seven per cent. the standard. This is one criterion by which to judge the state of nutrition of any child, but there are other factors involved, and it has seemed to some of us interested in this work that a child can be up to the standard of weight for its height and still be sufficiently undernourished to attract attention and require active treatment. Dr. George Newman, chief medical officer of the Board of Education for England and Wales, clearly has this in mind when, in his annual report for 1915-16 he defines malnutrition as "a low condition of health and body substance. It is measurable not only by height and weight and robustness, but by many other signs and symptoms." These signs are the color, the brightness of the eyes, the carriage, the disposition, sleep, digestion, regularity of the bowels, and the condition of the muscles.

Malnutrition in childhood is the underlying reason for the alarming proportion of defects and rejections found in the physical examination of recruits in the late war. It has been estimated by Emerson and other observers that about a third of all school children are undernourished, and yet this school age is the one most neglected by the average practitioner and medical school teacher.

The student, whether undergraduate or graduate, has the importance constantly impressed upon him of the feeding and general care of the infant up to the end of the first year of life; there is much less attention paid to the welfare of the child during the next period of early childhood, whereas once he reaches the school age he gets scarcely any attention at all.

If the school child has glaring defects they are noted by the school physician in his routine examination, but he cannot compel their correction. As a result there is in every community a veritable army of children whose appearance is such that with a casual looking over they will pass as normal in health and nutrition, whereas they may be in such a state of subnutrition as not only to render them more susceptible to disease but also to prejudice their chance and right to grow up to normal adult height, weight, and health.

Causes of malnutrition may be divided into real disease or abnormal condition, and faulty hygiene and diet. In the first class three conditions occupy the foreground, namely, diseased tonsils, tuberculosis, and concealed or latent congenital lues. Tuberculosis is usually glandular in its origin in childhood and the mediastinal gland groups should

*Read before the Medical Society of the County of Kings, Brooklyn, New York City, October 19, 1920.

especially be suspected. Here the x ray and D'Espine's sign will help in the diagnosis. Our conception of this sign is based upon the original interpretation of D'Espine (1) himself, who wrote: "The first signs of bronchial adenopathy are furnished by the auscultation of the voice, and are observed almost always in the immediate neighborhood of the vertebral column, between the seventh cervical and upper dorsal vertebræ, either in the supraspinous fossa or lower down in the interscapular space. They consist in a timbre added to the voice which one may call whispering (*chuchotement*) in the first stage, and bronchophony in a later stage." We have always considered any whispering bronchophony below the level of the seventh cervical vertebra as presumptive evidence of the existence of enlarged bronchial glands, whether tuberculous or not.

Persistent failure of a child to gain after the performance of corrective measures, such as tonsillectomy and dental repair, is always suggestive of either tuberculosis or congenital lues. In the absence of a positive Wassermann test certain dental stigmata may help in the diagnosis of lues. These are the separation of the upper central incisors first described by Roberts and the presence of accessory cusps on the upper permanent molars first reported by Sabouraud.

Diseased tonsils are now looked upon, with other factors in nasopharyngeal obstruction, as more common in the cause of malnutrition than carious teeth. One reason for this is that at the age when undernourishment is most marked, namely, the preschool and early school years, caries exists mainly in the persisting deciduous teeth, whose apices and roots have been partially or wholly absorbed, and hence focal infection from apical abscesses is physically improbable.

Cyclic vomiting or food idiosyncrasies may be found to be causative factors in many cases representing real food sensitization, which may be verified and the treatment indicated by doing the skin tests with the various proteins. Organic disease of the kidneys, blood, intestines, especially the presence of intestinal parasites, must be ruled out or corrected before the case will respond to the general treatment laid down for the undernourished child.

The second class of cases are not due to real disease, but to errors of hygiene or diet, or to the abuse or improper use of exercise and muscular activity. Food may be insufficient in many ways. It may be insufficient in quantity and, therefore, cause constipation from lack of bulk in the bowel, or it may be deficient in calories or vitamins, or both. Especially to be mentioned and condemned are tea, coffee, candy and ice cream between meals, cake, thin broths, too much fluid at meals, and similar errors in diet.

Factors other than food in the causation of malnutrition were well brought out in a paper read before the Child Welfare Convention in New York in May, 1920, by Dr. Hugh L. Chaplin. We can heartily endorse his statements regarding the importance of insufficient sleep, improper ventilation of rooms during sleep, too short lunch periods, insufficient or too much exercise, uncleanliness of the

body, and many other faulty habits of life. The undernourished child should be looked upon as a sick child and his habits and activities should be regulated and not left to him to decide. These children are possessed of a restless spirit out of proportion to their physical strength, and if left to their own inclinations will exhaust themselves and prevent the desired gain in weight and strength. It has been found that these children become physically tired in the early afternoon and, therefore, it has been made a universal rule in this work to insist on a rest period of preferably a whole hour after school, with the taking of a light lunch of bread and butter and a glass of milk to restore the flagging energy of the undernourished body.

Within recent years there has been a startling awakening to the vital importance of the malnutrition problem in school children, and, as the most efficient and practicable method of combatting the evil has been found to be the nutrition class, it would seem that a brief history of class methods deserves a place here. Investigation of the literature reveals the fact that as far back as 1890, Dr. Minor, of Asheville, N. C., used the class method of treating tuberculosis in his private patients. However, it was not until July, 1905, that this method was applied to poor patients by Dr. J. H. Pratt, of Boston, who in that month organized the Emanuel Church Tuberculosis Class, which met at the Massachusetts General Hospital, and for which funds were provided by the church from which it derived its name. This was the first attempt to treat poor patients in their homes in a large city. The patients were given directions as to hygiene, rest, outdoor air, and other essentials, and were instructed to keep a record of their temperature, hours of rest, food taken, action of the bowels, and other data. This record was brought to the weekly meeting of the class, where it was gone over by the medical director, who gave such individual advice as seemed necessary and then gave a talk to the whole class. It was happily seen at the outset of this class work that a social service worker or visiting nurse was indispensable, and this agrees perfectly with the experience of everyone who has since attempted to conduct a class of any kind, whether in tuberculosis, cardiac disorders, or nutrition. In 1906, Dr. John B. Hawes, 2nd, also of Boston, organized the Suburban Tuberculosis Class, with equally good results, and from that time on the class treatment has been allied to various conditions with gratifying results.

Having taken up the development of the class method of treatment, we naturally go on to the application of this method to the treatment of nutritional disturbances in children especially of the school age. It seems that the first serious attention to the problem was given in England during the Boer war, when the war department was chagrined at the enormous number of rejections of applicants for enlistment in the Army and Navy. This gave rise to an investigation, after the war, of the health conditions in the schools, resulting in the providing of school lunches in the endeavor to correct malnutrition. These lunches were finally given up as inefficacious.

On this continent Dr. W. R. P. Emerson (2), of Boston, was the pioneer not only in calling attention to the widespread existence of malnutrition in school children, but also in organizing classes for its treatment. In the fall of 1908 he collected fifteen children at the Boston Dispensary, who were the weakest and poorest nourished of four or five thousand children seen during that year. He laid down rules of rest, hygiene, diet, and of conduct of the class, which have required remarkably few changes up to the present time, and he has regarded from the beginning as indispensable the services of a good social worker to visit the homes of the children. By the aid of such a worker it is possible to find out on what floor the child lives and, therefore, whether excessive stair climbing has a bearing on the case, whether there is overcrowding in the household, whether the mother is preparing or knows how to properly prepare the food prescribed.

Having secured the assistance of such a social worker, the next important point in the organization of a nutrition class is the preparation of a proper physical examination blank. Emerson again was the first to draw attention to the necessity of a complete standardized blank form. Whatever form is adopted there are a few essentials to its rapid and practical use, namely, the placing in such a prominent position as to be seen at a glance, the child's age, height, weight for height and age, average normal weight for height and age, number of pounds below weight, and percentage below weight. In most blanks available these figures are placed in such a position and in such a part of the form as not to be easily found. Other requisites are suitable rooms for weighing, accurate scales and measuring rods, a large table of weight standards so placed as to be seen at a glance; if possible, a food exhibit in wax or other plastic material which may be studied by the children and their mothers while awaiting their examination, and which may be used by the class director or nurse for demonstrating relative food values.

A special point which has been taken up in the Brooklyn Hospital Nutrition Class, and which presents great possibilities, is the utilization of what is otherwise wasted time in the presentation of suitable moving picture films, or the instructive and amusing antics of Cho-Cho the Health Clown, or the dazzling appearance of the Health Fairy. The Health Department of the State of New York has educational motion picture films available for this purpose. In order that the nutrition class or clinic may be able to do its best work without handicap, there should be the closest interlocking and cooperation of the other clinics in the hospital, such as the eye, ear, nose and throat, the orthopedic and the surgical. Furthermore, there should be active and real cooperation of the indoor department of the hospital so that cases sent into the hospital for treatment or operation should have the corrective measures advised by the nutrition clinic carried out, and of the greatest importance, so that a complete and accurate record of such treatment should be sent back to the clinic for the intelligent further nutritional management of the case. Of great value in the actual conduct of the class have been found

two forms, for which we are indebted to Dr. Charles Hendee Smith, of Bellevue, namely, the home record sheet and the complete diet list for the guidance of the mother in the preparation of the food. The home record sheet is given to each child at its first visit to have recorded thereon a full report of activities and food taken for forty-eight hours, and this is repeated when at any time the child ceases to gain and a cause for such failure is sought. A suitable weight chart is necessary, competition is encouraged by the offering of rewards for gain in weight, or carrying out of corrective measures, and, finally, in order to know definitely the efficacy of hygienic, dietetic and corrective measures, no medicine is given where it is possible to avoid it.

By the carrying out of these simple measures, without the administration of any medicine, whether tonics or otherwise, a large group of undernourished children have been made to gain in a nutrition class at Brooklyn Hospital at almost one and a half times the normal rate. The actual figures of the class record for six months will be considered elsewhere.

From a review of the literature, from personal interviews with other workers in this field, and from personal experience in the conduct of a nutrition class, the following conclusions seem justified:

1. Malnutrition is widespread in children, especially those of the school and preschool age.
2. The class method is the one of choice in the treatment of malnutrition cases.
3. Essentials in the efficient conduct of a nutrition class are a trained social service worker, a thorough physical examination recorded on a standardized blank, correction of organic defects and of faulty diet, insistence on rest periods during the day, the arousing and sustaining of the child's interest.

SIX MONTHS' EXPERIENCE WITH A NUTRITION CLASS.*

BY LOUIS M. RUDERMAN, M. D.,
Brooklyn, N. Y.,

Clinical Assistant in Pediatrics in the New York Post-Graduate
Medical School and Hospital, and in the Brooklyn Hospital.

The nutrition class of the Brooklyn Hospital commenced its work at about the beginning of the current year with a small initial attendance. Membership in the class was limited to children of school and kindergarten age five per cent. or more under weight. The class increased in size so rapidly that after two months no more new material was added, and intensive work continued with the fifty children in attendance. This number has formed a basis for our present report and conclusions.

Before proceeding with our figures it should be borne in mind that the average child we had to deal with was rather satisfied with the old factors of its environment, and that the work which we attempted to do imposed a sort of burden which some were unwilling to assume. Thus, it had been the custom of our average child to rise late, eat a hurried breakfast without washing its hands and face or brushing the teeth. The midday meal would be rushed through in the same manner. After school the child would remain playing in the street till sunset or later, or would be put to some quasi-profitable task at home. After the evening meal the child would resume its recreation outdoors, often until midnight. Toothbrushes as personal property were almost unheard of, and a bath was either a monthly feature or a pleasure indulged in only during the warm season, when the family enjoyed its weekly immersion in the surf.

The nutrition class came and superseded this unhygienic routine by a more rational regimen, more healthful and natural. There was a good measure of inertia to overcome, and the work often taxed all the ingenuity of physician, nurse, and social worker. The mother, whose cooperation was essential to our success, was often hard to win over, due chiefly to her ignorance of our purpose and to the novelty of the idea. She probably considered our efforts an interference with her domestic régime, hence the indifference which occasionally militated against our endeavors. To these factors must be added the poor intellectual material generally prevailing in our field of operations. Our nurse has had to contend with these obstacles, and even after much patient coaching, we have often received but a weak response. For example, a child advised to take an afternoon nap would be put by the mother to the task of pulling bastings or sewing on buttons, and as a result she lost her opportunity either for sleep or for outdoor exercise. Again, a mother of seven children, one of whom is the object of our study and help, would not prepare any cereal for the morning meal when they were accustomed to bread and butter and coffee. It was therefore much easier for us to give advice than for them to follow it.

The following figures are based on our records:

Total number of children, fifty.
Period of observation, six months.

Average age, eight years eight and one half months.
Average height, forty-nine inches.
Average weight on admission, fifty-two and one half pounds.
Normal weight for age and height, fifty-seven pounds.
Average per cent. under weight on admission, eight.
Average weight at the end of six months, fifty-four pounds thirteen ounces.
Normal weight for age and height at the end of six months, fifty-eight pounds.
Average per cent. under weight at the end of six months, five and one half.

ANALYSIS OF OUR FIGURES.

Attendance.—The average number of visits of each child was nine and five tenths, or about thirty-five per cent. of the total. The older children were more faithful in this regard, since distance and the weather did not interfere so much with their attendance. The younger members, however, had to come accompanied by a parent or an older child, hence the larger number of absences. Influenza and the usual seasonal respiratory diseases kept some children away for a month or longer. However, once the interest was acquired, many children presented themselves every Saturday morning for a number of weeks in succession.

Age.—The youngest member of the class was five and the oldest fourteen. The older children could be reasoned with more successfully and their co-operation gained more easily than the younger ones, who could not fix their attention very long, and in whom the interest in the class was likely to lag quickly.

Weight.—Our standard was the table of weights for both sexes at different ages and heights issued by the Child Health Organization. We assume that a normal steady gain in weight indicates general good health, except in cases of myxedema, nephritis and other infrequent conditions. Our aim has been to regulate the life of the child so that it would show a gradually mounting weight curve, although such a curve often showed many capricious variations which at times were difficult to explain. One child would gain but little under most careful supervision and strict obedience of orders as to diet and hygiene. Another would gain considerably in spite of poor all around management. While a child of eight or nine years should gain two pounds in six months, our children showed an average gain of two and one half pounds, reducing the percentage under weight from eight to five and five tenths. There was no great accuracy in weighing, since the children were weighed in their stockings, with all their clothes on, and their clothes would vary inevitably with the season and the weather. Again, the scales themselves were a considerable source of error, since they varied under changing conditions of weather, roughness of handling, and length of time in use. However, all these errors are minimized when the figures covered fifty children for a period of six months.

Defects.—The detection and elimination of defects formed a large and important part of our work. After a thorough physical examination, various defects were discovered and noted. Twenty had one or more carious teeth; these children were referred for dental treatment. Four were found to have stigmata of congenital lues, and our diagnosis was

*Read before the Medical Society of the County of Kings, Brooklyn, New York City, October 19, 1920.

confirmed in each instance by the Wassermann test; these too were referred for treatment. Nineteen had diseased tonsils and adenoids; ten had them removed and the others are awaiting their turn. Twenty-four showed a positive D'Espine's sign, the meaning of which has been ably discussed by Dr. Donnelly. One had kyphosis and one scoliosis; one had phimosis; one had spastic paraplegia.

Procedure.—The general procedure with the class was as follows: Each new member at his first visit underwent a complete physical examination, and all findings, both positive and negative, were entered on a well planned and comprehensive chart. Here a prominent place was reserved for the summary of defects, which determined our treatment of the case. Height, and weight for height and age, were recorded, as well as the normal weight according to our standard table of weights. Laboratory work, such as a Wassermann test, blood count and urine examination, was done if necessary. Whenever any special examination or treatment was indicated, the child was referred to the several special departments of the hospital. Upon revisits the child was weighed and the weekly gain or loss in weight recorded. Then followed an individual conference with the child and the parent. The daily routine of the child was closely reviewed, and the questions of diet, sleep, play, and personal hygiene were thoroughly gone into and advice given accordingly. If there was a loss in weight this conference was particularly earnest and searching. The work of the morning was wound up with a short, simple and direct talk by one of the staff, addressed to the children and parents, epitomizing the experience of the morning and drawing conclusions therefrom. Sometimes it took the form of a quiz, utilizing the apperceptive mass of the children in teaching them the elementary principles of diet, hygiene and health.

CONCLUSIONS.

While these fifty children are still below par in state of nutrition, considerable improvement has been shown during the period of our work, being now only five and five tenths per cent. under weight. It must be remembered that these children came to us on account of their poor nutritional status. We have apparently succeeded in raising them to a nutritional level, where they are accomplishing what is expected of a normal child in this regard. They are all quite familiar with what we are trying to do, and are desirous of going ahead with the work. They are enthusiastic about it, and a friendly rivalry has sprung up among them as to the greatest gain in weight. By gaining the child's confidence and by showing it the way we hope to prosecute the work with even greater success than heretofore. We believe that if similar work is undertaken in every congested district of our larger cities it will greatly contribute toward making stronger men and women and better citizens.

Edema in Children Due to Fat Starvation.—A. B. Grubb (*Western Medical Times*, June 1920) says that edema in children is very often due to fat starvation and will respond within a few days to butter and cream.

SIMPLIFIED INFANT FEEDING.*

A Rational Feeding Program for the First Year of Life.

By FRANK HOWARD RICHARDSON, M. D.,
Brooklyn,

Assistant Pediatricist, and Chief of Children's Clinic,
Brooklyn Hospital.

Infant feeding, whether simplified or complicated, is something to be approached with caution. The changes have been rung upon it so often and in so many different keys that one feels like treading lightly and asking for a special dispensation for discussing it. And yet I think that no one will deny that infant feeding needs simplifying, if there is any subject within the broad scope of modern medicine that does. There are, perhaps, a number of reasons for this. Pediatrics, along with a number of other subjects in the medical curriculum that are of greater age as recognized specialties, is considered a minor subject in our medical schools, and is crowded out of the students' time and interest by other supposedly more important subjects. And yet pediatrics is the only branch of the whole array that deals with the well organism, and the only specialty that must be practised by the general practitioner.

As a result of this compression of a large and important subject into such a very small compass, the professor and instructors are inclined to emphasize the striking cases, the types less commonly encountered, rather than to dwell upon those far commoner and hence (to them) less interesting problems of everyday occurrence, and especially those concerned with infant feeding. The subject of infant feeding itself is one that has given rise to most acrimonious debate, due to honest divergence of opinion on the part of widely differing schools of thought. This difference of opinion as to what constitutes a satisfactory system for the feeding of infants has been able to persist as it has, because of the relatively wide limits of tolerance possessed by different infants, and by the same infant at different times for the most widely differing articles of diet. We have each of us but to consult our very recent memory in order to recall some perfect specimen of babyhood that has arrived at this condition on some feeding that we would have said must surely lead to speedy marasmus—explicable on no other grounds than the tremendously wide limits of food tolerance possessed by some babies.

The fact that such widely differing schools of thought could each of them point to a highly satisfying and successful series of cases, has led each group to believe that it had fairly solved the problem of infant feeding. It has also caused each group to doubt the possibility of attaining the equally successful series of cases claimed by the proponents of some entirely different set of principles. All have perhaps failed to put proper emphasis upon the fact that a great body of babies, fed according to any old methods or no methods at all, were worrying along perhaps almost as well as some of their special series had been doing. They had been

*Read before the Pediatric Section of the Medical Society of the State of North Carolina, at the Sixty-seventh annual meeting, held at Charlotte, N. C., April 21, 1920.

studying especially the sick baby, with his greatly narrowed limits of food tolerance due to the food injury that he had sustained; and had failed to attempt to formulate, from the experiences of this large mass of carelessly fed but fairly healthy babies. This is a simple method that could be readily taught the average student, graduate or undergraduate, and by him passed on to the average mother or nurse. In other words, the student has been taught a complicated method of feeding, desirable enough perhaps in special cases of food injury, but by no means essential for the great mass of well babies. Accordingly, he has been well nigh helpless in the face of the demand of the mothers for instructions for the feeding of their well children. This occurred because he had never been taught a simple system which simple folk, with a well baby, would take the time and trouble to follow.

The result of this lack of a definite routine procedure for use in the case of the average well child, such as can readily be taught to, and learned by, the average medical student, and by him translated into simple instructions for the average mother or nurse to carry out from day to day, can frequently be seen. We know that many otherwise able and conscientious physicians never attempt to interfere in the management of the well babies of their families. They regularly allow some elderly female to use her experiences of a generation ago to decide proportions, dilutions, quantities, and feeding intervals, for instructing the young mother when to take her baby away from the breast! Others, when appealed to, turn with a sigh of relief to the proprietary foods, which never fail to promise most flattering results—and at times, let us be frank enough to admit, achieve them. Many babies, we know, with the broad limits of tolerance that we have spoken of, survive this catch-as-catch-can process. Many more succumb.

While granting that we must individualize, even with our well babies, just as we individualize in cases of typhoid fever and in appendectomies, we can standardize and teach infant feeding just as we standardize and teach typhoid therapy and surgical technic. It does not seem too much to ask that the outlining of general principles should precede rules for specialization to meet individual conditions.

I have been brought to believe, from a survey of my own experience, that a large proportion of the cases that are referred, or drift, to the man practising pediatrics exclusively, whether in private practice or in hospital work, are feeding babies that could have been handled perfectly well by the family physician. He has failed, from the lack of a definite technic, to apply in his infant feeding cases the routine procedures which he is wont to apply in other cases. In other words, the pediatricist is achieving much of his reputation as the result of his successes with easy feeding cases, instead of being compelled to tax his skill and ingenuity over the difficult ones alone. If this is true, then there is a serious flaw somewhere in the program of medical education today. For the future welfare of the race is in the hands, not of the pediatricist, who sees comparatively few of the entire infant popu-

lation, but of the family doctor, who, sooner or later, sees the vast majority of them at least once in their lives. But it is to the pediatricist that the family practitioner, when in the embryo stage represented by the medical student, looks for his instruction in this most important matter. If we fail him (and my memory of the instruction given me during my undergraduate years leads me to think that we are failing him), can we blame him when he allows that more plausible teacher, the detail man from the proprietary food concern, to usurp the seat in the teaching chair that has been so inadequately filled?

And yet, hand in hand with this admitted unfamiliarity with the intricacies of infant feeding on the part of the great majority of the medical profession, goes a most amazing readiness to wean babies for the most trivial and inadequate of reasons. When one has struggled as desperately as every man in this section has done, over the artificial alimentation of a puzzling case, one is simply awestruck at the *sang froid* with which babies are taken away from the breast, every day, for causes so trifling as to be laughable, were not the results likely to be so serious and even tragic. "The baby doesn't get enough milk"; "I never have been able to nurse my babies"; "My milk is blue and watery—I know it doesn't nourish the baby"; "My baby didn't gain this week"; "My milk poisons the baby," or any one of a dozen other such statements that should mean nothing more radical than an inquiry by the physician into the state of nursing affairs, and some simple adjustment or explanation, ushers in the change from nature's feeding, which works so well that no one needs to understand it, to bottle feeding, which is admittedly the poorest of substitutes, and is wretchedly understood by the most learned. As often as not it is the grandmother, the aunt, or the nurse, who blithely crosses this Rubicon, with never a qualm over future hazards and never a regret over bridges burned behind. One can hardly imagine a shipwrecked sailor's pushing away his life preserver, or a mountain climber tossing away his hobnailed boots; and yet either of these would be taking a far less serious risk than is thus imposed upon the infant whose breast alimentation is thus discontinued for these absolutely inadequate causes.

I, personally, am firmly convinced of what is by no means universally conceded or recognized, namely, that practically every mother can succeed in nursing her own child. I say practically, advisedly, in the face of the testimony of the textbooks, which are fond of citing cases of congenital or acquired intolerance on the part of certain infants toward their mother's milk. I am willing to go a step farther and concede that probably each man here can call to mind one or more cases in his own experience in which every effort to keep a baby on its mother's milk failed ignominiously. And yet, to strike a quick percentage, what tiny fraction of a per cent. is represented in the practice of anyone who recalls such a case of so-called toxicity or idiosyncrasy, as compared with the total number of babies he has seen? We have all of us heard or read of the existence of two headed calves, and

yet we do not ordinarily construct our stanchions so as to accommodate these rare freaks of nature.

I do not assert that every mother can carry her baby through the nine months that we set aside for lactation, without help, but I do say that, given a realization on the part of the mother and of her medical attendant, of the truth in her particular case of what both recognize to be true in the vast majority of cases; and every man who wishes it can reduce his panel of exclusively bottle fed babies almost to the irreducible minimum supplied by motherless babies, and those that have been weaned three or four weeks before he sees them. And, if we are to credit the results of Moore, of Portland, Oregon, as set forth in his fascinating paper (1), even this minimum may prove not to be an irreducible one, for he records a case of reestablishment of breast feeding after eight weeks of weaning, and another after eleven.

Granted, then, that mother and physician are in accord, and resolved to do their best to keep the baby on the breast, what can we do to help them? In view of the universally admitted superiority of breast feeding, it is rather surprising that we can find so little, relatively speaking, of real practical help in the textbooks or in the literature, to aid us in this task. The task is a twofold one: first, the maintenance of lactation, and, secondly, the adjustment of the milk to the baby, or of the baby to the milk. In comparison with the volumes and reams devoted to the intricacies of artificial feeding, the space given to the problems connected with the far more common form of breast feeding, seems almost negligible. I want to outline the regimen that has been found most successful here, emphasizing the details, which are perhaps the most important feature in the management. In a word, this consists in the inauguration of what is variously known as auxiliary, complementary, or supplementary feeding.

By whatever name we call it, let it be distinctly understood that what is meant is offering the baby a bottle, with a formula appropriate to its age, weight, and general condition, after every breast feeding, and letting him take as much or as little of it as he will. What is not meant is alternate breast and bottle feeding, for reasons that will be dealt with directly. The baby may be kept anywhere from five to thirty minutes at the breast, until he shows, in short, by his restlessness and the tossing about of his head, that he has about exhausted the possibilities of the one breast. He is then allowed to swing over to the bottle, previously heated and in readiness, and permitted to take as much as he will of the complementary feeding. It is probably well within the bounds of truth to say (grandmothers to the contrary notwithstanding) that a reasonably well baby never overeats, if given a food of the proper strength. Colic, so-called, from this cause can, far more often than is realized, be proved to be nothing but hunger, by allowing the child to take even more of the food than he has already taken. Even that infallible argument, "Why, doctor, I know it's colic; he just draws his little legs up on his stomach when he cries," will fail of effect when the mother sees the colicky baby

fall asleep just as soon as he is allowed to be the judge of his own capacity. In other words, we are quite safe in allowing the baby in this way to tell us how much too little breast milk he is getting.

The following ideas should gradually be inculcated in the mind of the mother. It is especially useful, in this connection, to give a small slip or folder, preferably typed or printed in simple language, embodying these points:

1. That she should get away from the baby at least once in the twenty-four hours—for the sake of both of them.

2. That she should get enough sleep, eight hours representing a minimum rather than a maximum.

3. That worry is a great milk reducer. If the doctor can keep up the baby's weight and satisfy his appetite with complementary feeding, and give the mother confident assurance of ultimate success, he can generally obviate the untoward influence of worry.

4. That she may eat whatever she pleases, within ordinary bounds of reason, provided it does not cause indigestion on her part. The baby will not be affected by what she eats.

5. That excessive amounts of milk, cocoa, beer, or even water, do not necessarily, or even usually, aid in improving either the quality or the quantity of milk produced. That such excesses, on the contrary, usually end in harm, by spoiling the good appetite so necessary to lactation, if not actually upsetting the digestion.

6. That, in general terms, the same regimen that produces health and strength and bodily well being produces milk.

7. That no special diet can greatly modify the chemical constituents of the milk. The best opinion today is emphatically agreed on this. Further, some authorities believe that quantity alone can be altered—that the quality is, in an overwhelming majority of cases, always good.

8. That a laboratory test of the character of the milk is never of any practical use. The only test that is worth while is the practical test as to its effect on the baby. If he is hungry, or is failing to gain, he should have complementary feedings until the breast supply becomes adequate, as shown by these two criteria.

9. That the milk never disappears beyond recall suddenly, say, within twenty-four or forty-eight hours. Such an apparent vanishing of lactation is always evanescent, if complementary feeding is instituted promptly. The temporary diminution of the milk secretion can in this way always be made up for, the baby be tided over, and an enforced weaning be done away with.

10. That the care of the nipples is a most important phase of the periods of later gestation and lactation. Where a mother has depressed nipples, it should begin a month or two before the birth of the baby; gentle manipulation for a few minutes daily will make these easy for the baby to manage. Cleanliness, hardening by the application of half strength alcohol, and protection by the employment of inch square bits of sterile waxed paper, are important aids in keeping the nipples fit. Bismuth and castor oil, equal parts, may be used for incipient

cracking. Many women find that their nipples will not stand the wear and tear incident to nursing a child on both breasts at each feeding. Nursing on alternate breasts is usually advisable. However, as early milk is thin and watery, compared with later milk, which is richer, or strippings, which are very high in fat, we may if we wish diminish the fat content of what we are offering the baby by allowing him a shorter period at each of the two breasts at one feeding. As he fails thus to empty the breasts completely, we must be on the lookout, in such cases, for a reduction in the milk supply.

11. That we know of but two galactagogues. One is the stimulation of the infant suckling at the nipple. The other is the complete emptying of the breast at each nursing. These can be temporarily simulated; the first, by the breast pump and nipple massage, the second, by the breast pump and manual stripping of the breast, preferably after the manner described by Moore, of Portland (1). But the best agency of all is the one that combines the two, namely, the nursing baby.

12. That milk is like the manna that the Lord provided for the children of Israel: it cannot be stored up in the breast nor saved there for future use. A thorough understanding of this will do away with that bane of the doctor who is trying to improve a breast supply, namely, the alternate feeding of breast and bottle (supplementary feeding proper). This is frequently indulged in on the mistaken supposition on the part of the mother or her friends that there is not enough milk for all the feedings, and that in this way it can be eked out. Lacteal glands, like muscle tissue, work better the more they are called upon to perform, within physiological limits. The surest way in which to dry up a breast supply is to skip several feedings a day.

There seems to be no reasonable doubt that a moderate amount of breast milk does remove the disadvantage of the bottle feeding. Whether it is a question of carrying over antibodies from the mother to the baby, or whether it is a question of vitamins, or whatever the cause, we know that the child on complementary feedings shares much of the good fortune of the entirely breast fed infant. Then, too, after weeks or perhaps even months, the breast may begin to function to such an extent as to render further artificial feeding unnecessary, either temporarily or until weaning time. Such a simple solution as this, of a feeding problem, never offers itself unasked, in the case of the entirely bottle fed baby.

A fair degree of familiarity on the part of the attending physician with some comparatively simple form of infant feeding procedure to employ for the complementary feeding is, of course, necessary. Surely, however, this is not too much to ask of any man who is dealing as extensively with women and children as is the general practitioner.

And so, back we come to the favorite topic of pediatricists, infant feeding. The practitioners (and they are not few) who refuse to admit that there is such a specialty as pediatrics, taunt us with the gibe that every pediatric meeting, whatever its announced topic, either starts out or ends up with a

fuss over infant feeding. If a personal experience is allowable, I confess that after years in hospital and clinic work with children, it is still with fear and trembling that I approach an ordinary feeding case; and it is largely a matter of chance what feeding mixture such a new case would receive at my hands. I felt convinced that the old, complicated methods on which, *pediatrically speaking*, I had been brought up, were somehow wrong; and yet I did not know what was right. My feeling of dissatisfaction with the old methods may perhaps best be expressed by an illustration from life. If the operation of a trolley car were such a delicate, complicated matter that no one but an Edison could compass it, and you needed fifty trolley cars to handle the traffic of your city, then you will agree with me that the trolley car, as a means of handling your traction needs, would fail as a working, practical proposition. For there are not enough Edisons available to go around. Similarly, if it takes a Holt, a Morse, or a Kerley to feed your baby and mine, Mrs. Jones's and Mrs. Brown's, then infant feeding as taught today, in the East at least, is a failure. But we know that it is by no means as rare an occurrence as we could wish, to have a mother bring back to us, after two or three months' absence, a big fat baby that we have failed to make gain on the most scientific formulæ, with the triumphant remark, "Oh, Doctor, see what Blank's Food did for my baby!" Not pleasant, is it? Nor yet, as sometimes has happened to the best of us, to have Grandma's mixtures preferred by an ungrateful child to our elaborate formulæ! Such occurrences compel serious consideration.

The first step that I would urge in the simplifying of infant feeding, then, would be to keep every baby on the breast. I grant you at once that such a dictum as this, solemnly enunciated without further amplification, would constitute at once an insult to your intelligence, and an admission of my ignorance of the state of medical knowledge today. I should not have the effrontery to urge upon any body of physicians—much less upon a group of men engaged wholly with the problems of infancy and childhood—the already universally acknowledged superiority of breast feeding over the best of artificial feeding. This has been so generally conceded, and the literature has been piled so high with reports, experiences, statistics, and conclusions, to this effect, that it would be a waste of time to try to find anyone who would oppose what has come to be considered almost an axiom of pediatric practice. What I do want to stress, however, is the disparity existing between our theory and our practice in this regard. What I do want to plead for is the realization, first upon the part of the individual practitioner and through him upon the individual mother, that what both know and concede to be true in the great mass of cases, is in all probability true in the individual case that they are considering, and whose weaning they are proposing. No one ever states that bottle feeding in the abstract is better than breast feeding. It is only when we urge a mother to keep her own baby on the breast, even at the expense of some pains and effort on her part and ours, that we meet with any opposition

to the continuance of breast feeding. And we certainly do meet with it, as every one of you will testify with me.

Some time ago my attention was called to what was to me an interesting attempt to join the two systems, namely, the percentage and the caloric ideas of infant feeding. I believe that Dennett (2) has done more than anyone else to popularize this union in a workable technic. In order to fulfill the requirements that we set for ourselves in naming this investigation, we must produce something that is really simplified. It must be, not a head splitting, arithmetical jumble of proteins, carbohydrates, fats, and calories, but a simple, straightforward rule of thumb working system.

The part in our scheme that the percentage method is to play, was to determine how best to make our mixture digestible—a matter that the so-called caloric method never attempted to help us with. This simple point Chapin absolutely disregards in his diatribes against calories, in which he attempts to reduce the whole idea to the ridiculous by suggesting that we furnish the necessary calories to the youngster in the form of coal oil.

Without getting ourselves into the usual arithmetical tangle by comparing the percentages of the three food elements in human milk and in cow's milk, let us recognize that there are three elements that may under certain conditions give us trouble in adapting the milk of the cow to the stomach of the human—namely, fat, sugar, and protein. We will disregard the salts, about which we know as yet so painfully little. Let us dispose of the danger due to the fat by reducing it to a very low amount, by diluting ordinary cow's milk with twice as much water, i. e., one third milk and two thirds water. This same process will reduce the harmful potentialities of the sugar by reducing it so far that we shall later add sugar to our mixture in order to have enough to approximate it to the human norm. The protein can be disposed of even more simply by subjecting the diluted milk to a boiling process for three minutes, which completely breaks up the curd when acted upon by the stomach juices, as has been conclusively demonstrated by Brennehan, of Chicago, in his classic work on boiling milk. That the protein of the milk is "the cause of many of the nutritional disorders encountered in infancy" is categorically denied by Grulee (6). He is sure that the so-called casein curds are only mechanically irritant, and that this source of trouble is eliminated by boiling. The only possible objection to this, that it may cause scurvy in time, is done away with by the feeding of orange juice.

If we agree to start any child that comes to us on a mixture of one part cow's milk and two parts water, boiled together for three minutes, with no sugar added, we shall at least be giving a mixture that can do no harm. For the fat is diluted far below the amount found in human milk, the sugar is almost absent, and the casein, the protein constituent, has been rendered harmless by boiling, so that it will form a finely divided curd when it meets with the digestive juices of the infant's stomach. Any possible ill effect of the boiled milk we shall eliminate by feeding a little orange juice once or

twice a day. If we start with ten ounces of milk and twenty ounces of water, this will probably be insufficient. We can prove this by multiplying ten, the number of ounces of milk, by twenty, the number of calories in an ounce of milk, the water having no caloric value. This, our initial formula which we agree is digestible, is worth two hundred digestible calories. While it is much better to give too little of a digestible food than to give any amount of an indigestible one, if we are to look for a gain we must eventually come up to the digestive requirements which is best measured in calories. How are we to ascertain what the caloric need is? By multiplying the number of pounds the baby weighs by fifty, which is an average calculation of the requirements of the average child for each pound each day, we shall arrive at the number of calories that we must eventually give the baby in assimilable form. Starting with our trial or initial formula of ten ounces of milk and twenty ounces of water, worth two hundred calories, we may gradually strengthen this until we have brought it up to the number of calories that we have determined upon as a normal daily feeding for the baby. Our strengthening must be in terms of two factors only, namely, milk with twenty calories to the ounce, and sugar, with thirty calories to the level tablespoonful, five level tablespoonfuls, or 150 calories, may be taken more or less arbitrarily as the total sugar content at which to aim. This mixture is probably better borne in the form of dextrimaltose than in that of either cane sugar or milk sugar. In order to decide how many ounces of milk we shall eventually give our baby, we may subtract 150, the number of calories to be contributed by our five level tablespoonfuls of sugar from the total number of calories previously determined upon (by multiplying the number of pounds the baby weighs by fifty, his daily requirement to the pound). This total, divided by twenty (the number of calories to the ounce of milk), gives the ounces of milk needed.

This leaves us nothing more to determine but the amount of water to be used in the final total feeding. In order to do this, we shall simply have to determine the total bulk to be given the baby in the course of the day, which will be the number of bottles to be given, times the number of ounces in each bottle, determined by any rule that you have been using in the past. A general average might be represented by seven (which gives bottles enough for a feeding every three hours during the day, and one night feeding), times three, four, five, six, or seven, the number of ounces to the bottle, according to the age of the child. This bulk must be furnished by the water plus the milk, as the sugar goes into solution. As the number of ounces of milk required has previously been determined, we need only add water to bring up the total to the total bulk desired.

Now we need not aspire to reach this desired haven of the optimum number of calories at a bound. Grant that our baby may, and probably will, be hungry long before we have advanced him from the ten ounces of milk and twenty ounces of water, on which we started him, to the optimum formula that we have decided he must ultimately

reach. But all of us are committed to the principle of making haste slowly, in feeding babies, and at least we do away with the formerly commonly accepted twenty-four hour starvation period. The hungry baby worries the mother with his crying, but the child that worries the doctor is the baby that has no appetite.

Leaving all theory aside, the practice is this: Start virtually every baby on a mixture of ten ounces of milk and twenty ounces of water, boiled together for three minutes, with no sugar added. The caloric value of this is 10×20 , or 200. Experience will tell you when it is safe and advisable either to give a stronger mixture or a greater bulk at the start for this trial formula, as we may call it. With this weak strength and small amount, the preliminary starvation period, that we all used to insist upon, has been found quite unnecessary and a loss of valuable time, in most straight feeding cases. Add an ounce of milk a day. In this way the caloric value increases twenty a day. Add a level tablespoonful of sugar (preferably in the form of a malt sugar) gradually, every few days, in place of the increase in the milk, computing the value of the food on those days by adding thirty calories for each level tablespoonful of sugar added, instead of the twenty that would have been added by the addition of an ounce of milk. Five level tablespoonfuls of sugar is a good average quantity to aim at. In order to determine whether water should be increased, left as it is, or decreased, we must know how much bulk we want our baby to have in the twenty-four hours. This is easily arrived at by multiplying the number of feedings (say six or seven) by the number of ounces the baby is to receive at each feeding (which averages an ounce a month—more in the early months, of course, and less in the later). The difference between this total and the number of ounces of milk will represent the amount of water needed—as the sugar dissolves and so occupies no bulk. Before long, the juice of half an orange a day may be added.

The question of the best interval at which to feed is a point which is variously settled by different schools. My own custom has been largely the result of the method described by the homely phrase "cut and try." The two hour interval I use only in the case of premature babies; and the two and a half hour interval only as a step or half way stop in the course of changing from the two hour interval on which a baby may be when first seen, to the three hour interval at which I always prefer to start. As soon as the baby is doing perfectly well on this—by which we understand that he is being fed at 6 a. m., 9 a. m., 12 m., and 3, 6, and 10 p. m., and once during the night—and seems perfectly satisfied to wait from one feeding to another, and occasionally sleep till well along toward morning, I advise the mother to dispense with the night feeding, by giving first water when the baby wakes and cries, and finally omitting both nursing and water. This is the routine for babies who are not seen at birth; such babies do not receive any night feeding at all, being given warm water at two o'clock or later if they wake, which they soon cease to do. As early as the end of the first month, I

suggest to the mother that she will probably find it easier for both the baby and herself if she can change over to the four hour interval. If the idea appeals to her, I have her allow the baby to remain as long as he will from feeding to feeding—three and a half hours if he will not remain four hours—for about a week. Before the end of that time, a well fed baby is usually established on the four hour schedule. The same free and easy method is used at the age of three or four months, if the baby is satisfied and the mother cares to try omitting the 10 p. m. feeding. These changes are so much easier for the mother, and involve so much less handling of the baby, that it is usually easy to persuade the mother. It is hardly worth insisting upon, however; and is especially contraindicated if the baby is hungry, and ready for the bottle at the end of the three hour interval.

A most valuable adjunct to employ at times in the management of difficult cases is that much talked of agent, dry milk. Like most other proprietary preparations, it has its very definite dangers, in its likelihood to become a very intolerant master, as soon as it gains a place in the minds of the laity. In the child who has suffered a food injury, it is often a valuable aid, with the lowered fat content that at least one brand offers, and the apparently increased adaptability conferred by the heating process. If one has reason to doubt either the intelligence of the zeal of the one who is to prepare the complementary food, this is an efficient and valuable ally. Its caloric value is given as sixteen calories to the level tablespoonful.

A word as to the management of premature infants, in order to cover the various phases of the feeding of the first year of life. It is coming to be realized more and more that it is a waste of time—nay, of human life—to attempt the feeding of the premature infant with anything other than human breast milk, either whole or diluted. Strengths and intervals may well be left to the individual feeding the individual case. I am persuaded that the obtaining of the tiny amount of breast milk needed for the first days and weeks of the life of the premature infant, is by no means the difficult or impossible matter that we are likely to believe. That community must be a tiny one, indeed, in which there is at any one time but one nursing baby. And it should be most rare to fail to find a mother who, if the need were fully and carefully explained to her, would be glad to spare the few drops necessary to save the life of the starving baby. In the larger community it is easier; in the hospital, comparatively simple. Cooperation between the obstetricians and the pediatricists has in more than one instance resulted in the establishment of some central agency, at which the parents of the infant whose need for human milk is urgent, can be put in touch with the mother who is willing to supply, on a financial basis, a stated amount of breast milk a day. A more interesting method has been the feeding of the premature infant by means of a pipette or Bredl feeder, with a diluted breast milk expressed from a mother in the maternity ward, while the supply of its own mother was started by placing to her

breast a needy baby from the pediatric ward, who greatly benefits by the operation, until the premature baby can get its supply direct, by nursing at its own mother's breast.

Weaning is a procedure which entails no suffering on the part of the mother or child, since the brutal old custom of abrupt weaning was done away with. At about the sixth month, the mother is told to precede each breast feeding with a tablespoonful or two of a cereal. As soon thereafter as one wishes, the vegetables may be added, one by one, as baked potato with milk, spinach, carrots, mashed peas and beans. As these additional articles are judiciously used to expand the baby's dietary, it will naturally become less and less dependent upon the breast milk, which, toward the end of the nursing period, it will be using more as a beverage than as a sole dependence for nourishment. Milk, either diluted, and without sugar, or straight, may be added as desired. In this way, the change from breast feeding to general diet is made so gradual as to be almost imperceptible. It is only fair, in this connection, to mention the paper in which Morse, of Boston, sums up very fairly his objections to this procedure, and his reasons for adhering more strictly to the older custom of introducing these articles of diet considerably later. The change can be made as gradually from the four hour feeding intervals to the more conventional hours of meal times. The six o'clock feeding becomes a seven o'clock breakfast with cereal, milk, orange juice, and bread. The ten o'clock feeding becomes the prenap lunch of crackers and milk. The two o'clock feeding is easily recognized in the afternap dinner, with baked potato and milk, one other vegetable, bread or toast or zwieback, and a simple pudding. The six o'clock feeding is less deeply camouflaged, appearing as supper, with crackers and milk, and stewed fruit. The omission of eggs in any form, and of the elaborately prepared beef broth or scraped beef, is intentional. The value of the former is more than problematical; the labor spent on the latter is out of all proportion to its value, which has undoubtedly been greatly exaggerated.

I have tried to give you my articles of faith with regard to the management of the feeding of the ordinary baby—one that approximates the ordinary. (For no mother will ever admit that her baby could be classed as ordinary, by the dullest imagination.) Endless variations from the average may be made, to suit the individual baby, and to increase its flexibility in the hands of the individual infant feeder. A necessary part of the technic, in actual practice, that I have not attempted to bring out, consists in the rendering of frequent reports and maintaining constant touch between mother and doctor. This is absolutely essential, for checking up results, to see if directions are being carried out, and to detect and correct errors arising from a misunderstanding of directions. (In my own case, this is covered by the morning telephone consultation hour, at which time mothers are encouraged to telephone in reports and questions, with absolute freedom.)

Some such technic, flexibly and humanly applied,

that may easily be taught to any man who has to deal with babies, will carry perhaps ninety-five per cent. of our babies safely through the first, or critical, year of life. If this is true, and I believe that a large number of men might easily be found whose experience will confirm it, we may reasonably leave the remaining five per cent. or less to be discussed in some more highly technical treatise than I have attempted here.

SUMMARY.

1. Infant feeding, as taught until recently in the schools, urgently needs simplification.
2. The first step in simplification, and the most important for the welfare of the race in the future, is the maintenance of breast feeding, partial or complete, in the majority of our babies.
3. Such a statement alone is inadequate. Proof of the assertion, as well as help to the mother in accomplishing it, are needed. This consists in the adjustment, as I like to call it, of the breast to the baby, or the baby to the breast.
4. I have attempted to show how any man may keep that wonderful ally, Nature, on his side, and in many cases, take all the credit while he allows her to do most or all of the work.
5. To do this, requires a reasonable familiarity with some reasonably simple form of infant feeding procedure, for use in connection with the breast feeding, at some time during the period of lactation. I have tried to formulate the simplest that I have yet found.
6. A useful servant, but one that must be watched lest it assume the mastership, is some form of dry milk.
7. The successful care of any goodly proportion of premature babies presupposes the employment of breast milk in all cases.
8. Breast milk is not the rare thing we like to consider it—we can get it for the premature infant, if we go after it.
9. Weaning is a gradual affair—as such it may be accomplished without disagreeable effect upon either mother or child, if it is begun early enough.

THE IMPORTANCE OF THE MICROSCOPICAL EXAMINATION OF HUMAN MILK.

BY LOUIS GERSHENFELD, PH. M., B. SC.,
Philadelphia,

Professor of Bacteriology and Hygiene, Philadelphia College of
Pharmacy and Science.

Considerable work has been done on the chemical, microscopical and bacteriological examination of cow's milk. Experimentation on human milk has, unfortunately, been mainly confined to its chemical examination, inasmuch as the latter determination has been found of great value in solving many problems of infant feeding. But in attempting to see whether a product is being furnished that may be regarded as fit, from a chemical viewpoint, many pediatricists and physicians overlook the fact that preparations are being administered to children that, in many instances, are detrimental to their health. It is with this fact in mind that I always advise a careful microscopical examination in addition to the general routine chemical examination.

It is difficult to formulate standards for cow's milk, due to the fact that many questions are to be considered. The farmer is interested in milk production so as to secure a reasonable financial return. The same is probably true in regard to all others who handle and sell this product. The sanitariat and the consumer, however, consider the milk problem only from the point of view of its effect on the health of those who use it. It is, therefore, apparent that the question of formulating standards on cow's milk with as little discrepancies as possible, is one which will be open, to a greater or less extent, to misunderstandings, due to the fact that many phases of the whole problem must be taken into consideration. Such is, however, not the case with human milk. For here, after all, no problems are encountered as are observed in cow's milk, and its effect on the health of the child is the only question to be considered.

SOURCES OF BACTERIA IN HUMAN MILK.

There is no doubt in my mind that human milk is rarely, if ever, bacteria free. Specimens that were collected under the most favorable conditions showed the presence of bacteria. This is not due to the fact that the healthy milk gland does not secrete a sterile product, but mainly for the reason that bacteria probably find their way through the nipples and other sources. Furthermore, there is little cause for arguing this question, for, after all, whether milk secreted by the milk glands is or is not germ free, it is a known fact that the milk at the time it is taken by the child, contains bacteria.

The bacteria of the healthy mammary glands form but a small porportion of the total bacterial content in milk consumed during nursing. The skin of the mother, directly or indirectly, through clothing, handling, etc., contributes the abundant quantity of bacteria found in human milk and fed to the child. Within the last four months two hemolytic streptococci infections in nursing infants were traced by me to human milk. In both cases, the physical examination of the mammary glands of the mother by the attending physician showed no inflammation,

and the microscopical examination of the milk did not show any abnormal quantity of pus cells or cellular matter. It is, therefore, more than probable that these microorganisms found their way into the milk from the skin of the mother. How many pediatricists and physicians advise the cleansing, washing, or merely wiping with a wet cloth, of the nipple and surrounding area, before nursing? And how many mothers actually take such precaution?

In six different samples of human milk, collected under conditions almost identical with actual conditions at the time an infant is about to begin nursing, after a careful bacteriological examination I found only two of the samples of such a bacterial count as to regard it fit for consumption. The other four had a bacterial count ranging between 1,110,000 to 4,260,000 to the c. c. In the case of cow's milk, we hear of the cleansing of the skin of the cows, the hands of the milker, the vessels used for collection, and other implements. Why not observe precautions of cleanliness in the case of human milk?

It cannot be pointed out too frequently, that the excessive bacterial contamination in human milk is not only avoidable, but unnecessary. It can be prevented to a large degree by closely guarding the simple rules of cleanliness. This involves no increase in expense. It usually means less suffering, little or no worry, and, if anything, a decrease in expense in the long run. The time may come that the science of bacteriology will develop to an even greater exactness than it is today, and the direct relationship between many of the diseases of children may be traced to mother's milk, contaminated carelessly from the skin.

In addition to the previously outlined sources of contamination, there may be another: that is, from a diseased mammary gland. The latter, when diseased to such an extent that a physical diagnosis reveals the fact, quickly places the attending physician on his guard. But it is those diseased conditions, wherein the mother apparently feels no discomfort, and where, nevertheless, an inflammation (or mastitis) exists, which produce a serious source of danger.

It has been my privilege to examine numerous specimens of human milk, which, though the chemical analyses showed perfect samples, the microscopical observations, however, revealed the fact that they were highly contaminated with bacteria, lymphocytes, polymorphonuclear leucocytes, epithelial cells, and other cellular matter. In most of these instances, the mother felt no discomfort, while the nursing infant showed little or no progress. In many of them various diseased conditions prevailed. This was afterward found to be caused by the use of contaminated milk. It is almost impossible to attempt to tabulate my findings in the many samples mentioned. In the first place, a total bacterial count was made only when asked for by the physician and experimentally in the few instances reported. A microscopical examination was, however, made on every sample. The Stokes method was used, a smear being made from the fat layer as well as from the centrifugalized sediment. In many of the instances a quantitative estimation of the leucocytes was made, the Doane Buckley method

(as reported by them in 1910 before the laboratory section of the American Public Health Association) being used. The epidemiological connection between various attacks of illness in children and the use of the milk of mothers suffering from diseased mammary glands (not observable by a physical diagnosis) is not altogether clear, and the causative agents (i. e., types of microorganisms or toxins) concerned therein are still obscure.

Little work has been done in regard to the occurrence of pathogenic and nonpathogenic bacteria in human milk, whether found naturally or through contamination. The occurrence of disease producing bacteria have been reported by some workers every now and then. To attempt and formulate standards is not an easy task, for anyone familiar with analyses of breast milk is aware of the existence of wide variations in chemical and bacterial compositions not only in samples from different individuals but also in portions obtained from the same sample at different intervals. The structure of the mammary glands and their mechanism of secretion, together with the histological changes taking place during the periods of lactation, are familiar to all. The chemical examination of milk and the methods of correcting a faulty chemical composition have been studied thoroughly and considerable data are available, from which valuable information can be obtained. But the literature pertaining to the microscopical and bacteriological examination of human milk is far from complete, and the little that is available is uncertain. A more direct recognition of infectious diseases traceable to breast milk, obtained from a diseased mammary gland or introduced through other infectious human material, is still to be produced by a close and thorough scientific study. Most of the information available is merely assumed and an exact degree of danger from this source is needed.

This short exposition is the outgrowth of my personal observation. The subject is of the greatest importance and it is my belief that one of the most pressing needs of the present time is a more thorough investigation into the relationship of human milk and the nursing infant, from microscopical and bacteriological viewpoints.

1831 CHESTNUT STREET.

XERODERMA PIGMENTOSUM.*

By I. S. RAVDIN, B. S., M. D.,
Philadelphia.

This disease was unknown until 1870, when Kaposi (1) described it with a report of four patients. Three years later he reported briefly and tabulated thirty-eight cases. Since that time over eighty-five cases have been reported. Many observers regard this condition as an aggravated form and sequel of common lentigenes; others regard it as potentially a malignant disease. It usually develops in early life (in the present case the mother asserts that the pigmentation was present at birth), and is characterized by overgrowth of pigmented

epithelium, especially on the exposed surfaces, as the face, scalp, neck, upper shoulders, hands, and forearms. In our case the scalp was not nearly as much affected as were the other exposed surfaces.

The pigmentation is always more marked in the summer, and may disappear for one or two winters, when it finally remains. Shortly afterward telangiectasis and atrophic white spots appear, giving the skin a scarred character similar to that seen after long x ray exposure. According to Dalous and Constantin (2), they are the most marked features of xeroderma. The cicatricial like areas are smooth, shiny, and wrinkle very much as does the senile skin. There is a tendency toward the coalescence of these areas. The sensibility of the atrophic areas becomes lessened, and glandular secretion is not so active.

FIG. 1.—Patient, H. M., in author's case of xeroderma pigmentosum.

The skin becomes darker, which, on close examination, is seen to be due to the excessive freckling.

The disease may continue for months or even years, in this apparently benign character, but sooner or later more pathological characteristics become apparent. Wartlike growths appear, which are overgrowths of the lentiginous spots. As in our case, ectropion, blepharitis, conjunctivitis, and even ulcerative keratitis are likely to occur. There need be no dependence of one lesion upon the other, however, according to Kaposi, the lentiginous areas become telangiectatic, later scaly, and finally there is atrophy of the affected skin. Crocker (3) has reported a case in which the disease remained quiescent for about six years, but as a rule there is

*From the Hospital of the University of Pennsylvania.

a gradual progression, so that sooner or later to the symptom complex is added the appearance of ulcerating tumorlike processes, malignant in character, belonging to the epitheliomatous or sarcomatous group. This is the time at which the malady becomes a grave one. Kreibich, Pernet, and Halle (4 and 5) say the epitheliomata may be of the type of acanthoma or of rodent ulcer type, while Unna finds that they are often pigmented as in sailor's carcinoma. The case which we are reporting is similar to those described by Hutchinson (6) as *lentigo maligna juvenalis, v. senilis*, in that his cases of progressive freckles of the cheek and eyelid became the seat of epithelioma.

The disease is usually confined to the skin or mucocutaneous junctions, the internal organs rarely becoming involved. Death does not usually occur until many years after the lesions appear, and is

FIG. 2.—Same patient as in Fig. 1, after treatment.

due to the exhaustion from pain and the effect of the malignant ulcerative lesions. In exceptional cases the disease becomes stationary after a number of years.

The etiology is not established. Councilman (7), Magrath (8), and Corbett (9), think the exciting cause is exposure to sunlight acting on the skin of congenitally and constitutionally predisposed subjects. On account of the behavior of the disease and its occurrences in two or three members of a family, Rouviere (10), White (11), Brayton (12), and Rüder have suggested a parasitic etiology, but this has not been substantiated. Kaposi believed it due to a congenital formative and nutritive anomaly of the vascular and pigmented portions of the papillary layer of the skin. Recently a number of these cases with epitheliomatous change have been reported by G. W. Grier (13) as being treated with x ray with very good results.

CASE.—H. M., aged nine, was admitted to the service of Dr. G. P. Müller and Dr. J. P. Crozer Griffith, University Hospital, January 30, 1920, the chief complaint being a sore on the nose. The mother said that the child was slightly pigmented at birth, but this became very much exaggerated about six weeks later. It was associated, according to the mother, with an eczema, which was characterized by oozing and scaling. The pigmentation increased with each succeeding year. It was especially marked during the summer months, when the skin became very red, and this was also the case when the child was exposed to an excessive wind. In August, 1919, the patient noticed a small papule, wartlike in character, about the size of a pea, on the bridge of the nose. It was very hard and, according to the mother, the top was black. It enlarged very rapidly, but never ulcerated or bled. At first there was very little pain, but this increased as the tumor enlarged. On December 27th she entered one of the state hospitals, where the tumor was cauterized. There was a rapid recurrence which gradually extended along the lower margin of the left eyelid. The mass bled now very freely.

The physical examination showed a fairly well nourished child about nine years old. The scalp appeared scaly and was pigmented. There was a marked injection of both conjunctiva with a marginal blepharitis. The left lower lid was ulcerated, the ulceration being continuous with the fungating mass over the bridge of the nose. This mass was about the size of half a dollar, and was craterlike in character. The skin, especially that of the face, neck, hands, forearms, and upper part of the chest and back, resembled that of a very old individual, there being numerous leucodermic areas interspersed between the areas of deep pigmentation. The skin over these areas was smooth, shiny, and wrinkled very easily. It resembled the skin of those who have been subjected to prolonged x ray exposure. The pigmentation was most marked on the back of the neck, the dorsum of the hands, and the face. There was a pigmentation, with ulceration of the mucous membrane of the lips and inside the mouth. The mass on the nose was fulgurated, as was the growth on the lower eyelid. One week later the patient was treated with fifty mgms. of radium for four hours. When last heard from, in March, 1920, the patient had not improved.

The pathological report, from the Laboratory of Dermatological Research, presented by Dr. Weidman, was as follows:

Slide No. 1: Showed none of the histology of skin, but consisted of closely placed large squamous cells with broad markedly coalescent cytoplasm and large but pale nuclei. There was no good pearl formation, although from time to time there were sufficient small concentric arrangements of keratin to distinctly indicate an attempt thereat. Small foci of lymphocytes occurring around small blood vessels were the only things left to indicate the original fibrous stroma of the parts invaded. The extreme disorderly arrangement of the squamous cells and their highly atypical and hyperchromatic nuclei could leave no doubt of the squamous carcinomatous nature of this disease.

Slide No. 2: This time the surface epiderm was shown over one side of section. All of the layers were represented. Interpapillary pegs were markedly elongated, broadened, irregular in form, and extended deeply into the underlying corium. At opposite end of section the epiderm dipped downward, and became continuous with a large mass of squamous epithelial cells which were arranged in the classical and characteristic fashion of squamous cell carcinoma of the prickle cell type. The underlying corium was practically entirely occupied by the tumor elements in this section. They were arranged in the usual interlacing intercommunicating trabecular fashion with extensive permeation of lymphatics, and showed exquisite examples of pearly body formation. At the more peripheral borders the stroma was heavily infiltrated with lymphocytes.

Summary of microscopical description of skin from back of neck: A marked hyperpigmentation of rete cells, occurring irregularly as to intensity along different stretches of the freckle. There was a little irregularity of interpapillary pegs and in one place a slight exfoliation of epiderm in the floor of a surface pocket. The chromatophores of the corium were also a little more conspicuous than normal. Intradermal fat was noted.

EMPHYEMA IN CHILDREN.

Report of Sixty-four Consecutive Cases.*

BY ELIZABETH GLENN, A. B., M. D.,
Philadelphia.

Empyema in children is a very interesting subject. The statistics given below are those of the Children's Service of the University Hospital since 1907:

Discharged, cured, twenty-four; discharged, improved, twenty-eight; died, twelve; total, sixty-four. Length of stay in hospital, under one month, twenty-two; under two months, twenty-four; over two months, six.

It is interesting to note that the mortality in these children, all of whom were under twelve years of age, was only 18.7 per cent., while the average adult mortality ranges from twenty per cent. up.

*From the Children's Service of the University Hospital. Reported through the courtesy of Dr. J. P. Crozer Griffith and the Surgical Service.

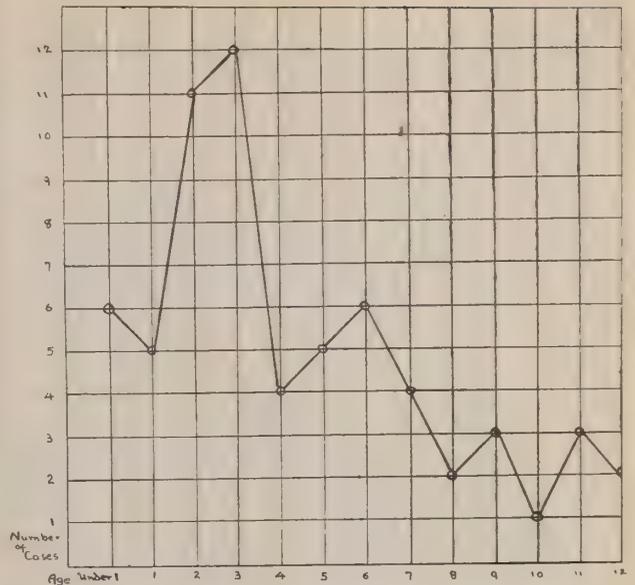

Chart showing mortality from empyema in sixty-four cases.

AGE INCIDENCE AND MORTALITY BY AGE.

Age	No. of cases	No. of deaths
Under 1 year.....	6	4
1 year	5	2
2 years	11	2
3 years	12	1
4 years	4	
5 years	5	
6 years	6	2
7 years	4	
8 years	2	
9 years	3	
10 years	1	
11 years	3	1
12 years	2	

This may be partly due to the fact that many of these cases were admitted to Dr. Griffith's service with a primary pneumonia, the empyema developing in the hospital. Surgical intervention was, therefore, prompt. Thirty-seven rib resections were done, with six deaths; twenty-seven thoracotomies, with six deaths.

Another fact worthy of note is the preponderance of leftsided empyemas in children. In thirty-four of our cases there was leftsided involvement, in twenty-three rightsided involvements, and in seven the histories are deficient in stating the location. Two of the empyemas originated on the left side and involved the right side secondarily. Both of these patients died. There is also a marked preponderance of males, there being over twice as many males as females. These admissions were to a ward where no distinction is made as to sex in admissions. There were forty-four males and twenty females.

The great majority of these cases were post-pneumonic, fifty-four being due to this cause. Of the two tuberculous empyemas, one did not recur after drainage. The primary infections were as follows: Pneumonia, one with typhoid, fifty-four; influenza, three; pulmonary tuberculosis, two; scarlet fever, one; unspecified, four.

Although the mortality usually given for empyema in children under one year is 100 per cent., in our series of six cases the mortality is only 66.6 per cent. If we subtract these six cases from our

total number of cases, the general mortality would be only 13.6 per cent. Of the twenty-three patients cured before discharge, eleven had been operated on in one week or less after the presence of pus was suspected, five more within two weeks of this time. The average length of stay in the hospital after operation of those operated on in less than a week from the onset was thirty-five days, while for those operated on one week later, it was forty-three days.

Conclusions must be drawn cautiously from a series of this number, but it is safe to conclude the following:

1. The incidence in males is greater than in females.
2. The left side is more often involved than the right.
3. If the mortality rate for empyema in children under one year is excluded, the death rate is lower in children than in adults.
4. In children under one year the mortality in our six cases was 66.6 per cent., instead of the 90 to 100 per cent. usually given.
5. In the postpneumonic empyemas, where the patient is operated on within the first week after onset, the average stay in the hospital was shorter and the proportion of cures higher than in those operated on at a later time.

THE WEAK FOOT IN THE CHILD.

Flexible Flat Foot.

BY H. SCHEIMBERG,
Brooklyn,

Lecturer on Mechanical Orthopedics, The First Institute of
Podiatry, New York.

In an article of scientific interest, it is natural to expect a direct statement of fact, devoid of sensation or sentiment. I shall attempt to comply with this essential in presenting a few preliminary considerations that prove the common weak foot (or, as it is sometimes called, the flexible flat foot) in the child to be not only a medical paradox but also a national calamity. That it is a national calamity becomes evident from the fact that from sixty to seventy per cent. of the children, particularly in the metropolitan centres, are through numerous examinations found to be afflicted; in that the condition most often remains ingrown instead of outgrown; and because the weak foot too often becomes the forerunner to permanent postural defects, creating or enhancing other organ disorders and bringing with it economic inefficiency and often failure in later life. It is manifestly a medical paradox in that with the exception of the few orthopedists, who give the feet only incidental study and treatment, or of the few podiatrists, who treat the feet alone, there is no specific attention being paid by the medical profession to the development of a rational policy on this important phase of child welfare.

We need not travel far to obtain direct evidence. We observe the curious spectacle of thousands of children who actually required trained medical guidance being brought to the shoe store for diagnosis and treatment of foot trouble. The treatment gener-

ally takes the form of a brand shoe that is sold without understanding the actual need of the pathological instance at hand. Additional treatment often obtains in the further sale of commercial arch supports or archsupport shoes. It is amazing to note how lacking the agencies are to furnish reliable advice or treatment and to see how this deficiency

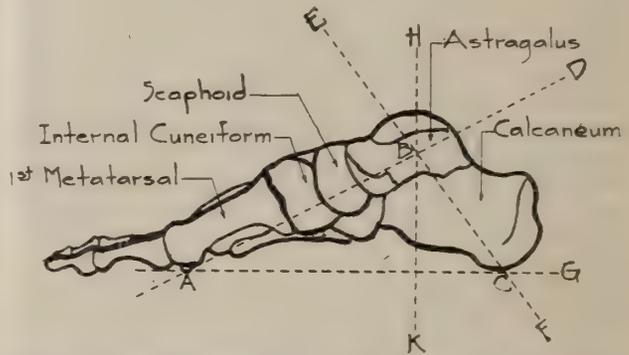

FIG. 1.—The foot viewed as an arch consisting of two pillars, line A-B and line B-C, with the astragalus as the keystone.

serves generally to confuse a frantic, foot sore and nervous populace in its search for advice.

A little thought shows this neglect to be such a serious detriment to child welfare as to make some action imperative. Parents should be instructed not to depend on shoe stores or stock arch supports for the cure of foot conditions. The results from such sources are too often such as almost to warrant legislative interference of some kind. I have in mind at the present writing several instances of tuberculous ankle joints and arthritides in the feet which, under the incentive of selling arch supports at a commission, were diagnosed in shoe stores as flat foot, and where accordingly valuable time was lost before the true state of affairs was made known at a hospital or in the practitioner's office. When occasion arises, parents should be cautioned to have the child's foot examined by the physician or specialist first as is done with the other organs. Periodical inspections of the feet of children in public institutions should be made a routine as for other body deficiencies. In treating a foot condition in the child, the general practitioner should be prepared, if he advises shoes or supports, to check these items in connection with his other treatment. The physician certainly does not leave the prescribing of medication to the druggist. Yet with feet, it is common to shift the responsibility to the shoe clerk, and the public has thus in time become accustomed to regard the shoe clerk's knowledge of feet as superior to that of the doctor and diagnosis as within the province of the shoe store. As a matter of fact, the shoe clerk cannot be prepared under the strain of making sales or by virtue of previous training to be the logical guardian of the child's foot. He is incapable of differentiating between cases of foot ailments of a localized nature and those ailments that reflect constitutional, nervous or mechanical disorders elsewhere in the body. This differentiation constitutes a prime requisite for the successful diagnosis and treatment of any foot condition. Further evidence of these facts is furnished by the histories of the thousands of patients who eventu-

ally arrive at the office of the practitioner or at some hospital for advice after having experimented many years with shoes and arches and where the disability again often finds its source elsewhere than in the feet.

Military authorities require those who care for the horse to have a preliminary knowledge of the anatomy and physiology of the locomotive apparatus of this animal. The shoeing of the horse is generally considered an art of the highest utility toward the preservation of the animal's efficiency, and this expert care is but natural and proper. The growing child, however, whose foot is not an incoordinate mass like the horse's hoof, and which is called upon for a greater delicacy of function as indicated in the grace and elasticity of the human gait, is recklessly relegated to such empirical factors as stores and arch support specialists. Thus the weaknesses are permitted to develop and create later disability. This situation might be ludicrous were not its outcome so serious. It is obvious that the attention and action of all agencies in caring for the child are thus challenged.

Incidentally, we see the general public depending upon corn cures for relief from excrescences that generally reflect a malposition of the delicate structures of the foot, which malposition occasions undue friction or pressure at the point where the excrescence occurs. Here it is again evident that minor orthopedic measures and scientific guidance are needed in preference to the much lauded proprietaries heralded as a cureall for foot ills.

So extensive is the effect of this neglect upon children that if legislation were enacted and rigidly enforced to prevent the diagnosis of foot ailments in shoe stores, or this legislation to permit such diagnosis only through the employment of a specialist, the community would thereby eliminate a potent factor in undermining the vital efficiency of present and future generations. This suggestion of medical specialists in stores may sound unusual; but a little thought proves it logical and essential. Experience has demonstrated the logic of this routine so far as the eye is concerned, as the leading optical concerns now employ oculists. The penalties for the neglect of foot ailments are certainly as exacting as for the neglect of the eye.

As to the increase and extensive prevalence of weak feet in children and the fact that the condition as hereafter explained more often remains in-

grown, we again have ready evidence. Institutional statistics are constantly making this fact plain. It was particularly brought to light with the great number of rejections from military service in the early recruiting for the late war and before an order was eventually issued to reject no more foot cases. On several occasions when I have examined groups of children for this ailment, the percentage of those who showed little or more advanced symptoms of this condition was about sixty. This percentage I find confirmed by those who have had occasion to make special examinations for the same ailment.

That the present attitude of the general public is in nowise likely to reduce this proportion of weak feet is very likely. There is a too frequent tendency to regard most pains where present as rheumatic or neurotic; or to depend, as mentioned, on shoes or supports as cures, or to be misled by a popular fallacy that pain in the lower extremities is of little consequence, will right itself and warrants no special attention. It is, however, to the credit of some of the more progressive shoe manufacturers and stores that the nature of shoe advertisements is assuming a different tone that would indicate a healthy awakening. Where formerly style and wear were featured in the advertisement,

these concerns are now directing attention to proper fitting and to general foot care in the child, and thus parents are being benefited. The neglect of the child's foot can hardly be blamed entirely on the parent, as it seems unlikely, assuming the latter to have been properly advised, that there should result a willful neglect of the child's feet to the detriment of a later economic efficiency and earning power, and which neglect might later bar the child from desirable positions in civil or military life.

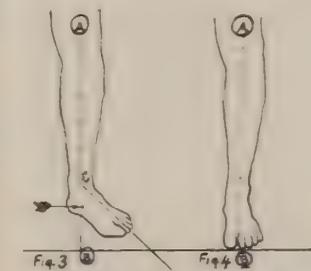

FIG. 3.—The incorrect attitude in standing or walking. Line of body weight A-B. Pressure through this line being concentrated at keystone region of arch as indicated by arrow. This attitude contradicts the leverage function of entire foot by diverting the muscular action from leg to foot. The consequent overstretching of the inner muscles and ligaments predisposes to an inward displacement of the pillars of the arch, particularly with prolonged standing characteristic of many common occupations.

FIG. 4.—The correct attitude in standing or walking. Leverage action of the foot facilitated by undiverted muscular action and the fact that body weight now falls over entire length of foot. The segments of the longitudinal arch are kept from falling inward by the direct action of muscles from leg to foot. (This attitude in marching would mean a gain of about one inch to the step as compared to attitude of Fig. 3 where about an inch is lost. In a march of about thirty miles with its average of 2000 steps to the mile, there would be a clear gain of about one mile, while the same thirty miles performed with the feet as in Fig. 3 would incur loss of a mile in distance).

me, as it seems plain that pliability of bone lends itself as much to natural distortion as to natural therapeutics, particularly where bones are meeting the pressure of body weight as in the case of the lower extremities. The extensive prevalence of flat

feet in the adult consequent so often to weak feet in the child proves that the condition of weak foot is not so readily outgrown as is generally thought.

The subject of weak foot (flexible flat foot) will be principally discussed from the viewpoint of a visible mechanical deformity, commonly seen in children, and irrespective of its prime etiology, existing as an end result of any one or more of a variety of causes herein-after enumerated.

The weak foot may be defined as a foot which in contour and action resembles a perfect foot until weight is borne on it as in standing when it assumes an attitude of deformity corresponding to flat foot, and as later detailed. The change under weight bearing is due to the inability of muscles and ligaments to maintain sufficient tension to hold the superimposed weight. The term weak foot or flexible flat foot is preferable to flat foot, the latter being restricted to the later fixed stage where the deformity is visible even with the foot off the ground. As with flat foot, the condition is generally found in both feet instead of one foot alone, though the term seems to imply an affection of one foot alone. The weak foot may be congenital; more often it appears to have been acquired through a variety of factors to be outlined.

As to congenital cases, I do not refer to the relatively infrequent congenital talipes valgus where there is some contraction of tissue and, therefore, resistance to manual correction, or to paralytic conditions. I have in mind the common form with unrestricted active or passive motion of the feet and which becomes apparent as soon as the child starts to stand and walk. If present before locomotion commences, it would seem difficult to identify the condition so as actually to class it as congenital. This must be so, because a weak foot is generally identified by a change of contour from the attitude of rest to that of standing. We cannot, however, get the infant in arms to stand for us. Even if the infant could stand unassisted, the additional adipose tissue under the child's arch, together with the lack of complete development of this arch (which can only occur consequent to muscular activity) would still make the diagnosis of a purely congenital case difficult if not impossible. Of course, in the relatively more rare cases of congenital talipes valgus, the deformity is visible even with the foot at rest.

Assuming, however, a case to be purely congenital, its prime etiology as with other congenital deformities remains speculative. It is impossible to

state definitely to what extent prenatal influences have contributed to the condition, or whether post-natal influences in the period before walking begins might not have been chiefly causative particularly with a history of defective assimilation.

When viewed, however, as an acquired condition, or when we observe the cases that are distinctly acquired, the etiology is more definitely assignable to a single or combined operation of any of the following: A too rapid growth or increase in weight; confinement by illness; sudden strain after such confinement; local tissue effects of certain illnesses themselves; improper support of the foot during prolonged confinement to bed; city pavements; commercial arch supports; improper attitudes in standing or walking; the distortion at the ankle induced by favoring a part, as with excrescences such as corns, callosities, or ingrowing nails; or as with sprains of the ankle joint; improper footwear. Among the relatively rarer causes which, though not bearing on the common weak foot under discussion, may be mentioned for completeness, are found: spasm of the peroneal muscles (spastic weak foot and really an inflexible form); genu valgum (knock knee), where the foot is forced into valgus by the outward swing of the legs which concentrates the weight of the body on the inner arch; paralytic talipes valgus; or accompanying the early

or rachitic type of genu varum (bow leg). The prime etiology, however, may nevertheless be obscure in those cases where, for example, we find weak feet that have developed in children who give no history of illness, pain or trauma, and who besides are light in weight and fairly muscular. An inquiry into the causes mentioned seems to indicate that, excluding disease, faulty nutrition and the like, two factors stand out prominently as being directly predisposing and which will be referred to seriatim. At least, no intelligent treatment of this condition can occur without primary attention to the elements of attitude and footwear.

ATTITUDE.

So far as the stability of the human foot or efficient gait is concerned, we have erred by teaching the child to toe out in standing or walking. To appreciate why turning the toes outward is decidedly antagonistic to good foot function, let us observe some anatomical peculiarities of interest and the arch itself. In Fig. 1, we see that this arch

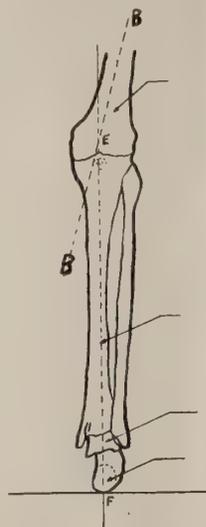

FIG. 5.—Posterior view of skeleton of right leg, showing the slight but normal knock-knee existing in the standing position due to inclination of femora from hips to knees. Line B-B shows approximate inclination of femur. Weak feet reflect themselves in an inward shift of the tibia, thus an approximation of the knee joints thereby with an increased tilting of the femora creating more or less secondary knock-knee. The reciprocal relationship between weak feet and knock-knees is thus evident.

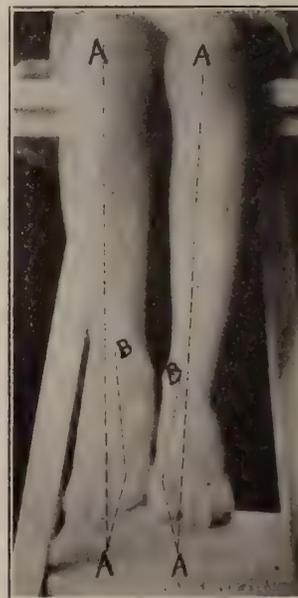

FIG. 6.—Normal feet at rest. This may also illustrate the weak feet at rest in which attitude no abnormality is ordinarily visible. Lines A-A pass about centrally through ankle joints as with the same normal feet standing in Figs. 7 and 8. Short dotted lines A-B in their angulation at the metatarso-phalangeal joints show how in the rest attitude, the large toes abduct from median line of body and lean over against the second toes.

may be conveniently referred to as consisting of two limbs, the os calcis, line B-C, forming the posterior and shorter limb, while the anterior segment, line A-B, is formed by the bones in front of the astragalus and which extends to the heads of the metatarsal bones, the astragalus itself forming

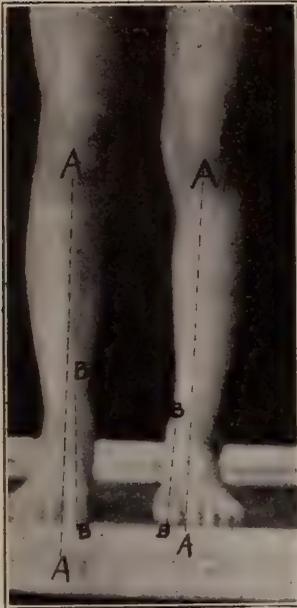

FIG. 7.

FIG. 8.

FIG. 7.—Anterior view of normal feet in standing position. Long dotted lines centralize through ankle and foot in contrast with the weak foot standing in Fig. 9. Short dotted lines B-B show in each case how large toe has now swung away from the second toe so as to point toward line of progress and bear body weight. A space is now evident between the first and second toes.

FIG. 8.—Posterior view of normal feet in standing position. Contrast (with respect to the ankle joint) the locus of this line in the weak foot standing, Fig. 10.

a sort of keystone and being the first structure to receive the direct body weight which is transmitted vertically through the tibia. The first anatomical peculiarity that is immediately apparent is concerned with the relationship of the bones of the foot, as shown in Fig. 2. Here we note that the os calcis as the posterior segment of the arch is not centralized under the weight bearing axis of the foot, line A-A, but that the greater part of its body is outside of such axis. We observe in addition that the greater area generally of the weight bearing foot is outside of this same axis. Now we should also bear in mind that in the normal standing attitude, the astragalus or keystone rolls slightly downward and inward on the os calcis until it, the tibia, the knee joint and the hip joint, are checked from inward dislocation by powerful muscular tension, and which muscles are principally located or act at the inner side of the entire leg. The muscles between the knee joint and the foot which directly keep the arch with the keystone intact by a combined tightening are the flexors of all the toes, and the peroneus longus which tend to flex the longitudinal segments of the arch; the tibialis anticus which by tension from its upper origin in leg has an adducting and inwardly rotating effect on the internal cuneiform and first metatarsal bones, thereby tending to invert the sole and to throw the weight of body on outer side of foot and thus less weight

on the inner or springy and more elastic side of foot; the tendon of the tibialis posticus which passes directly beneath the inferior calcaneoscaphoid ligament, on which ligament the head of the astragalus reclines; and in a lesser measure, this inferior calcaneoscaphoid or spring ligament extending from the inner surface of the os calcis to the scaphoid.

Thus the body is actually resting on an arched foundation that is not centralized beneath it, and with this there exists a normal tendency for the weight of the body to force inward the posterior segment or heel bone as a result of which the keystone or astragalus and its superimposed structures tend to slide in and off the foot in normal standing and more so, of course, in walking, which tendency receives a powerful muscular check. This check, however, can operate most efficiently if direct muscular action is not diverted as shown by the correct attitude in Fig. 4, instead of the incorrect one in Fig. 3. We see in the correct attitude how the muscles act directly in maintaining the arch and effecting graceful locomotion because the line of action through these muscles is a straight one and is not diverted by the break at point C of Fig. 3. We observe also that in the correct attitude, the direction of body weight, line A-B, continues as it should through the length of the weight bearing foot. In the incorrect attitude of Fig. 3, the weight of the body is, as shown by the arrow, concentrated against the keystone region of the arch instead of through the length of the foot and thus together with a diverted muscular play, the tendency of the ankle joint to roll inward is enhanced. In other words, in the incorrect attitude the greater area of the outer and normal weight bearing foot has been

FIG. 9.

FIG. 10.

FIG. 9.—Anterior view of weak foot (flexible flat foot) standing. Note displacement laterally of longitudinal arch with its secondary pronation at ankle joints. Thus this condition is often mistaken for so-called weak ankles.

FIG. 10.—Posterior view of weak foot (flexible flat foot) standing.

relieved of its share of work which is being added in weight at the very point in the arch that was intended mainly for elasticity, thus lessening the spring by this pressure of added weight. The incorrect attitude thus contradicts the normal action

of the various muscles referred to in preserving the integrity of the arch and general body balance and occasions mechanical strain. Such an attitude if maintained habitually helps to produce a weakening of the arch by an overstretching and relaxation of muscles and ligaments, and when accompanied by other factors that may weaken the general or local musculature, as overweight, overstrain, disease, and the like, can only result in a natural lateral and inward displacement of the component segments of the arch, lines A-B and B-C, Fig. 1, and which is the prime objective symptom of the weak foot hereinafter detailed.

It should not be assumed, however, that this muscular play against an arch that tends to fall inward means defective construction on the part of Nature. As a matter of fact, a midplay at the tarsal region is thus effected that makes for the grace and elasticity characteristic in man who, of all bipeds, carries his weight constantly on two feet with most remarkable ease. Besides this lateral midtarsal play is safer than a vertical up and down flexibility of the arch because of the danger entailed to the delicate plantar vessels and nerves by compression between the body and the ground if the arch could rock up and down. The needed vertical elasticity is sufficiently compensated by the ready flexibility of the knee joint itself. Thus where correct attitude is maintained, the muscular play is such as to amply offset what might otherwise be a mechanical difficulty.

An observation of the alignment at the knee and hip joints reveals another anatomical peculiarity that indicates a reciprocal relationship between weak feet and knock knees, explaining why both conditions invariably coexist, and which confirms the necessity for the attitude of Fig. 4. By reference to Fig. 5, showing the posterior skeletal view of the right leg standing, we see that the thigh bones incline inward toward the knees, which, in view of the proximity of the knees, must occur because the upper ends of the thighs at the hip joint are separated in standing by the normal breadth of the pelvis and the extended necks of the femora. The normal inclination of the femora is then inward to the knees, which really means that there already exists a normal amount of knock knee in the standing attitude, the knees tending to collide with any tendency acting from below that would throw the tibia and thus the knee joint inward. But here again, as with the tendency of the leg to roll in on the foot counteracted by muscular resistance, we have the muscles and ligaments in the upper leg and thigh counteracting (by tension and outward force) the knock knee tendency. This again is a natural provision for a useful lateral mobility of the limb, the necessary vertical flexibility being facilitated as stated by simple knee flexion. But the improper attitude shown in Fig. 3, which makes for the inward displacement of the arch by interfering with normal muscular tension, similarly diverts the direct action of the muscles concerned in checking the tendency to knock knee, though in a much slighter degree, by rotating the entire leg outward.

A résumé of the foregoing furnishes these facts:

That there exists a normal tendency to weak foot and knock knee; that this tendency if unrestrained would interfere with the stability of equilibrium and efficient locomotion; that such tendency is checked through muscular tension from hip to heel; that this play between muscle tension and joints is a physiological necessity to elasticity and to protection of the delicate plantar structures in the arch concavity; that the muscles concerned can best act if their action is direct, not diverted, and that direct action or pull of the musculature can only occur when the feet are kept parallel in standing and particularly in walking.

The foregoing discussion is, of course, not intended to be exhaustive as to the relationship between incorrect attitudes and weak feet. What is made plain, however, is that as a prime element of physical education with children, no time should be lost in making the correct attitude of Fig. 4 a fixed routine.

FOOTGEAR.

The numerous objections justly advanced against the vicious types of shoes worn by adults does not warrant discussion here as such do not entirely apply to children's shoes. This is so, fortunately, because the community has become sufficiently civilized as to not put fashion above health with the child's foot by encasing it in tight, narrow and short shoes. Even the girl is allowed a few years lease of foot life before being started on the painful, disabling errand of competing with the Chinese lady in transforming an exceedingly useful organ into a monstrosity. One element of interest concerns us with respect to the shoes of the adult female that may bear on the child's foot. I have in mind prenatal influences that operate to induce a predisposition to foot ailments generally and the weak foot in particular. Here we should view with no little suspicion as a possible contributing agent, the high heel and narrow pointed shoes that are worn by the women especially while pregnant. Such shoes, by compressing the toes and restricting the elasticity of the gait, weaken the muscles which are concerned in maintaining the integrity of the arch, and thus through the generations may result in conferring a predisposition to weakness of the arch by an evolutionary degeneration of muscles and ligaments.

What is of direct concern, however, with the footgear of the child, is the faith of the public in a commercial market flooded with anatomic, orthopedic, and Dr. Blank shoes, to which we have previously alluded. Curiously enough, the importance of other elements of foot pathology are overlooked when it is assumed that a certain manufacturer's label in a shoe is curative. In the fitting element alone, it should be borne in mind that the feet of children vary in contour and action, and as to contour do not follow the very few patterns of the shoe manufacturer. Some feet are long and thin, some short and thick, some highly arched; some have low arches, some possess delicate heel cushions; one child may throw more weight on the ball, another on the heel; most children throw more weight on the inner margin, but some throw weight on the outer margin; ligaments of the knee or ankle may

be weak or disease may have weakened certain structures, and so on.

These and many other considerations do not necessarily call for a special shoe in every case, but should be met by trained medical guidance in fitting with the required modifications provided. Even in the normal child's foot, in view of the rapid and varied growth, it is plain that merely depending on a branded shoe out of stock is insufficient care. The urgent necessity in the case of the pathological foot is thus undeniable. The specific essentials of correct fitting are later mentioned in connection with treatment.

WEAK FEET.

The weak foot occurs commonly in both sexes and generally affects both feet. Its mechanical pathological condition is decidedly peculiar. When off the ground its appearance as mentioned is normal; under weight as in standing or walking it becomes deformed. At rest, there is practically nothing wrong to be seen. A normal range of motion, active and passive, is apparent; there is no muscular restriction or spasm, and only the experienced hand and eye of one who had made a study of the foot might recognize the defect by plantar flexion while viewing the foot plantarwise. Fig. 6 shows a normal foot at rest and will serve as well to illustrate the weak foot at rest. In standing, as shown in Figs. 7 and 8, the line of body weight in the normal foot seems to run straight through the ankle joint on to the arch. When weak feet bear body weight, as in Figs. 9 and 10, we see indications of the inability of the muscles and ligaments to maintain a normal relationship between the segments of the arch and manifest in the abduction of the forefoot, reflecting the angulation through the longitudinal axis of the foot at the astragaloscaphoid articulation with the convexity inward. The head of the astragalus now becomes prominent in front of and lower than the internal malleolus. The posterior view of normal standing feet, Fig. 8, shows the tendon Achilles to be a straight line all the way to its insertion into the heel bone, while in the standing weak foot, Fig. 10, the line of the tendon Achilles curves in and under the ankle joint and in an outward direction at its termination. This curvature of the heel cord in the weak foot reflects the inward collapse of the rear segment of the longitudinal arch, the heel bone itself, whose upper articulating surface has swung inward and its lower weight bearing area outward.

THE FEET AND THE SKELETON.

The feet being obviously the foundation of a relatively heavy and flexible skeleton, we can understand that the weak feet must induce a secondary misalignment of other structures above. There is, therefore, almost invariably a secondary knock knee accompanying, although, of course, an independent form of knock knee may exist without the weak foot influence. But the weak foot creates its own degree of knock knee due to the adduction of the os calcis toward the median line of the body. On top of the heel bone rests the astragalus and, on top of the astragalus, the tibia. The astragalus in the weak foot condition cannot follow the same inward and lateral tilt of the heel, because of its being

firmly wedged between the tibia and fibula, but, as previously mentioned, follows a natural tendency to slide in and forward on the os calcis. With the astragalus the tibia also moves inward through its length and thus the knee joints tend to approximate. That even slight weak foot induces adduction of the knee joints toward the median body line may be demonstrated by placing the finger tips on the patellæ while standing and then voluntarily rolling the two ankles inward. This inward ankle rolling simulates in great measure the mechanical pathological condition of the weak feet and the secondary inward shifting of the knee joints will be easily perceptible.

SECONDARY CHANGES.

Above the knee joint, secondary mechanical deviations are similarly reflected. In advanced cases, particularly with a heavy child, manual palpation at the hip region while having the child voluntarily adopt the normal position and then comparing this with the effect of allowing the child to fall into the weak foot attitude, will demonstrate the referred misalignment at the pelvic region during the weak foot attitude. With this we get an accompanying increase of curvature at the lumbar spine (lordosis) and, of course, the corresponding projection of the abdomen. The increased lumbar curve again often reflects itself in a mild stoop of the shoulders and thus a flattening of the chest results.

The symptoms in individual cases vary as to number and degree. The following is a résumé of typical effects: the child tires easily, is disinclined to play much, rests often, wants to be carried after walking a little, complains of general undefined strain, may show little appetite, and is irritable. It may awaken at night, complaining of unlocalized foot and leg pains. There may be a general nervousness without apparent specific cause, and a complaint of pain in the head or back. As a result of these effects, its school work may be below the average. The shoes wear at the inner heel and sole, and at times holes may be worn at the region of the internal malleolei due to excessive friction and even occasionally to the knocking of the ankle bones in walking. The child is often brought for examination because it frequently stumbles and falls. This stumbling and falling is, of course, occasioned by incorrect posture, the abduction of the forefeet and the referred misalignment at knee, hip and lumbar joints, which materially interferes with a normal gait.

In other cases, the child is brought for examination because excessive intoeing has first attracted the attention of the parents. In walking, the child either toes in or out, but rarely maintains the feet parallel. When the child toes in, it indicates nature's efforts to conserve the integrity of the arch through an instinctive impulse in the child to throw the body weight on the outer and stronger side of the foot. When the child toes out, it may be a symptom of this impulse being too weak or having lost its resistance in combatting the weakness of the affected structures.

(To be concluded.)

Remittances should be made by New York Exchange, post office
or express money order, payable to A. R. Elliott Publishing Co.,
or by registered mail, as the publishers are not responsible for
money sent by unregistered mail. Remittances from Foreign Coun-
tries should be made with International Money Orders.

Entered at the Post Office at New York and admitted for transpor-
tation through the mail as second class matter.

NEW YORK, SATURDAY, DECEMBER 18, 1920.

DIPHTHERIA TOXINS.

It would appear from the recent experimental work carried out by Ménard that the bacillus of diphtheria contains two toxic substances, namely, lipoids and proteins. Both orders are toxic, but differ in their effects. The lipoids, above all, produce local lesions. Injected subcutaneously, intravenously, into the trachea or peritoneal cavity, they invariably provoke local lesions characterized essentially by a rapidly occurring necrosis and fibrinous exudate. This combined necrosing and fibrinoplastic action should lead us to regard the lipoids as possessing an important part in the production of local complications in diphtheria, false membranes, and bronchopneumonia. On the other hand, the local action of the proteins is very trifling or nil. But when introduced into the circulation they are extremely toxic and possess a peculiar affinity for the nervous centres. The lipoids also possess the property of fixing to a certain extent the soluble toxin, and this toxin, when secondarily freed, may be the cause of serious tardy accidents.

These experimental results have led Ménard to suppose that although diffusible toxin of the diphtheria bacillus plays the most important part in diphtheritic intoxication, the constitutive poisons of this bacterium must have a no less important action, the lipoids in producing local lesions, the proteins in causing general accidents, although it is as yet impossible to specify their exact nature. Finally, it is perhaps possible that the late occurring accidents of diphtheria are the result of the freeing of the soluble toxin fixed to the microbic lipoids them-

selves and to those of the tissues in which the organism pullulates or that it impregnates in remote parts. Antidiphtheritic or antitoxic sera have no prophylactic or curative action on the lesions determined by the constitutive poisons of the bacillus of diphtheria. It would certainly appear that this likewise applies to bactericidal sera in general. The practical conclusions of Ménard's experiments, given the present state of our knowledge, is that to the use of antidiphtheritic serum, whose exhibition should invariably constitute the basis of the treatment of diphtheria, the prudent application of selected antiseptics should be added, by means of spraying and irrigations, care being taken not to injure the mucosæ. This is also the best means of sterilizing the nasopharynx in germ carriers.

THE CAUSATION OF RICKETS.

The causation of rickets is still an undecided question, but, of course, it is a complex one. A finger cannot be pointed at a single factor as the definite cause. The condition has been for many years ascribed to errors of diet, to lack of fat and excess of carbohydrates in particular, to unhealthy living conditions, to a deficiency of calcium salts, to aberrant or lacking function of one or other of the internal secretions, or even to an infection or intoxication. However, the exact causes are not yet known. Its origin remains obscure.

Dr. Findlay, in the report of the British Medical Research Committee for 1918, draws attention to the fact that in rickets there exist hyperplasia of cartilage, deficient absorption of that tissue with imperfect calcification, and defective formation of bone. He holds that a disturbance of calcium metabolism is not infrequent, but that loss of calcium is not invariable even in acute rickets. In his opinion the entire matter of calcium metabolism both in health and disease requires revision. He believes that the condition is due rather to unhygienic living than to diet deficiency. Dr. Eric Pritchard, in a paper contributed to the *British Medical Journal*, November 15, 1919, expresses the view that the essential and central feature of rickets is the want of calcification or mineralization of developing bone due to the existence of requirements for calcium which for the time being are more urgent than those of developing bone, namely, the necessity for neutralizing or compensating an existing acidosis. Chronic conditions of malnutrition of whatever kind or from whatever cause arising, finally terminate in acidosis, and all varieties of malnutrition during

infancy and early childhood tend to terminate in rickets. Other factors, such as want of muscular exercise, impure air, lack of sunshine, bad housing, and overfeeding, play important parts. Miss Margaret Ferguson states frankly as a result of an investigation undertaken by her into the social and economic factors in the causation of rickets that the evidence is against dietetic cause of the disease, but she does think that unsatisfactory conditions in the home and particularly inadequate air and exercise are potent factors in determining its onset.

In Vienna at the present time there seems to be an almost universal incidence of rickets among children of the poorer classes when older than one year, and both rickets and scurvy have frequently developed in breastfed infants, often when less than six months old. But these facts do not go far toward solving the problem, because conditions, both dietetic and unhygienic, are as bad as possible in Vienna, although perhaps, the dietetic factor seems to intrude itself more obviously than that of environment. Undoubtedly the causation of rickets is complex and the views of Dr. Pritchard appear to be the most rational, that diet plays the most important part, overfeeding for example, but that several other factors must be taken into account. Rickets may be a deficiency disease in that it is due to diets which are unbalanced because they contain too little of those substances which include antirachitic factors and too much of those substances deficient in this respect.

PARADOX.

Syphilis is good. This is the position held by some of the delegates at the convention in Washington on venereal diseases the week of December 6th. How could they in any possible way twist themselves into this paradoxical attitude. First let it be understood that these delegates were typical reactionaries. This will explain much. But let us, in all justice to them, go on and develop their point of view. These men and women opposed education in regard to venereal prophylaxis. They held that it would lower our morals if we knew how to use certain methods for the prevention of syphilitic and gonorrhoeal infection. They stated that a certain number of men abstained from illicit intercourse from fear of infection. If this fear was removed it would increase the number of contacts and prostitution. Therefore, the knowledge of the possibility of infection by syphilis kept men chaste. If this last barrier was broken down it would influence the morals of thirty per cent. of the men who were chaste, according to their figures. These

men would no longer restrain themselves, and would join the larger group who were not influenced by fear. For this reason the knowledge of prophylaxis must be kept from men. Syphilis in the guise of a punishment for transgression would serve a definite purpose. Syphilis was good, for it was the only thing that kept chaste the good men whom they wanted to protect.

If all this is true, affairs are in a lamentable state. The remedy cannot come by suppressing knowledge. If the fear of syphilis is the only thing that keeps men chaste, then there is something fundamentally wrong with our moral code. These matters should receive attention from the men and women who are engaged in trying to improve moral ethics. If the group engaged in this work at present cannot solve the problem without the aid of syphilis and gonorrhoea as their henchmen they should abandon their tactics and seek an occupation for which they are better fitted. As medical men we cannot allow these people, who confess their inadequacy, to invade our field and try to prevent us from imparting the knowledge of medical science to all men and women who care to learn. We cannot permit these incompetent puritans to fill our hospitals and allow twelve per cent. of our population to suffer from syphilis and a large number from gonorrhoea when we have means at our disposal to prevent infection of the majority. We use the Credé method to protect the eyes of the newborn infant. Why not a similar method for the prevention of venereal disease?

All this talk of venereal prophylaxis lowering morals and increasing contact is childish. With the general introduction of prophylaxis education will follow and the real danger of infection will be shown. At present it is a vague, half formed idea. The necessity for venereal prophylaxis will be a constant warning and serve to decrease contact among all groups rather than to increase it among the chaste who are chaste through fear of syphilis. If men are chaste through fear of syphilis alone and have no other moral factor in their makeup, there can be little real worth in them. If there are other factors, then the protection from venereal infection will not change their attitude.

Venereal prophylaxis will not solve the venereal problem. Many other factors are to be considered. Prophylactic stations will not solve the problem, nor will education alone. But all of these weapons should be used just as is being done at present in the State of Pennsylvania. If the uplifters lose ground through the education of men and women, let them redouble their efforts in other directions and perhaps they, too, will come nearer the truth in their quest for morals.

PHYSICIAN AUTHORS: JOHANN C. F.
VON SCHILLER.

German militarism, now happily a thing of the past, had no more bitter opponent than Johann Christoph Friedrich von Schiller, an obscure army surgeon who became the Fatherland's beloved "Poet of Liberty." Schiller knew military bondage at its worst, and hated it with all his heart. This hatred generated a love of liberty which dominated his whole life. The passion for freedom, the instinct of revolt, was ever present in his writings. From the very beginning, when as a school boy he began writing lyrics, his work breathed defiance against the feudalism of the period, and this defiance never subsided. Instead, his zeal for correcting abuses grew with the years so that by the time he wrote *William Tell*, his last completed work, liberty had become to him a mania, a religion. Schiller was perhaps the earliest spiritual predecessor of the Revolution of 1918. The seeds of discontent which he planted against military despotism were a long time in bearing fruit, and the revolution came about with such a tragic mixture of circumstances that sometimes one is likely to overlook the fact that any pioneering whatever was done. Schiller's influence was indirect, but those who have read him and his successors know that the end of Hohenzollernism was not wholly a thunderbolt out of the blue sky, much as it seemed to be at the time.

Schiller was born on November 10, 1759, the son of an army surgeon, and early evinced a liking for the study of medicine. But whatever liking he had for the profession was driven out of him by the distasteful conditions under which he had to study and practise, and he quit at the earliest opportunity. To put it bluntly, he deserted. That was his only way out. At fifteen he had been conscripted into a school established by Duke Karl Eugen of Wurtemberg. This school was operated along the severest military lines, and that it should grate on young Schiller's sensibilities was inevitable. In 1780 he qualified as a surgeon, but instead of being allowed to choose his own field of practice, he was forced to become physician to a regiment stationed at Stuttgart, at eighteen florins a month—about seven dollars. Even under these unsatisfactory conditions Schiller might have continued his medical work in the army had it not been for the fact that the iron handed duke attempted to repress the literary activities with which the young surgeon sought to beguile the hours of his leisure. Schiller had slipped away from the army post on two occasions to attend performances of his first drama, *The Robbers*, at the court theatre in Mannheim. On the first occasion his unauthorized leave was

not discovered, but on the second he was out of luck. The duke not only imprisoned him for two weeks but also forbade him to write any more dramas. After serving his sentence Schiller fled to Bauerbach, in Thuringia, and not only his military career but also his medical career came to an abrupt end. *The Robbers* was written while Schiller was still at the military academy. Finished when he was nineteen, it has been called "probably the greatest triumph ever achieved in the entire field of literature by one so young." It has its faults, to be sure, but for a school boy of nineteen it is truly remarkable. The drama has been described as a declaration of war against the feudalistic society of the period, denouncing with burning zeal the social and political crimes of the day.

Schiller is best known as a poet. His lyrics have had an immense popularity in Germany. He also turned out much ballad poetry of bold and simple outline. There was a more or less steady flow of this poetry from his pen throughout his career, despite his ambitious activities in the fields of the drama, history, and philosophy. Germany has produced no poet more beloved by his countrymen. Although Goethe excelled him in nearly every field and Heine outstripped him in lyric perfection, it was Schiller whom the German people took to their hearts. He is a giant figure in German literature, but in world literature his rank is somewhat subordinate. Somehow his genius fails to enthuse those not of Germanic temperament and background. Even in Germany, where his star blazed supreme for more than a century, there is said to be less enthusiasm for him. He is slowly going out of fashion. But his decline is likely to be very slow. He is still a textbook for German youth and his words are still in the mouths of men.

Of Schiller's dramas, *William Tell* has produced the deepest and most enduring impression. His dramas are full of grave eloquence, and considerable coarseness, but critics have pointed out that no very exalted moments mark his work. His best mood was one of dignified melancholy. In the first period of his literary career he wrote three prose tragedies, followed by a blank verse tragedy, *Don Carlos*. During the following years he studied and wrote history and philosophy. His histories include *The History of the Revolt in The Netherlands* and *History of the Thirty Years' War*, both written with splendid dignity and both immensely popular. He also wrote a volume of *Historical Memoirs*. His philosophical writings were largely an elucidation and widening of Kant's theories. Kant's *Critique* and Schiller's *The Robbers* appeared in the same year, 1781.

Goethe and Kant both had an immense influence on Schiller's work. Goethe's influence was direct. The two were inseparable friends during Schiller's later years. It was under Goethe's stimulus that Schiller won fresh laurels in poetry at the time the two were coeditors of *Die Horen* and *Thalia*. In the last six years of his brief span of life Schiller produced five verse tragedies and part of a sixth. All are dominated by the idea of Nemesis. Schiller's admiration for Greek tragedy in his last few years left him always in search of subjects in which the Greek idea of destiny prevailed: *Wallenstein* was the most ambitious of the list, *William Tell* the most popular. The other three also are on historical subjects—*Marie Stuart*, based on the life of Mary, Queen of Scots; *The Maid of Orleans*, and *The Bride of Messina*. He also translated and adapted *Macbeth* and Gozzi's *Turnadot*, Racine's *Phedre*, and two comedies by Picard. In the last two months of his life he began a new tragedy, *Demetrius*, based on Russian history, which remains a fragment in two acts. Schiller died in 1805 at the age of forty-five. Personally he was one of the most lovable of men. As his great admirer, Thomas Carlyle, pointed out, he "had all the good qualities of the German character in a high degree and few of its defects."

POET AND PHILOSOPHER.

Poet philosopher, Henri Bergson has been called, sometimes with profound appreciation, sometimes with disparagement. Is he a poet, is he a philosopher, and in either capacity does he effect any benefit to humanity? All men are full charged with poetry, according to his doctrines, for all are inseparably one with the stream of living, compact with all that has been, and charged with the possibilities of what may be. But even in the form of life at the head of the stream, the human, this fullness is dumb. It manifests itself only imperfectly, restrained, yet always bursting the bonds of static definition or of the materialism which it has set itself.

Amid this multitude of restrained and unwitting poets there arises occasionally the rarer poet of expression. He sets forth in winged words the truth of these created limitations which are ordinarily recognized as the sum of life. Much more he proclaims the compressed power which creates these, only again to outflow them. This is pregnant poetry. It is a philosophy of life which men crave, even if they know it not. Many philosophers have so befuddled their task of discovering the meanings in life that for such an one as Bergson it is fitting

to seek a new term. Philosopher, lover of wisdom, should become lover of life. His love of life is simple enough, genuine enough, to search for its meanings exactly where they are displayed, just within our vital activities. The term humanist ought to cover the depth of his insight and the elasticity of his vision backward into the depths of *Mind Energy*, or onward into its unceasing creative activity. Therefore we may borrow this term from the "humanist" thinkers. Bergson reveals kinship with those philosophers who come down to examine the every day matters of the human mind, a common kinship with each separate human existence. This appears both in the translator's introduction to a recently appearing handbook of some of Bergson's investigations into mental facts, as well as in the actual text throughout the book. [*Mind Energy*. By Henri Bergson. New York: Henry Holt and Company, 1920.]

Bergson sets forth there in such forceful manner so many much disputed or even ordinarily undiscovered mental facts that it may be profitable to analyze into the duller but more familiar language of every day some of his more compact expressions. A few of them brought before the reader now and then may recall him to the dynamic intensity whereby alone man "inserts his free action into this material world." Often for physician, commonly for patient, life has lost its savoriness or the flames of enthusiasm have died down under the ashes of depression. Image it as we will, the poet philosopher restores the flavor, revives desire. He directs telling words into the heart of facts. Knowledge of them is power, his spirit of comprehension of them enkindles determination. It is a privilege of the present day to examine the words and enter into the inspiration of this writer.

PROPER MEDICAL ATTENTION.

It is gratifying in these days of sullen reproach by labor against employers, to learn that one injured seaman, an illiterate Porto Rican, was able to obtain compensation which satisfied even his union. The law is that a ship carrying above fifty passengers beyond cabin passengers must provide a doctor. In this case there were not fifty. The man scratched his hand on a rusty nail and the steward gave him a bichloride tablet to dissolve for bathing, and some iodine to paint the wound. However, it grew worse, and he had to have the hand amputated on arrival in New York. The contention was that there was time before the ship left the Antilles to see a doctor, and the steward ought to have recognized the necessity. The man was awarded ten thousand dollars, though the doctor called said the steward had erred through ignorance of the danger.

News Items.

Deaths from Automobile Accidents.—During the year 1919 there were 7,969 deaths from automobile accidents in the Census Bureau's registration area, which comprises about eighty per cent. of the country's population. This is an increase of 444 over the total for 1918.

A Union Health Centre.—A health centre has been established at 131 East Seventeenth Street, New York, by the International Ladies' Garment Workers' Union, to guard and promote the health of the workers in the garment industry. This institution, the first health centre to be established on an industrial basis, will serve the 100,000 workers of the union. The formal opening will take place Saturday evening, December 18th, at 7:30 o'clock, and among the speakers will be Dr. Royal S. Copeland. Dr. George M. Price is director of the institute.

Walter Reed Hospital Damaged by Fire.—Two of the psychopathic wards of the Walter Reed Military Hospital were destroyed by fire on Sunday, December 12th. The two wards, in one of which the violently insane were confined and in the other psychopathic patients received treatment, contained about seventy-five patients. The fire threatened to spread to other wards, including several in which disabled war veterans were patients, but it was checked. One patient, a soldier, is missing, and it is believed that he was burned to death. Several were injured, but none seriously. The loss is estimated at \$25,000.

Medical Association of the Greater City of New York.—A stated meeting of the association will be held in Dubois Hall, New York Academy of Medicine, Monday, December 20th, under the presidency of Dr. George L. Brodhead. The program will include the following papers: Use of Radium in Gynecology, by Dr. Howard C. Taylor; Use of Radium in Surgery, by Dr. W. S. Schley; Use of Radium in Genitourinary Diseases, by Dr. B. S. Barringer. Among those who will take part in the discussion are Dr. Robert Abbe, Dr. James Ewing, Dr. William S. Stone, Dr. D. C. Moriarta, Dr. C. E. Field, Dr. James A. Corscaden, Dr. George Willis, Dr. Oswald S. Lowsley, Dr. E. L. Keyes, Jr., and Dr. Winfield Ayres.

Dietitians Wanted by the Public Health Service.—The United States Public Health Service announces that dietitians are needed in the hospitals of the service. Women graduates of schools of household economics, who have had student training or hospital experience in civilian or Army hospitals, are eligible for appointment. The work, which has to do with the victualing of the hospitals, was transferred a year ago from the pharmacists to a newly established dietitian service. The section has steadily expanded, but owing to the opening of many new hospitals and the enlargement of those already in operation the dietetic personnel is as yet not nearly up to the requirements. Applications for appointment should be made to the Surgeon General, United States Public Health Service, Washington, D. C.

Bequests to Hospitals.—By the will of the late Commodore Elias C. Benedict, the Flower Hospital and the Ophthalmic Hospital, of New York, will each receive \$150,000.

By the will of the late Francis Lynde Stetson, St. Luke's Hospital and the Lying-In Hospital, New York, will each receive \$25,000.

Psychopathic Hospitals for Soldiers.—Senator Wadsworth, of New York, has introduced a resolution authorizing the Secretary of the Treasury to lease from New York State a \$3,000,000 hospital for the care of nervous and mental disease cases among disabled soldiers, which would be built in New York city. The resolution also would give the Treasury Department authority to lease any other hospitals built for like purposes by other States.

Life History of Mosquito Shown in Moving Pictures.—A new motion picture film, prepared at the request of the United States Public Health Service, presents the life history of the mosquito, especially of the kind that transmits malaria germs and costs the United States people about \$200,000 a year by so doing. The film was exhibited for the first time at the meeting of the Southern Medical Association held recently in Louisville, Kentucky.

Women Ask for \$4,000,000 Appropriation to Reduce Infant Mortality.—The women of the United States have asked Congress to appropriate \$4,000,000 to carry on a campaign of education among young mothers. They call attention to the fact that last year there were 250,000 deaths of infants in America, or about 20,000 a month, and most of these deaths could have been averted by proper attention. In 1918, 23,000 mothers died from preventable causes. Fully eighty per cent. of the cases investigated showed that lack of care was the principal cause of death. The Sheppard-Towner Bill which will be presented to Congress soon provides for an appropriation of \$2,000,000 at first, with an annual increase until the sum equals \$4,000,000. The various states will be asked to cooperate by appropriating dollar for dollar with the federal government.

Inadequate Hospital Accommodation for Ex-Service Men.—Surgeon General Hugh S. Cumming, of the United States Public Health Service, calls attention to the fact that additional hospital facilities are needed for the treatment of former service men and women, and recommends the appointment of an administrative head for the three major agencies involved in rehabilitation work. Emphasizing the need for additional hospital facilities, Dr. Cumming pointed out that twenty thousand patients were receiving hospital care from the Public Health Service on July 1, 1920, compared with two thousand in October, 1919, and urged that Congress make available funds for new construction. Many of the hospitals now owned and operated by the Public Health Service are dilapidated. These patients will require treatment for long periods of time, and their demand is for care and treatment in governmental institutions.

Police Association Oppose Hospital Project.—

The Patrolmen's Benevolent Association, which has a membership of nearly 10,000 of the rank and file of the uniformed force, has gone on record as being opposed to the proposed \$5,000,000 Police Hospital. Opposition to the hospital is based on six points, among which were that the patrolmen did not wish to be regarded as objects of charity, and that there was no need for such a hospital.

Child Labor Increasing.—

The National Child Labor Committee calls attention to the fact that in spite of increasing adult unemployment more children left school to go to work in 1920 in many industrial centres than in 1919. Fourteen states report an increase in child labor during the first six or eight months of 1920. In New York city 5,283 more children applied for work permits in the first six months of 1920 than in the same period last year, but in the last three months there has been a decrease in applications so that the total increase is only 2,353. In Baltimore County, Md., there were 4,064 more applications for work permits up to October 31, 1920, than in 1919, while during the summer the Chicago authorities reported an increase of 13,000, and in Minnesota there was an increase of 193 per cent. since 1915.

Yellow Fever Control.—

A new factor has been introduced in yellow fever control by the possibility of rendering persons immune to the disease by vaccination. People going to tropical countries are now being vaccinated at the Broad Street Hospital, the vaccine being furnished by the Rockefeller Institute. This vaccine for yellow fever was discovered by Dr. Hideyo Noguchi, of the Rockefeller Institute. The first shipment of vaccine from the Rockefeller Institute to tropical countries was made a year ago, when three hundred bottles were sent to Mexico. Other shipments have been made since then, the latest on November 10th. All vaccine supplied to Mexico is sent to the Mexican Department of Health, which arranges for its distribution. The Central American countries are so well convinced of the efficacy of Dr. Noguchi's vaccine that they are permitting travel without quarantine detention of those who have been successfully vaccinated.

Boston Meeting of the A. M. A.—

The local Committee on Arrangements for the annual meeting of the American Medical Association, to be held in Boston, June 6 to 10, 1921, has been organized as follows: Chairman, Dr. F. B. Lund; secretary, Dr. Richard H. Miller. Subcommittee on finance: chairman, Dr. Hugh Williams; secretary, Dr. Channing Frothingham; treasurer, Dr. A. William Reggio. Subcommittee on sections: chairman, Dr. William H. Robey, Jr.; secretary, Dr. H. Archibald Nissen. Subcommittee on exhibits and printing: chairman, Dr. D. F. Jones; secretary, Dr. George Gilbert Smith. Subcommittee on hotels: chairman, Dr. John T. Bottomley; secretary, Dr. Stephen Rushmore. Subcommittee on entertainments: chairman, Dr. C. A. Porter; secretary, Dr. A. W. Allen. Subcommittee on registration: chairman, Dr. A. S. Begg; secretary, Dr. Samuel R. Meaker. Subcommittee on clinics: chairman, Dr. J. C. Hubbard; secretary, Dr. R. S. Eustis.

Meetings of Local Medical Societies.—The following medical societies will meet in New York during the coming week:

MONDAY, *December 20th.*—New York Academy of Medicine (Section in Ophthalmology); Medical Association of the Greater City of New York; Psychiatric Society of Ward's Island; Yorkville Medical Society.

TUESDAY, *December 21st.*—New York Academy of Medicine (Section in Medicine); Federation of Medical Economic Leagues.

WEDNESDAY, *December 22nd.*—New York Academy of Medicine (Section in Laryngology and Rhinology); New York Society of Internal Medicine; Brooklyn Pediatric Society.

THURSDAY, *December 23rd.*—New York Physicians' Association; Ex-Intern Society of Methodist Episcopal Hospital, Brooklyn; Hospital Graduates' Club, New York.

FRIDAY, *December 24th.*—Academy of Pathological Sciences; Audubon Medical Society; New York Clinical Society; Brooklyn Society of Internal Medicine (annual).

Personal.—Professor C. E. A. Winslow, of Yale University, will direct the public health work of the League of Red Cross Societies in Europe, and has been granted leave of absence for five months, beginning February 1, 1921.

Dr. A. Strachstein has been appointed chief of clinic and cystoscopist to the Bronx Hospital.

Dr. George L. Laporte has resigned as assistant professor of clinical medicine at the College of Physicians and Surgeons, Columbia University. His resignation took effect on December 1st.

Surgeon J. W. Kerr, of the United States Public Health Service, sailed for Europe on November 20th, with Commissioner General of Immigration Caminetti, to assist in the investigation of emigrant conditions in Europe.

Dr. Arthur S. Tenner announces his return from the Near East and will resume practice at 70 East Fifty-sixth Street, New York. Dr. Tenner, formerly a captain in the Medical Corps, U. S. Army, served in Turkey and Syria as chief eye surgeon of the Near East Relief Expedition, residing in Aleppo, Syria, for the past year and a half.

French Physician Acquitted.—A noncommittal verdict has been rendered by the judges at Nimes, France, in the case in which the parents of two girls brought suit against Dr. Mazel for damages for the death of the girls while under his medical care. The case against the doctor was that he employed an unskilled nurse, who, by not paying proper attention to the cleanliness of surgical instruments, aggravated the illness of the girls, and that the doctor did not follow the prescribed treatment. The father of the girls, Commandant Arnaud, sued for 200,000 francs, and at the same time the charge of criminal homicide was brought against the doctor by the public authorities.

The court, after long deliberation, brought in a verdict acquitting the doctor, refusing damages to Commandant Arnaud, and at the same time refusing the counterclaim for one franc damages brought by the doctor. Commandant Arnaud will have to pay the costs. In the verdict the judges state that they found that the nurse employed did not take proper precautions, and that the doctor ought to have supervised her work more closely. The death of the patients, they found, did not, however, result from neglect, and it was on that that they based their judgment.

Book Reviews

NEW BOOKS ON PEDIATRICS.

Diseases of Children. Presented in Two Hundred Case Histories of Actual Patients Selected to Illustrate the Diagnosis, Prognosis, and Treatment of the Diseases of Infancy and Childhood. With an Introductory Section on the Normal Development and Physical Examination of Infants and Children. By JOHN LOVETT MORSE, A. M., M. D., Professor of Pediatrics, Harvard Medical School; Visiting Physician to the Children's Hospital, and Consulting Physician to the Infants' Hospital and at the Floating Hospital, Boston. Third Edition. Illustrated. Boston: W. M. Leonard, 1920. Pp. v-639.

Diseases of Nutrition and Infant Feeding. By JOHN LOVETT MORSE, A. M., M. D., Professor of Pediatrics, Harvard Medical School; Visiting Physician to the Children's Hospital; Consulting Physician to the Infants' Hospital and the Floating Hospital, Boston; and FRITZ B. TALBOT, A. B., M. D., Chief of Children's Medical Department, Massachusetts General Hospital; Physician to Children, Charitable Eye and Ear Infirmary; Consulting Physician at the Lying In Hospital, and at the Floating Hospital, Boston. Second Edition, Revised. New York: The Macmillan Company, 1920. Pp. ix-384.

Manual of Diseases of Children. By JAMES BURNET, M. A., M. D., M. R. C. P., Physician for Diseases of Infancy and Childhood at the Marshall Street Dispensary, Edinburgh. Second Edition. Illustrated. New York: William Wood & Co., 1919. Pp. i-416.

Principles and Practice of Infant Feeding. By JULIUS H. HESS, M. D., Professor and Head of the Department of Pediatrics, University of Illinois College of Medicine. Illustrated. Second Revised Edition. Philadelphia: F. A. Davis Company, 1919. Pp. i-343.

Leitfaden der Kinderheilkunde für Studierende und Ärzte. Von Dr. WALTER BIRK, Professor d. Kinderheilkunde a. d. Universität Tübingen. Erster Teil; Säuglingskrankheiten Vierte, verbesserte Auflage. Mit 25 Abbildungen im Text. Bonn: A. Marcus & E. Webers Verlag (Dr. zur. Albert Ahn), 1920.

Leitfaden der Kinderheilkunde für Studierende und Ärzte. Von Dr. WALTER BIRK, Professor d. Kinderheilkunde a. d. Universität Tübingen. Zweiter Teil; Kinderkrankheiten mit 10 Abbildungen im Text und auf einer Tafel. Bonn: A. Marcus & E. Weber's Verlag (Dr. zur. Albert Ahn), 1920. Seiten 138.

Diagnostik und Therapie der Kinderkrankheiten. Mit speziellen Arzneiverordnungen für das Kindesalter. Ein Taschenbuch für den praktischen Arzt. Von Prof. Dr. F. LUST, Oberarzt der Universitäts-Kinderklinik in Heidelberg. Zweite neubearbeitete Auflage. Berlin N-Wien I: Urban & Schwarzenberg, 1920. Seiten vi-471.

Morse, in his textbook on *Diseases of Children*, has followed the excellent example set by Southard and Green in publishing his works in the form of case histories. While we have been accustomed to seeing case histories quoted in papers and even in textbooks, we have not had them presented to us in the same way before. In this instance the emphasis is placed on the case history. It is an individual example. It acquires individuality by virtue of the variations it possesses and these variations are the puzzling things encountered in medical practice which make a differential diagnosis difficult. Autopsy reports frequently tell the final story of a wrong diagnosis. We are too prone to seize on a symptom or syndrome in a certain case and conclude our diagnosis, forgetting for the moment that other diseases may present a similar train of symptoms. From the study of case histories, or, we

may say, the study of additional patients, for that is all it amounts to, we learn to look upon each patient as an individual suffering from some maladjustment to surrounding conditions; we realize that a certain individual, even an infant, will react much the same to many different infections or afflictions. In this way the patient becomes the more important, the disease the less important problem.

Morse takes us to his clinic and presents two hundred case histories of actual patients. His object is to illustrate the diagnosis, prognosis, and the treatment of the diseases of infancy and childhood. He also gives an introduction which deals with the normal development and physical examination of infants and children. We are told all this on the frontispiece, but it covers the ground. A book of this kind acts as a stimulus to the practitioner, for it brings to him the familiar phases and conditions as he encounters them at the bedside and at the clinic. It is far more stimulating than the cut and dried statements generally found in the ordinary textbook.

This is the third edition of the work. In it the table of growth for the first four years has amplified, a blood pressure table has been added, there is additional comment on congenital obliteration of the bile ducts, obstetrical paralysis is discussed and directions given for serum treatment. The entire section on the gastroenteric tract has been rewritten, and case reports given of indigestion from an excess of breast milk, of artificial food, of fat in artificial food, of sugar, of maltose, and of starch. A valuable chapter has been added on the home modification of infant foods and the determination of their composition and value. The directions for the administration of salvarsan and mercury have been extended. Many other parts have been added to and changed. There has been no fear shown in discarding methods proved to be superseded by others more advantageous, nor in adopting others more efficacious, no matter from what source they came. More light is shed on tetany, the treatment of whooping cough, nephritis, food values, and enuresis. There is a freedom in the handling of these subjects that is gratifying. The book falls naturally into three divisions, the normal child, infant feeding, and the diseases of children. More could be said in praise of the book, but the practitioner can readily see the advantage of a textbook which handles the problem from the viewpoint of the case history, and Professor Morse has the faculty of giving a most human touch to the subjects he brings before his readers.

* * *

Morse and Talbot have revised their textbook on *Diseases of Nutrition and Infant Feeding*. The methods described are those taught in the Harvard Medical School. The various aspects of infant feeding are described. The advantages and disadvantages of changes from normal feeding are taken up in detail from the chemical and biological viewpoints. The proteins, fats, sugars, starches and

salts are taken up and discussed in turn. Breast feeding also occasions disorders. The subject of the wet nurse is also presented. Then the diseases of the gastrointestinal tract are discussed in detail, and the book closes with a section on the diseases of nutrition. A very broad attitude is taken throughout the book and extensive references are given.

* * *

Burnet's small book on the diseases of children covers an extensive field. When pediatrics first became a specialty a book of this scope would have been considered an undertaking of some magnitude, but today, with the subdivisions of feeding, nutrition, infections, and various other disorders, and the groupings of the newborn, the nursing child, it is convenient to have a small textbook for reference which will cover the entire field which has been so finely subdivided. The divisions are necessary for the scientific worker, but they serve little purpose for the practitioner. The first two chapters on the examination of sick children, which might have been made to include all children, and the points of difference between adults and children, are of especial value. Usually the physician thinks he knows how to approach a child and how to handle it, but careful observation will show that if he would give the matter more thought and heed the admonitions of men of experience, like Burnet, they would make better progress. Burnet is sometimes very vague in his treatment, and is especially prone to make general sweeping statements. He assumes frequently, under this heading, that the physician knows what to do, even to the point of completely ignoring his generalized instructions when they are not found satisfactory. In the chapter on mental and nervous disease, many statements are made in regard to diagnosis, and more especially in regard to treatment and prognosis, to which the modern neurologist will take exception. There is too much generalization and apparently in this field the author is not as much at home as in some of the other sections of the book. Burnet makes a needless apology for the inclusion of the diseases of the ear, nose and throat. This section is a most necessary one, for frequently diseases which would eventually become systemic can be detected by a careful observation of these special organs. Again, much information of value will come from a careful examination of these anatomical parts in every case.

* * *

Hess presents no new or startling ideas in his book on the *Practice of Infant Feeding*. In fact, most of the ideas set forth are a résumé of the work of other writers. However, he has endeavored to pick out the best methods, the most simple and the most satisfactory, and give them to the reader in a simple fashion so as not to complicate matters too much. The computation of feedings and feeding time for the general practitioner has always been somewhat of a puzzle and frequently a bore. It is hard for a busy physician to realize the difference in the dietary between his own and a very young infant. It is hard for him to realize that the

amount of care and mathematical calculation required to make a correct feeding scale for each infant was at one time necessary for him. This book will serve as an efficient reminder and will also enable him to establish a correct diet for the most difficult feeding case in a minimum amount of time.

* * *

New editions of Birk on the diseases of the nursing child have been rather prolific. Less than a year elapsed between the third and fourth editions. Due to the adverse living conditions in the central European countries, on account of the war, many new problems have confronted the pediatricists. Birk is very thorough in the field he covers. In his analysis of feeding conditions he presents some graphic formulæ which are extremely simple. When he speaks of the chemistry of food he is somewhat didactic. He goes into a careful examination of the comparative values of cow's milk and breast milk.

First we have the pathology and physiology of the stillborn, the premature child and the so-called normal child. Then come the nursing problems and hygiene, the disorders of alimentation, and finally the various diseases and disorders. The book is of especial value to the pediatricists in this country, for it contains a vast amount of work which was done in the Germanic countries during the war and which has been inaccessible to the physicians in this country.

* * *

Birk's second book on the diseases of children older than the nursing age is a first edition and should not be confused with his book for nursing children. Here he handles in a very satisfactory fashion the common infections. He places more emphasis on the treatment and diagnosis. He does not pretend to cover the entire field, but the subjects he covers are well done. His writing is not involved and has a certain amount of wholesome vigor that takes away from the ordinary textbook monotony. On the whole, his presentations are good. The second book of the series is not as finished as the book on suckling infants, but contains many illuminating deductions.

* * *

Lust is rather ambitious in attempting to cover a rather extensive territory in his book on children's diseases, or, more accurately, the therapy of pediatricians. This is the second edition of his book, yet we may look upon it as his first, for while the first edition was published in 1918, on account of the war it was not available in this country.

A goodly portion of the book is devoted to the formulæ of various therapeutic measures, prescriptions, régimes, etc. These are not as valuable in this country as they may be in Germany, for in regard to drugs and methods our line of procedure is at variance with theirs in many respects. The merits or demerits of the various schools need not be gone into. However, many physicians in this country will avail themselves of the opportunity of finding out what progress has been made in the Central European countries during the years of the war.

TYPHUS AND RELAPSING FEVERS IN SERBIA.

The Serbian Epidemics of Typhus and Relapsing Fevers in 1915. Their Origin, Course, and Preventive Measures Employed for their Arrest. An Etiological and Preventive Study Based on Records of British Sanitary Mission to Serbia in 1915. With Maps and Charts. By WILLIAM HUNTER, C. B., Colonel, A. M. S. Reprinted from the *Proceedings of the Royal Society of Medicine*, 1919. Vol. iii, Section of Epidemiology and State Medicine, pp. xxix-158. London: John Ball, Son & Daniels-son, Ltd., 1920. Pp 158.

This little monograph has been prepared with great care and is an excellent piece of work. Typhus, once the nature of the disease and the manner of its transmission were known, was thought to be wiped out, but the wars of man and life in the trenches brought the disease back in epidemic form. It swept through Serbia like a prairie fire and scarcely a family remained untouched. It was here that Hunter made his studies. He presents them now that the benefits of his findings may be applied in the countries which are yet in a state of war. Typhus is still rampant in Poland and parts of Russia. In certain districts it occurs in endemic form; in parts of Mexico and on the lower east side of New York City. It seems strange that this dreadful disease, which is so easily eradicated, should still be prevalent. Perhaps with a reappearance of a semblance of sanity among the peoples of earth typhus will become extinct. In the meanwhile there is still need for a study of the malady and no more complete work has been offered recently than that of William Hunter.

LIMITS AND FLUXIONS.

A History of the Conceptions of Limits and Fluxions in Great Britain from Newton to Woodhouse. By FLORIAN CAJORI, Ph. D., Professor of History of Mathematics in the University of California. With Portraits of Berkeley and Maclaurin. Chicago and London: The Open Court Publishing Company, 1919. Pp. viii-299.

He who professes to give an account of men who have cleared a path, to tell of their work and its value, should remember that insufficient references annoy rather than help. To pretend that a man or a book is so well known that full titles are not necessary is really a lazy way of escaping trouble and makes the real student distrustful of the whole work. To seek an initialless author and his book (wrongly titled) makes the most patient reader sadly sigh or strongly swear. But no such emotion will tarnish the welcome given to Florian Cajori, for he marshals his exponents of limits and fluxions in admirable order, and, not only that, but the full title and date of the work of each is supplied. The audience room is crowded—Newton, Berkeley, the celebrated Bishop of Cloyne, Maclaurin, a keen disputant, Carnot, D'Alembert, L'Grange, Cauchy, all with their own ideas and unwilling to admit those of Newton. There is a doctor, too, George Cheyne, of Edinburgh, who, besides the differential calculus, also treats the pathological calculus, and, besides that, atheism and other more light subjects. A few of the men are denying that the circumference of a circle, or any other curve, can be identical with the periphery of any polygon whatever. Berkeley also wrote to Iurin, "For a fluxionist writing about momentums to argue that quantities must be equal

because they have no assignable difference, seems the most injudicious step that could be taken; it is directly demolishing the very doctrine you would defend. For, it will thence follow that all homogeneous momentums are equal, and, consequently, the velocities, mutations or fluxions proportional to these are likewise equal. There is, therefore, only one proportion of equality throughout which at once overthrows the whole system you undertake to defend."

The dispute waxes hot, but, with the main statements of each man in Cajori's book, we can follow the argument easily, or, being amply, richly leisured, the arguer's own books. Among the disturbing pile of volumes in the educational booksellers this should be the one the tired man will get most help from on the subject. Certainly it shows the amount of thoughtful work put into it.

THE DARK MOTHER.

The Dark Mother. By WALDO FRANK. New York: Boni and Liveright, 1920. Pp. 376.

The book is too long, the sentences too short. The book with all its length arrives at no particular place. The sentences, often only choppy groupings of words, finish nothing, explain comparatively little, splash color about with too much of the disjointedness of ineffectual pain.

And that is it. The reader feels that there must be behind the book an author who is vainly catching at life in many directions, ignorant of a "canalization" that brings its fragments into relation to purpose. His pages give one the sense of acquaintance in part with many partial urges, but not yet developed out of their childish separateness. There are evidences of deeper psychic penetration into some of these phases. There are episodes of revealing discussion of the relation of parents and children, of brother and sister, both running with the lives of the main characters of the book. These family relationships with their dominations, their fierce reactions, their estrangements, their drawing power toward unsafe dependence, all these are handled with insight into their real significance. They follow with the sharply individual character drawings that fill the many pages of the volume.

Unfortunately, Frank has been unable to gather all this into that undefined unity which makes a work of art. Such a work must represent the scattered elements of the real world. It must, however, at least point a synthesis, which is only that same canalization which finds in the elements the material by which it travels onward. It is the same with some of the more external promises of the book. They lead us to expect something of the light of thoughtful fiction upon political and economic questions of two decades ago. The promises soon fade. Like the stories of the chief characters themselves, their mentions seem to be unrelated to a goal.

The lives of Tom and Cornelia have been beaten upon early by the blows of a father, which have prevented wholesome unity in its most essential sphere, their own true inward selves. They cannot unite their scattered impulses. Both achieve material success, but both are divided as to their deepest needs. So was their attitude toward their father

split into the ambivalence of love and hate. Strange wonder that Tom lives a conscious double life with himself, and Cornelia's creativeness puffs itself out in a final renouncement of the boy David. She realizes the maternal in her love, but its hopeless incongruity also, as only a gathered reaction against father and brother entanglement.

David's life carries the dreams of the ideal. Yet it, too, is an unsatisfactory picture of one knows not what. The same cool, meaningless separateness lies between his attempts to hold his ideal and to find the world of harder things. A curiously crass carnalism seems as little to disturb the tenor of his aims as in any way to perform any service really linked with those aims. He, too, struggles purposeless in the more embracive sense. True, his fleshly affairs give him some glow of awakening, but one asks whether such mere casualness marks the life of men and women so generally as the author would lead us to believe. These incidents, just like all the sketchy pictures of the great city where the story moves, show distraughtness in the mind of the writer. The book is too indicative of partial trends, of an unsynthesized grouping of interest, to be real literature.

DOMNEI.

Domnei. A Comedy of Woman Worship. By JAMES BRANCH CABELL. New York: Robert M. McBride & Co., 1920. Pp. viii-218.

Minstrelsy knew this story long ago as each one of us dreams it to himself today. A life devoted to the fairest lady, a heart sworn to her service, with torture and waiting, hardship and bitter fighting endured on her behalf.

The troubadours vied with each other to sing of such devotion; we have the privilege of living it breathlessly, painfully, and blissfully with Perion. This is not lovemaking according to note. The medieval songsters had their formulæ, but somewhere outside the rules laid down living beings loved; and here they are.

It is for you to discover the tender melody in Cabell's romance of Perion and Melicent. We can only tell you how they met and parted, how Perion, warring against the unbelievers, was captured by Demetrius of Anatolia, and how Melicent went in search of Perion. The story is vivid enough for any lover of adventure and brave deeds.

The men and women in it you must learn to know for yourselves, to recognize in your secret hearts all that there is of poetry, beauty, and unwavering truth in this simple tale.

TRUE LOVE.

True Love. By ALLAN MONKHOUSE. New York: Henry Holt and Co., 1920. Pp. vi-373.

The author had a collection of fine ideas on play writing, also on unity of nations, conscientious objectors, and war generally. They were all piled up on his study floor and he wanted to talk to the people about them. An essay? No; the subjects did not run smoothly together. There was that question whether an English soldier should marry a German girl. Why not write a novel? So he gathered characters who by their deeds would show forth his views.

The hero, playing his part, suddenly remembers he is a mouthpiece for Mr. Monkhouse, and talks accordingly, but too lengthily. Sister Mary and the German girl, Sibyl, whom Arden, the hero, marries, are fine characters, but they too are worried by the amount of information they have to give the reader and so become dull. There is so much which is good in the book that one may confidently say the author will be more at home with the characters he creates and the readers he hopes to gain in his second inky venture. The death of both hero and heroine rather indicate the author to have been a trifle tired of his own creations.

New Publications Received.

[We publish full lists of books received, but we acknowledge no obligation to review them all. Nevertheless, so far as space permits, we review those in which we think our readers are likely to be interested.]

CHILDREN BY CHANCE OR BY CHOICE. And Some Correlated Considerations. By WILLIAM HAWLEY SMITH. Boston: Richard G. Badger (The Gorham Press), 1920. Pp. 361.

ELECTRICAL TREATMENT. By WILFRED HARRIS, M.D., F. R. C. P., Senior Physician and Lecturer on Neurology, St. Mary's Hospital; Physician to the Hospital for Epilepsy and Paralysis, Maida Vale. Illustrated. Third Edition. New York: William Wood & Co., 1920. Pp. x-354.

THE SYSTEMIC TREATMENT OF GONORRHEA IN THE MALE. By NORMAN LUMB, O. E. B., Late R. A. M. C., Specialist in Venereal Diseases, and Officer in Charge of Division, 39 and 51 General Hospitals, B. E. F.; Clinical Assistant, St. Peter's Hospital for Stone. Second Edition. Philadelphia and New York: Lea & Febiger, 1920. Pp. viii-123.

ZEITSCHRIFT FÜR TUBERKULOSE UNTER MITWIRKUNG DER HERRN PROF. BABES (Bukarest), Prof. BANG (Kopenhagen), Geh. Med.-Rat. Doktor BEHLA (Charlottenburg), Dr. LEO BERTHENSEN (St. Petersburg) und so weiter. Herausgegeben von M. KIRCHNER, F. KRAUS, W. v. LEUBE, J. ORTH, F. PENZOLDT. Leipzig: Verlag von Johann Ambrosius Barth, 1920. Seiten 64.

PUBLIC HEALTH AND HYGIENE. In Contributions by Eminent Authorities. Edited by WILLIAM HALLOCK PARK, M. D., Professor of Bacteriology and Hygiene, University and Bellevue Hospital Medical College, and Director of the Bureau of Laboratories of the Department of Health, New York City. Illustrated with One Hundred and Twenty-three Engravings. Philadelphia and New York: Lea & Febiger, 1920. Pp. xvi-884.

SURGERY. ITS PRINCIPLES AND PRACTICE. For Students and Practitioners. By ASTLEY PASTON COOPER ASHHURST, A. B., M. D., F. A. C. S., Associate in Surgery in the University of Pennsylvania; Surgeon to the Episcopal Hospital and to the Philadelphia Orthopedic Hospital and Infirmary for Nervous Diseases; Colonel, Medical Reserve Corps, U. S. Army. Second Edition, Thoroughly Revised. With Fourteen Colored Plates and 1,129 Illustrations in the Text, Mostly Original. Philadelphia and New York: Lea & Febiger, 1920. Pp. xi-1202.

PRACTICAL BACTERIOLOGY, BLOOD WORK, AND ANIMAL PARASITOLOGY. Including Bacteriological Keys, Zoological Tables, and Explanatory Clinical Notes. By E. R. STITT, A. B., Ph. G., M. D., Sc. D., LL. D., Rear Admiral, Medical Corps, U. S. Navy; Commanding Officer and Head of Department of Tropical Medicine, U. S. Naval Medical School; Graduate, London School of Tropical Medicine, etc. Sixth Edition, Revised and Enlarged, with One Plate and One Hundred and Seventy-seven Other Illustrations Containing Six Hundred and Thirty-seven Figures. Philadelphia: P. Blakiston's Son & Co., 1920. Pp. xi-633.

Practical Therapeutics and Preventive Medicine

A Compendium of Treatment and Prophylaxis, Original and Adapted

Experimental Pneumectomy.—George J. Heuer and George R. Dunn (*Bulletin of the Johns Hopkins Hospital*, February, 1920) performed total pneumectomy on twenty-three dogs, with thirteen recoveries and ten deaths occurring from four days to two months after the operation. Six of the fatalities were caused by an epidemic of distemper among the dogs in the earlier part of the work. At autopsy none of these dogs showed infection of the parietal wound or pleura or leakage from the bronchial stump. The following causes were responsible for the deaths of the rest: Simple pneumonia unassociated with other evidences of distemper, one; starvation, two months after operation, one, with remarkable emaciation at autopsy, but no other cause for death; acute pneumothorax, two animals, as a result of leakage from the bronchial stump. In one of these failure to secure an adequate closure of the bronchial stump was intentional; in the other necrosis of the bronchial wall followed the application of an intentionally flattened, not rolled, metal band. The animals were kept under observation in some instances for a year, and were returned to the yards with the other dogs as soon as they recovered from the operation. They were apparently active, healthy, free from dyspnea, and held their own with the other animals. The technic for the lung excision is given in detail, together with various methods for treating the bronchial stump.

Treatment of Pneumonia.—J. W. Preston (*Virginia Medical Monthly*, November, 1920) notes that while type I serum is curative in type I cases, it has not come into general use because of the existing impracticability, outside of large centres, of securing prompt typing of pneumonia cases, as well as because of the minute detail necessary in the administration of the serum. Further, type I represents less than one third of all lobar pneumonias, and the great majority of cases in the past two years have been, not lobar, but bronchopneumonia. In most cases in which a severe type of pneumonia develops, the author has noticed some basis for it either in loss of sleep, physical exhaustion, mental upset, or an inability or unwillingness to remain quiet in bed in a room maintained at a comfortable temperature. The picture in severe bronchopneumonia is one of exhaustion of the vegetative nervous system, resembling that of shock, and the author's best results have been obtained from treatment such as would forestall or benefit shock. Such treatment excludes severe purges, any except the smallest doses of coal tar products, sponge baths, cold air, and all exertion, whether mental or physical. Of the drugs, opium, preferably in the form of codeine by the mouth, or one twelfth grain doses of morphine given hypodermically at intervals sufficiently short to control cough and restlessness, proved of greatest value. As adjuvant, atropine is a close second, but only in doses of one six hundredth grain, given with the opiate, e. g., hourly, until

some effect is noted, then at longer intervals. To sensitize the heart to digitalis action it seems advisable to begin with a small dose of the tincture, e. g., ten drops three times daily. This dose does not upset the digestion, yet is sufficient, should the circulation weaken, to enable one quickly to digitalize the patient by giving one half to one dram at a dose, repeated as indicated. A frequent cause of cardiac and respiratory embarrassment is gaseous distention. The diagnosis of pneumonia having once been established, frequent examination of the abdomen is strongly indicated. In addition to enemas and turpentine stupes, pituitrin is of the greatest service. It should be given early and at regular intervals in cases showing a marked tendency to distention. A small rectal tube introduced and allowed to remain in severe cases also affords pronounced relief. As a quick pick-up for the heart and for relief where there is an asthmatic tendency, adrenalin has seemed to aid, but its action is more transient. Hot mustard pastes applied early over the entire chest are a great help. Intravenous administration of glucose is destined to be of great assistance in patients not annoyed or upset by it, especially those with a tendency to acidosis.

Purpura and Meningococcic Septicemia.—P. Lereboullet and J. Cathala (*Paris médical*, October 30, 1920) point out that meningococcic septicemia is by no means a rare condition. In recent years cerebrospinal meningitis seems to have assumed purpuric and septicemic characteristics more frequently than before. The disorder may appear as a simple infectious purpura which continues clinically mild until the terminal meningeal symptoms supervene. Any case of rheumatoid purpura of obscure origin should lead at once to the suspicion of meningococcic septicemia. For the early detection of this type of purpura consideration should be given to the question whether the purpura appeared in a locality in which cerebrospinal meningitis had previously occurred. In one of Netter's cases the coexistence of cerebrospinal meningitis in the sister of a little girl of six years exhibiting purpura led to the discovery of the meningococcic origin of the latter. On lumbar puncture, cloudy fluid points definitely to meningococcic infection. A clear fluid does not, however, exclude such infection. A blood culture should be made on bouillon and ascitic fluid, but is often negative. Under exceptional conditions meningococci may be found by staining tissue sections of a purpuric spot, or the organism found in smears of bloody fluid from such a spot; or, again, it may be demonstrated in the fluid contained in the seropurulent vesicles sometimes formed on the surface of a pètechia. The meningococcus may likewise be sought in the pus from definite foci of infection accompanying the septicemia, as in suppurative arthritis or iridochoroiditis. In severe cases, even where the meningococcus cannot be identified, antimeningococcic serum should be given by intramuscular injection. If a polyvalent serum

is unavailable, B meningococcus serum should be chiefly used, as the B organism has been found in nearly all the cases of this type so far reported. The serum should be administered as soon as the suspicion of meningococcic infection arises. These cases are more frequently fatal than the ordinary forms of cerebrospinal meningitis.

Presence of the Tubercle Bacillus in the Blood Stream.—Sabathé and Buquet (*Presse médicale*, October 27, 1920), to demonstrate the tubercle bacillus in the circulating blood, collect six mils of blood in a test tube and allow it to coagulate. After the clot has contracted, some of the fluid is withdrawn by means of a pipette placed in contact with the clot and smears made and stained by the Ziehl method. Tubercle bacilli will be found in the blood of tuberculous patients by this procedure.

Sodium Citrate in the Treatment of Pneumonia.—L. Cheinisse (*Presse médicale*, February 14, 1920), commenting on Weaver's pneumonia treatment with large doses of sodium citrate, notes that observations with the viscosimetre on pneumonia cases would appear to justify the citrate treatment. The viscosity of the blood has almost invariably been found high in pneumonia, especially in comparison with the hemoglobin values. Hence the seeming advantage of acting remedially upon the viscosity and restoring it to normal. Sodium citrate may also be held to act by reducing the coagulability of the blood and by increasing its alkalinity, which is lowered in pneumonia.

The Bacteriology of Colitis.—H. L. Lyon-Smith (*Lancet*, June 12, 1920) considers that the usual methods of investigating the stool in colitis for the purpose of identifying the chief organism producing the inflammation are unsatisfactory. He points out that we are anxious to learn what bacteria is present in the mucosa rather than in the feces. In order to get as accurately as possible this information, he first gives a Plombière douche of a pint of warm water. Then a second injection of two or three pints is given and retained for six minutes while the patient is moved from side to side. The washing is received in a clean receptacle and is searched for particles of mucus which are placed in a sterile container to be kept for such examinations as seem necessary.

Control of Epileptic Seizures.—Irving J. Sands (*State Hospital Quarterly*, February, 1920), in discussing the control of epileptic seizures, gives the following summary of his findings: 1. Epilepsy in the present state of information might be best regarded as a disease entity, as nothing might be gained from including under the same caption those forms of convulsions which are occasioned by definite etiological agents and in which constant and definite pathological changes are seen at necropsy. 2. To combat convulsions the drug giving the most satisfactory results is luminal. A review of the literature and citation of cases are given to prove its usefulness and efficacy in the management of this disease. 3. Ordinary hygienic measures, proper exercise, hydrotherapy, rigid attention to the diet and to the bowels, are indispensable agents in controlling epileptic seizures.

The Dose of Iron.—Albert Adler (*Schweizerische medizinische Wochenschrift*, July 29, 1920), who is apparently Naegeli's assistant, discusses the dose of iron to be employed in chlorosis. In bad cases he gives from three to ten doses a day of 0.1 gram of reduced iron. The improvement in the blood reaches its acme in about three weeks. He is more enthusiastic than Naegeli concerning the benefit to be expected in the very bad cases.

Action of Iron in Chlorosis.—Naegeli (*Schweizerische medizinische Wochenschrift*, July 29, 1920) considers that chlorosis is in fact a torpor of the blood formation which differs in degree in different cases, and can scarcely be overcome in the worst. Iron, when given in sufficient doses, acts as a stimulant, particularly of the bone marrow. In this it excites a stormy reaction, which causes quantities of young elements to be thrown into the blood. Not only the hemoglobin elements, but the whole of the bone marrow appears to be stimulated.

The Milk Situation.—Howard Swift (*Boston Medical and Surgical Journal*, April 29, 1920) says that milk in a raw form often endangers the health of infants. The amount of immunity that is transmitted through infected milk for tuberculosis is an unknown quantity. Pasteurization, as called for by the present law, may not be so safe as is generally believed. There is a considerable loss of life and impaired health directly attributable to the use of infected dairy products. Under the present demand by the public, the producer cannot afford to manufacture a cleaner and better product. He urges a campaign to secure tuberculosis free milk.

Epidemic Hemeralopia Due to Lack of Vitamines.—R. Tricoire (*Paris médical*, February 21, 1920) states that epidemic hemeralopia may occur in the human subject when certain vitamins of group A are lacking from the diet. The condition may be classified as an avitaminosis, in conjunction with scurvy, which is due to lack of substances of the same type—liposoluble vitamins. Like other avitaminoses, epidemic hemeralopia develops only after the deficient diet has been employed for a certain period of time. Apparently the avitaminoses set in only after an actual incubation period, which, in the case of epidemic hemeralopia, is probably from three to four months. The hemeralopia disappears rapidly after the vitamins are supplied.

Diabetes in Wartime.—D. Gerhardt (*Schweizerische medizinische Wochenschrift*, February 19, 1920) says that during the war the food conditions were more unfavorable for diabetics than for any other class of patients, so physicians looked for a marked change for the worse in them. But these fears were not realized. On the contrary, the dietetic restrictions had a favorable influence, which he ascribes to the low calorie content of the food, the small proportion of albumin, and the large amount of vegetables eaten. Meat and cheese were not absolutely forbidden, and the diabetics did better than they could have been expected to do on a strict antidiabetic diet without careful medical supervision. He is inclined to think that too little carbohydrate may do harm, as well as too much, and that the entire quantity of food should be limited.

Proceedings of National and Local Societies

AMERICAN PEDIATRIC SOCIETY.

Thirty-second Annual Meeting, Held in Highland Park, Ill., May 31, June 1 and 2, 1920.

The President, Dr. THOMAS S. SOUTHWORTH, of New York, in the Chair.

Segregation of Pneumonia.—Dr. THOMAS S. SOUTHWORTH, in his presidential address, declared that pneumonia was today one of the greatest endemic plagues of the world, and one for which less had been accomplished in the way of limiting its ravages than for any other malady of like import save pandemic influenza. This, he said, was not due to lack of interest in the problem but rather to its complications, since the processes we called pneumonia were several pathological entities of diverse etiology, and with somewhat loosely correlated clinical manifestations. Untiring zeal had been expended to find a remedy for the pneumonias, but the possibility of guarding against their inception had not been considered as clearly. Here the field was a wide one worthy of further patient study. One avenue not properly guarded was the exposure of susceptible individuals in dangerous propinquity to active cases of the disease.

It had long been recognized that pneumonias were caused by microorganisms of recognized pathogenic virulence, yet it had been the custom to treat pneumonias in the general wards of hospitals and to place about them in the home the ordinary precautions of the sick room. Segregation of such cases might have been practised by thoughtful individuals, but the idea had not found its way into the general medical conscience nor been advocated widely in our literature. Dr. Southworth said that for years he had insisted, when possible, upon the prompt isolation of the first cases of pneumonia among children having measles with a resulting limitation of the number of cases and had extended segregation to all the pneumonias. The real question was not whether the case for the individual infectiousness of the pneumonias was fully proved to the satisfaction of the most skeptical but whether, as physicians, they were individually to assume responsibility for permitting exposure in cases of pneumonia which they would not permit in many types of much less serious illness, the latter having been declared quarantinable while pneumonias thus far had not been. The obligation was imperative to anticipate the day, not far distant, when the movement to control the scourge of pneumonia might make the retention of such cases in a general ward as repugnant to our medical sense of propriety as the retention of a case of open tuberculosis.

Studies on Blood Sugar: The Effect of Blood on Picrate Solutions.—Dr. DAVID MURRAY COWIE and Dr. JOHN PURL PARSONS, of Ann Arbor, described experiments which they had made tending to show that blood contained substances other than sugar which induced a color change in the picrate solution employed in the modified Lewis-Benedict blood sugar method. Under normal con-

ditions these substances did not interfere with the established normal range for this method. Under pathological conditions several of these substances which showed the most marked influence were epinephrine, acetone, and diacetic acid. Creatinine might interfere but did so in a less marked degree if we considered the comparative sensitiveness of the picrate solution to these substances.

As picrate solution reacted to smaller quantities of acetone than were normally found in the blood, the question might well be raised, "Do not the acetone bodies of the blood contribute to the established normal blood sugar range for the Lewis-Benedict test?" Still another question might be asked: "As epinephrine in infinitesimally small quantities induces a color change in picrate solution, is it not possible that this substance when thrown into the general circulation, as is supposed to happen in emotional states, may induce a so-called hyperglycemia without mobilizing the glycogen stores of the liver?"

Epidemic Encephalitis Lethargica.—Dr. LINNAEUS E. LA FETRA, of New York, stated that cases of a disease accompanied by profound somnolence and lethargy had occurred at various times in sufficient number to have been regarded as epidemics. It was evident both from the difference in the lesions and also from the results of animal experimentation that poliomyelitis and epidemic encephalitis were distinct diseases. In his experience epidemic encephalitis had not followed influenza with sufficient regularity to warrant one in stating that it was caused by influenza, though influenza might possibly predispose the patient to infection or increase the virulence of the prevalent virus.

After reviewing the recent work of Loewe and Strauss Dr. La Fetra presented an analysis of eleven cases of encephalitis seen at Bellevue Hospital since January 1, 1920. Of these eleven cases four were fatal. There was no relationship between any two of the patients and they did not live in close proximity to each other. In only two was there any history of influenza. The symptoms were variable, but in most instances there was marked headache accompanied by occasional dizziness; vomiting occurred in about one half the cases; pain in the eyes and cheeks compelling drowsiness was present in most of the cases. When the disease was well under way the outstanding features were lethargy, general weakness, and ptosis or paralysis of the ocular or facial muscles, with double vision in several instances. Fever was usually very slight, and lasted for only a few days. The spinal fluid was under little or no increased pressure, and in some instances was perfectly normal. It was noted that in the fatal cases there was a higher white cell count than in those where recovery took place. In most cases globulin was present, and there was an increase in the number of cells. The highest number of cells was 275 in a fatal case; the average number, however, ranged from fifty to one hundred, all of which were mononuclears. The fluid was

sterile on culture. Recovery took place gradually, there being first a return to consciousness, then a diminution of catatonia and paralysis, and last of all the asthenia and ptosis disappeared. Undoubtedly, as in poliomyelitis, abortive, mild, atypical cases of the disease occurred, many of them probably being unrecognized. The disease had to be differentiated from tuberculous meningitis, poliomyelitis, cerebrospinal syphilis, brain tumor and meningism. The mortality of the disease was about the same as that of poliomyelitis. How great a proportion of the patients might later show damage to the brain it was too early to state. The treatment, until a specific serum was produced, was symptomatic.

Acute Cerebrocerebellar Ataxia.—Dr. J. P. CROZER GRIFFITH, of Philadelphia, presented three new cases of encephalitis and a résumé of a case previously reported, all of them pointing to an involvement of the cerebellum as well as the other parts of the brain. The first case exhibited incoordination, nystagmus, affection of speech, confusion of mind, increased knee jerks, but no paralysis. This patient made a rapid and complete recovery. The second case exhibited a staggering gait, dizziness, incoordination, no nystagmus or affection of speech. This child showed some incoordination three and three quarters years later. The third patient had a staggering gait, strabismus, nystagmus, vertigo, mental backwardness, affection of speech; normal eyegrounds. A year later the symptoms were still present but improved. The fourth case exhibited early symptoms suggesting encephalitis lethargica. During improvement marked incoordination and affection of the speech became manifest. Recovery was very slow. At last report the slow speech still persisted.

The conclusion reached from a study of these cases and of seventeen cases previously collected from the literature, was that this was not a common condition but that it occurred more frequently than was ordinarily supposed, in which acute hemorrhagic encephalitis involved the cerebellum and which might be designated acute cerebellar encephalitis. With this disease there were always combined symptoms indicating an involvement of the large brain as well, and for these the title cerebrocerebellar encephalitis or cerebrocerebellobulbar encephalitis was to be preferred. The degree to which the process involved one or another part of the brain varied, but in all cases there was a combination of the symptoms affecting both regions. The cause of cerebrocerebellar encephalitis varied decidedly. In the majority of cases previously reported some infectious disease had preceded the attack. This was true in two of the cases reported in the paper; in the other two no such connection could be discovered. The symptoms were those mentioned in the cases cited. The prognosis so far as life was concerned seemed good. That clinical evidence of the disease would not persist was uncertain, but so far as statistics went it would appear that the disease would leave no traces in the majority of instances. Lumbar puncture was done in all the cases reported by the writer and was always negative.

The Significance of Xanthochromia of the Cerebrospinal Fluid, with Report of a Case in a Premature Infant.—Dr. ISAAC ABT, of Chicago, said this case was reported because of the yellow coloration of the spinal and ventricular fluid. The infant was thirty-seven days old at the time of death and was of eight months' gestation. Interest also attached to the case because of the occurrence of bronchopneumonia and pyelitis. Xanthochromia was found in the complete syndrome of Froin and in the incomplete syndrome of Nonne. Froin's syndrome included massive coagulation, while Nonne's syndrome included increased globulins, but not massive coagulation. The importance of cell increase was mentioned by some and ignored by others. Considering xanthochromia by itself was the simplest way of elucidating the subject. It was most frequently found in cases of tumor, inflammation, or trauma, cutting off part of the spinal canal. The cul-de-sac so formed usually contained a yellow fluid which coagulated *en masse*. The pigment comes from the blood ultimately. In addition to the process of transudation which occurred in a cord compression, it was readily seen that any condition which permitted red blood cells to escape into the spinal fluid might produce a yellow color when the red cells had been dissolved and the hemoglobin freed. The globulins were always increased in a yellow fluid, whether massive coagulation occurred or not. It might be due to transudate in the case of a tumor pressing on the cord; exudate in the case of a meningeal inflammation, and hemorrhage in cases due to trauma, inflammations, and tumors.

Increased cell count occurred in cases of meningitis, and was also found in cases of tumor and hemorrhage. In the last case the presence of red cells usually excluded other conditions, although blood might be present as a concomitant finding in tumors and meningitis. Pellicle formation was of little importance, was usually found in meningitis, and had been reported in a case of tumor without meningitis. Where the process had been of short duration and where the compressions had not been sufficient, massive coagulation might not occur. In fact, many writers stated that Nonne's complete syndrome was merely a precursor of Froin's complete syndrome. Some cases of Nonne's syndrome probably never reached Froin's stage. Similarly conditions causing hemorrhage might never give sufficient plasma and fibrin to cause coagulation. Another class of cases causing a yellow spinal fluid was that type associated with red cells in the fluid. Many considered this a separate syndrome and applied the name erythrochromia to it.

The case reported was that of a child brought to the hospital for special feeding. About the fourteenth day the temperature rose to about 106° F. and the child was seized with severe convulsions. The urine showed pyelitis, and upon examining the lungs patches of bronchopneumonia were found. The convulsions and the urinary and pulmonary findings persisted until the end. The anterior fontanel was tense and bulging. On the thirtieth day spinal puncture yielded four c. c. of distinctly yellow fluid. The fluid was clear but the first two

cubic centimetres yielded a filmy pellicle. The second tube containing two c. c. did not change. Three days later the right ventricle was punctured and twenty c. c. of yellow fluid was removed. In both specimens of fluid there were red cells, increased globulin, and increased cell count, most of which were polymorphonuclears. The child died on the thirty-seventh day and autopsy showed a fibrinous, hemorrhagic meningitis and encephalitis. There were subpial hemorrhages, marked internal hydrocephalus, subacute pyelitis, and bronchopneumonia.

Nature of the Reducing Substance in the Urine of Children Suffering from Nutritional Disorders.

—Dr. OSCAR M. SCHLOSS, of New York, said that the work of Langstein and Steinitz had led them to believe that this reducing substance was lactose or galactose. Experiments which he had carried out did not confirm this finding. The only reducing substance which he had found constantly present in perceptible amounts was glucose. There was usually a nonfermentable reducing substance similar to that found in normal urine. This might be lactose, but its amount was too small to identify it with certainty.

Bodily Mechanics in Relation to Cyclic Vomiting and Other Obscure Intestinal Conditions.—

Dr. FRITZ B. TALBOT and Dr. LLOYD T. BROWN, of Boston, stated that faulty bodily mechanics had been responsible for a great loss of efficiency among adults during the war. Many men broke down in France under the strain of training and war. Such large numbers of men could not be sent home and they were therefore given special physical training. This brought back eighty per cent. to full physical efficiency. Of seven hundred men entering Harvard University, twenty per cent. had good bodily mechanics and eighty per cent. had bad mechanics. The human machine might be far from the standard type and might yet be very efficient in spite of physical disability. Poor bodily mechanics were more easily prevented and corrected in childhood than in adult life, and time spent on training at this age produced more far reaching results than the same time spent on adults. Three abnormal conditions which came in children with poor bodily mechanics were so frequently relieved by correcting the posture that posture must be considered the principal cause or the principal contributing cause of these conditions, granting that all other causes were ruled out. Correcting improper posture often corrected chronic constipation, hastened the cure of recurrent vomiting, and the cure of certain types of acute abdominal pain in children.

An Epidemic of Hemorrhagic Diarrhea Due to the Streptococcus Mucosus.—Dr. A. D. BLACKADER, of Montreal, said he was summoned to Waterloo, sixty miles southeast of Montreal, because of an epidemic of diarrhea. The first case occurred on March 22d, five on the following day, and since then the number had increased to sixty-five in the town itself and there were other cases within a short radius. Adults composed about one fourth the entire number. The larger proportion of cases, however, occurred in children under the age of six

years. The attack began abruptly with high fever, nervous symptoms, and vomiting, and diarrhea set in early. Mucus and blood appeared in the stools and the amount increased rapidly as the stools became more frequent, and in the severe cases seemed to form almost all of the stool. Blood was a prominent feature in the stools in sixty per cent. of the cases. The attack lasted from a few days to twelve, fourteen or even twenty-one days. The temperature in the severe cases went as high as 106°, while in the milder cases it was comparatively low, 100° or 102° F. In a few cases there was no rise above normal. Notwithstanding the severity of the cases no deaths occurred. Examination of the stools in one case showed large numbers of chains of *Streptococcus encapsulatus*, and about an equal number of colon bacilli. There were very few other bacteria. There were no organisms of any of the types of *Bacillus dysenteriae*. In a second case examined there were large numbers of the *Streptococcus mucosus*. In searching for the origin of this epidemic an inspection had been made of the milk supply, but a careful study of the situation seemed to eliminate milk as the source of infection. The water supply came from springs and several of these were thought to be insufficiently protected against contamination. The epidemic occurred after a few days of pronounced warm weather when the snows melted rapidly on a frozen soil. The presence of such large numbers of the *Streptococcus mucosus*, associated with other streptococci and equal numbers of colon bacilli, and the absence of any *Bacillus dysenteriae*, indicated that the streptococcus must be regarded as the chief organism in the production of the epidemic.

Phlyctenular Ophthalmia and Its Relation to Tuberculosis.

—Dr. BORDER S. VEEDER and Dr. T. C. HEMPELMANN, of St. Louis, presented this study which was read by Dr. Hempelmann. He stated that there was a widespread impression among pediatricists that phlyctenular ophthalmia was closely associated in some way with tuberculosis, but many ophthalmologists were as yet unwilling to concede this relationship. In an effort to gather additional clinical evidence on this point, 196 children with phlyctenular disease were subjected to a careful study to determine the possible presence or absence of tuberculous infection. The study revealed an intimate association between the two diseases. Skin tuberculin tests were positive in over ninety-two per cent. of the cases. The results of the complement fixation test for tuberculosis were strikingly similar to those obtained in cases of proved tuberculosis. Tuberculous lesions involving other organs than the eye were definitely demonstrable in over half, and seemed probable in almost two thirds of the cases. Children observed over periods of one year or more showed an even greater proportion of tuberculous lesions, more than four fifths of this series giving such evidence. Cough, malnutrition, and history of exposure to other cases of tuberculosis were frequent. No other points were brought up in the study which would seem to have a bearing on the etiology.

VARIATION IN THE RATE OF INFANT MORTALITY IN THE UNITED STATES BIRTH REGISTRATION AREA.*

By RAYMOND PEARL, PH.D.,
Baltimore, Md.

Until recently it has been impossible to discuss on any accurate or satisfactory basis the infant mortality of any considerable portion of the United States. This difficulty has arisen from the fact that except in a few localities, notably some of the New England States, there has been in the past no adequate system of birth registration. The most accurate practical method of presenting the subject of infant mortality is to relate the number of deaths of infants under one year of age in a given time unit to the number born in the same time unit. Consequently one needs accurate birth statistics before infant mortality can be adequately discussed.

It is a matter of great satisfaction to everyone interested in the subject of infant mortality that at last there is well established a birth registration area for the United States, and four annual reports on birth statistics of this area have been issued to date by the census bureau. We are well embarked now on the policy of adequate birth statistics for the country and unquestionably within a comparatively few years the birth registration area will cover the major portion of the country as the death registration area now does. In the short period since the birth registration area has been established its growth in extent has been gratifyingly rapid. The first report on birth statistics for the year 1915 comprised data from an area including approximately thirty-one per cent. of the population of the country. The 1918 birth statistics report gives data from an area including fifty-three per cent. of the population. This furnishes a sufficient volume of material so that one may begin the mathematical analysis of some of the problems of infant mortality with some assurance of reaching valid conclusions.

The purpose of the present paper is a modest one. It aims simply to present briefly some of the facts of variation in rate of infant mortality in different geographic or demographic units of the population. The first step in the solution of any

problem is obviously a clear definition of the problem itself. We shall see, as we pass from city to city, town to town, or rural county to rural county, that the rate of infant mortality varies greatly. In a hypothetical, visionary community where the most perfect administrative control over infant mortality possible or conceivable had been attained this variation would largely disappear, the only residue of diversity between communities in respect of infant mortality being such as arose purely by the operation of chance, that is, from random sampling. Now, with the actually existing condition of variation between different communities in respect of infant mortality, it is obvious that there must be particular and presumably determinable reasons for each particulate difference which exists. Operating on a basis largely of empiricism and *a priori* reasoning, efforts to reduce infant mortality have in the past been attended with considerable success. Also, with the advance of general sanitation the death rate under one year of age has fallen enormously. Greenwood (1) quotes some interesting figures on the point from Farr, which we may well reproduce here to show how great has been the improvement.

Period	PERCENTAGE DEATHS UNDER FIVE YEARS.				
	1730-49	1750-69	1770-89	1790-1809	1810-29
	74.5	63.0	51.5	41.3	31.8

But after such a decline as these figures indicate the continuation of the business offers a difficult problem to the administrative official, whose procedures are grounded essentially only on the two pedestals of what he thinks has worked in the past and what he believes logically ought to work. The easy part of the conflict has happened and is in the past. To continue the good fight with the same relative measure of success, one presently must needs know more precisely than is now known the pattern of the causal nexus which controls and determines the rate of infant mortality. And it is real knowledge, not *a priori* logic, that is wanted. Let a single example illustrate. It has been maintained that excessive infant mortality is primarily the resultant of the so-called "degrading influences" of poverty, and such a contention stirs a warmly sentimental feeling of agreement in the minds of the well-meaning public zealous to do good. This relationship obviously ought to be true, therefore to a too common type of mind it must be and is true. But Greenwood and Brown (2) in what may fairly be regarded the most thoroughly sound.

*Papers from the Department of Biometry and Vital Statistics, School of Hygiene and Public Health, Johns Hopkins University, No. 18. Read before the Eleventh Annual Meeting of the American Child Hygiene Association, St. Louis, October 11-13, 1920. A preliminary and condensed abstract of a more detailed investigation of the subject to be published shortly.

critical, and penetrating contribution which has yet been made to the problem of infant mortality are unable "to demonstrate any unambiguous association between poverty . . . and the death rate of infants."

The plain fact is that before control or ameliorative measures can be applied with the maximum of efficient economy to the general public health problem of infant mortality we must know a great deal more than we now do about the factors which induce spatial and temporal differences in the rate of that mortality. But first we must get an adequate conception of the magnitude and character of the differences themselves. Let us, therefore, turn to the examination of the facts regarding variation in infant mortality in the United States birth registration area.

VARIATION DATA.

In this work we have studied the variation in the rate of infant mortality (deaths to the thousand births) for the following groups:

1. Total population in cities of population of 25,000 or over in 1910.
2. Total population in cities of under 25,000 population in 1910.
3. Total population in rural counties of registration states.
4. White population in cities of population of 25,000 or over in 1910.
5. White population in cities of under 25,000 population.
6. White population in rural counties of registration states.
7. Colored population in cities of population of 25,000 or over in 1910.
8. Colored population in cities of under 25,000 population.
9. Colored population in rural counties of registration states.

In order to make possible a better appreciation of the nature of the frequency distributions a chart (Fig. 1) has been prepared. This shows for the year 1918 the frequency polygons for the total population of, a, cities of 25,000 and over, b, cities of under 25,000, and, c, rural counties.

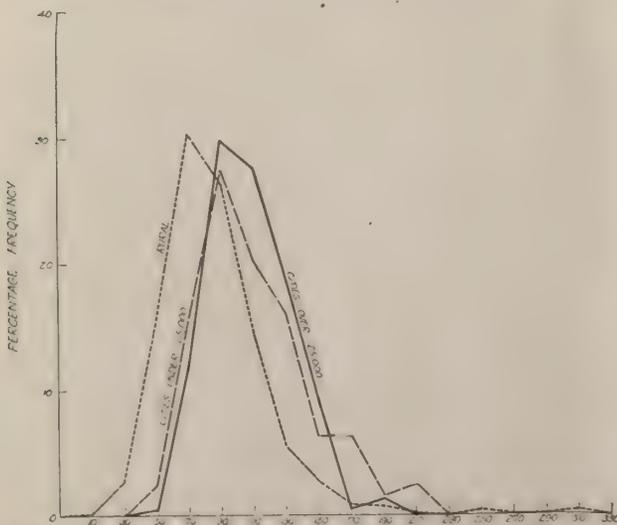

FIG. 1.—Frequency polygons showing variation in the rate of infant mortality in 1918 for the total population of, a, cities of 25,000 and over; b, cities of under 25,000; and, c, rural counties.

This diagram is fairly representative of all the distributions.

The most striking immediately observable feature of these distributions is the great range of variation which they exhibit. For example in 1918 the 236 cities of under 25,000 inhabitants showed infant mortality rates ranging all the way from the class 40-59 deaths to the thousand births to the class 300-319 deaths to the thousand births. The range of variation is even greater than this in the case of the distributions for the colored population. These extraordinarily large ranges of variation demonstrate perhaps more clearly than could be done in any other way the opportunity which exists for effective administrative control and reduction of infant mortality. If there are communities, as there are in plenty, showing infant mortality rates under a hundred deaths to the thousand births it suggests at once that it is possible if the right measures are systematically and effectively applied to reduce the infant mortality in those other communities showing very high rates to something like the level of these at present more fortunate communities.

In Table 1, are presented the chief physical constants¹ of the distributions of variation in infant mortality. These constants have been determined by the method of moments from the original raw data. (I am greatly indebted to my assistant, Mrs. Charmian Howell, for aid in the arithmetical work of this paper.)

The constants tabled are:

1. The arithmetic mean.
2. The median. This measures the value above and below which exactly half of the variates occur.
3. The standard deviation. This constant measures in absolute units the degree of "scatter" or variation exhibited by the distribution.
4. The skewness. This constant measures the degree of asymmetry of a frequency distribution. If a distribution is perfectly symmetrical on both sides of the mean so that if folded over upon the mean as an axis the two limbs would exactly coincide, the value of the skewness is zero.

From the data presented in Table I the following points are to be noted:

1. There is no certainly significant decline in the mean value of the rate of infant mortality during the four years covered by these statistics in any of the demographic units considered.

2. In 1918 there was a general tendency towards an increase in the mean rate of mortality over that which obtained in 1917. This increase is unquestionably to be attributed to the influenza epidemic of the autumn and winter of 1918. A careful examination of the rates by months will convince one that the mortality of infants increased materially during the period of the epidemic. Whether this increased number of deaths was truly to be charged to influenza does not concern us here. The important fact is that the rate of infant mortality markedly increased coincidentally with the existence of the epidemic. It is noteworthy that this increase in the infant mortality rate in 1918 is practically confined to the cities. The rural counties, whether

¹ For a very brief and summarized introduction to the modern mathematical treatment of frequency curves see Pearson, K. *Tables for Statisticians and Biometricians*, 1914, pp. lx to lxx. References to the basic literature on the subject will be found there.

for white or colored or total population, show little or no change in 1918 as compared with 1917.

3. There is no unequivocal difference in the mean rates of infant mortality in the larger as compared with the smaller cities. Considering the largest differences in mean rates for total populations in cities of 25,000 and over as compared with cities of under 25,000 there is no difference which is as much as even three times its probable error.

4. The mean rates of infant mortality are notably smaller in the rural than in the urban areas. This fact has, of course, long been well known. The first writer on vital statistics, in the sense in which we now understand that subject, Captain John Graunt, more than 250 years ago pointed out that rural communities exhibited generally a lower rate of mortality than urban communities. The difference between urban and rural rates of infant mortality is reflected just as clearly in the high absolute

that the greater the variation exhibited by a given class of the community in respect of infant mortality, the greater the chance of effective control and reduction of the average infant mortality by administrative measures. There can be no question that there is no field which offers so great opportunities in this direction as the colored population.

7. The skewness is seen to be positive in sign in every case but one. In that case (1916, cities over 25,000, total) the skewness is not significant in comparison with its probable error. With this exception the curves tend to tail off more gradually and farther towards the right end than towards the left end of the range. In other words, the rate of infant mortality in these different American demographic units tends generally to distribute itself in a substantially asymmetrical fashion about the mean, extremely high rates occurring more frequently than correspondingly low rates. This fact

TABLE I.

Constants of variation in rate of infant mortality (deaths under the age of one to the 1000 births)

Group		Year	Mean (2)	Median (2)	Standard deviation (2)	Skewness
Cities over 25,000 ¹ , Total	Total	1915	104.49 ± 1.78	102.76	26.14 ± 1.26	+ .3148 ± .0937

¹ In 1910.

² In concrete units, i.e. rate of deaths under 1 per 1000 births.

rates of the colored population as it is in the lower rates of the white population.

5. The mean rates of infant mortality are, roughly speaking, something like twice as high for the colored population as for the white population in each of the demographic units considered, and at all times. This again is a fact in general well known, but here we have precise figures on the point, with probable errors, which show definitely how tremendously poorer the negro baby's chances of surviving the first year of life are than the white baby's.

6. The cities of over 25,000 exhibit distinctly less variation in respect of infant mortality than do either the smaller cities (under 25,000) or the rural counties. The smaller cities and the rural counties exhibit about the same degree of variation relative to their means, but absolutely, in terms of standard deviation, the rural counties show less variability than the cities under 25,000. The colored distributions exhibit a much higher degree of variation in respect of infant mortality however measured, whether absolute or relative, than do the white populations. In general, it may fairly be assumed

might perhaps be taken to indicate that the task confronting the administrative control of infant mortality in the United States and yet to be accomplished is even greater than what has already been accomplished in the past, great and worthy of commendation as that is.

DATA ON THE LIMITATIONS TO ADMINISTRATIVE CONTROL OF INFANT MORTALITY.

We have seen that there is a high degree of variation in the rate of infant mortality as we pass from community to community. Some communities have infant mortality rates several times higher than those prevailing in other communities of the same size. This creates the presumption at once that proper administrative activity might reduce the rates of these abnormally high communities to a level commensurate with those found in the lower group. It is the purpose of this section of the paper to examine this presumption critically.

At the start it is evident that there are some causes of infant mortality which are, in their very nature, beyond hope of effective practical human control. Thus, children born with marked congenital hydrocephalus will presently die, in spite of

anything the health officer can do, no matter how active and intelligent he may be. There are many other causes of death falling in essentially the same category in this respect.

Not as any final or dogmatic settlement of the matter, but rather as a tentative first approximation made for the purpose of seeing whether any suggestive lead may appear, I have ventured to attempt to classify the principal causes of mortality in the first year of life into two groups. The first of these groups aims to include those important causes of infant mortality which are either, a, actually now effectively controlled by the efforts of health officials, either directly or indirectly through general sanitary and hygienic improvements, or, b, are obviously capable theoretically of control and amelioration if sufficient pains be taken. The second group aims to include those causes of infant deaths which are, in the nature of the case, out of the present range of effective practical, direct control or amelioration. Let us see what such a classification, to a first approximation, looks like.

TENTATIVE CLASSIFICATION OF PRINCIPAL CAUSES OF INFANT MORTALITY.

<i>A.—Causes of death actually now well controlled, or capable theoretically of direct control in greater or less degree.</i>	<i>B.—Causes of death not now capable practically of direct control.</i>
Measles	Tuberculosis of the lungs
Scarlet fever	Tuberculous meningitis
Whooping cough	Other forms of tuberculosis
Diphtheria and croup	Syphilis
Dysentery	Organic diseases of the heart
Erysipelas	Malformations
Tetanus	Premature birth
Meningitis	Congenital debility
Convulsions	Injuries at birth
Acute bronchitis	
Pneumonia	
Bronchopneumonia	
Diseases of the stomach	
Diarrhea and enteritis	
External causes	

One realizes that it is a bold thing even to set down such a classification as the above. It is certain to stir up the rancor of extremists in both directions. But extremists are nearly always wrong. Calm and unprejudiced persons will admit that some such classification as that here attempted is possible. Perhaps some further discussion of this classification may make clearer its point of view, and may win at least that measure of agreement with it which will at least permit the consideration of the discussion of its consequences which follows.

Taking column A first, presumably no competent health official would deny that the first five diseases in the list (measles, scarlet fever, whooping cough, diphtheria and croup, and dysentery) have been, can be, and are in greater or less degree effectively controlled in respect both of their incidence and their mortality. With this same group clearly belongs also diarrhea and enteritis, and convulsions, on the justifiable assumption that in the vast majority of cases convulsions in infants are consequent upon violent enteric infections, which clearly belong in the controllable class. Diseases of the stomach, as causes of death under one year of age, again in the vast majority of cases undoubtedly mean infection—filth diseases, in short—which come in the same category, so far as concerns control, as diar-

rhea and enteritis. Regarding the rest of the diseases in the A group (erysipelas, tetanus, meningitis, acute bronchitis, pneumonia, bronchopneumonia, and external causes), the point of view which led to their inclusion here is as follows: If the environmental conditions surrounding the infant in the community and in the home, and the care given it, were made as favorable as they might be made, and actually are in the homes of the hygienically intelligent well to do, the death rate from each of these causes would be enormously reduced relatively in comparison with what it actually is. As a matter of fact, visiting child welfare nurses are doing a mighty work in just this direction in many communities. They teach parents how to care for their infants, protect them from these infections, and nurse them to a non-fatal issue in many cases if they do get infected. No one who knows at first hand what child welfare public health nursing is actually accomplishing in these directions will question the putting of these diseases in the controllable column. Their mortality rate can be materially reduced if communities will take the trouble to go intelligently about it.

Now for the B column. The first three items are the various forms of tuberculosis. The fanatic will no doubt promptly and violently assert that nothing is so easily and readily controllable as these. But let us make haste slowly and remember certain things: First, that we are here talking about deaths under one year of age, that is fatal tuberculosis in the first months of life; and second, that our classification premises, in specific and stated terms, direct control, that is, control through agencies now capable of being brought to act directly upon the infant or his environment. Is any competent and experienced health officer prepared seriously to assert that he can, by measures applied to the infant or his environment, significantly reduce the mortality from tuberculosis in infants under one year of age? If anyone has the temerity to make such an assertion the instant demand will be for his evidence. It is, of course, recognized that the infant mortality rate from tuberculosis may theoretically be reduced, and presumably some time will be, by reduction of the prevalence of adult tuberculosis. But this is beside the point for present consideration, for reasons stated above, and from the further fact that administrative measures are not, in reality, controlling or ameliorating the infant mortality from tuberculosis.

About fatal congenital syphilis, fatal congenital organic diseases of the heart, congenital malformations grave enough to be fatal in the first year of life, and fatal congenital debility, there will probably be no dispute. Regarding premature birth, and injuries at birth, much the same reasoning applies, but with the additional consideration that presumably intelligent prenatal education of the mothers and improvement of prenatal environmental conditions would reduce these mortality rates in some unknown, but probably not very large degree. There is no tangible evidence that these causes of death are in effect administratively controlled in any appreciable degree in this country at this time.

Finally, it should be said that one occasionally

or amelioration at the present time, exhibit less than half as much variation in the rate of infant mortality for which they are responsible, as we pass from city to city or from state to state, as do

TABLE IV.

FREQUENCY DISTRIBUTIONS OF VARIATION IN RATES OF MORTALITY UNDER ONE PER THOUSAND BIRTHS FOR, A, CONTROLLED, AND, B, NONCONTROLLED CAUSES.

TABLE V.

VARIATION CONSTANTS FROM THE DISTRIBUTIONS OF TABLE IV.

Group	Mean	Median	Standard deviation
Cities, A, controlled causes.	49.46 ± 2.04	47.08	18.37 ± 1.44
Cities, B, noncontrolled causes	47.30 ± .90	46.15	8.09 ± .63
Cities, all causes	107.84 ± 2.75	102.86	24.78 ± 1.94
States, A, controlled causes.	42.00 ± 2.17	40.71	14.41 ± 1.54
States, B, noncontrolled causes	42.50 ± .83	42.27	5.52 ± .59
States, all causes	97.00 ± 3.03	95.00	20.07 ± 2.14

the class A causes of death, which are capable of administrative control. This relation is true, however the variation is measured. This is a novel result, of interest from several points of view.

In the first place, the suggestion lies near at hand that if the class A causes of death, which are controllable, show such great variation relatively as they do, it must mark an approximately equal variability in the zeal, intelligence, and efficiency of the administrative health officials of these communities. Anyone at all familiar with the organizations of municipal and state health departments in this country will find it extremely interesting to study in detail the entries of Tables II and III, noting how the class A (controlled) and the all causes rates fluctuate up and down, while the class B (non-controlled) rates stay, with a very few exceptions, so extremely constant. One will observe, with great satisfaction, what splendid work is being done in some communities in holding down to a low level the infant death rate from controllable causes. Table II forms a real justification of the faith that is in the public health official of vision. It shows that the infant mortality from controllable causes can be kept down to a low level, and is in some communities. In the following cities (seventeen out of thirty-seven) the rate of infant mortality from the controlled causes of class A is actually lower than the rate from the noncontrolled causes (class B):

New Haven	Cincinnati
Washington	Columbus
Worcester	Dayton
Grand Rapids	Toledo
Minneapolis	Providence
Albany	Richmond
Borough of the Bronx	Seattle
Borough of Queens	Spokane
Borough of Richmond	

These cities stand as examples of the fact that a considerable portion of the infant mortality rate can be effectively controlled on the basis of knowledge we now possessed.

SUMMARY.

This paper is a first biometric survey of the infant mortality statistics of the recently established birth registration area. It is to be regarded as preliminary to certain analytical studies of the problem of infant mortality now in progress in this laboratory. The chief results of the paper are first to set forth and discuss the chief analytical constants of variation in infant mortality in the different demographic units. This variation, which is large in amount, markedly and consistently skew in the positive direction, and markedly leptokurtic, defines and throws into high relief the fundamental public health or administrative problem of infant mortality. Why do the communities having rates of infant mortality higher than the mode occupy that position? Is it from causes capable of human control, or from causes beyond the present possibility of such control? A special preliminary analysis of the data for cities of over 100,000, and the registration states, indicates that causes of death capable of administrative control are chiefly responsible for the variation observed in the total infant mortality rate, while those causes of infant deaths which, for fundamental biological reasons, are incapable of being sensibly influenced or controlled at the present time by administrative measures, are a highly stable and constant factor, from community to community contributing little to the observed variability of the total infant mortality rate. In absolute terms, however, these causes of death not administratively controlled are responsible for roughly forty per cent. of the total infant mortality in the communities discussed.

JOHNS HOPKINS UNIVERSITY.

THE INFANT MORTALITY IN THE CITY OF WATERTOWN, N. Y.

During the Period of 1916 to 1919, Inclusive.

BY ISAAC W. BREWER, M. D.,
Watertown, N. Y.

Prior to taking office as health officer of the City of Watertown a preliminary survey of the vital statistics of the city was made. This disclosed among other things that the infant mortality was somewhat higher than obtained in other cities in the state of the same class. After taking office the study was extended to include the period from 1916 to 1919 and this paper is based upon that study. It showed that there were 2,996 births exclusive of stillbirths of which there were 115 or three and seven tenths per cent. of all the pregnancies recorded during the period. The records show that

there were also ninety-four premature births or two and seven tenths per cent. of all the recorded pregnancies. It therefore appears that six and four tenths per cent. of all the pregnancies resulted in disaster. Of the 3,111 pregnancies recorded 110 or three and five tenths per cent. were attended by midwives or members of the family. The greatest number of such deliveries was thirty-three in 1917 and there has been a decrease since that time.

In the following table are shown the births, stillbirths and infant mortality for each year and also the average for the period from 1911 to 1915:

TABLE I.

Average from	Year	Births	Stillbirths	Infant mortality per 1000
1911 to 1915...	137
1916	685	29	130	
1917	718	28	120	
1918	765	30	125	
1919	728	28	88	

The increase in the rate for 1918 is due to the epidemic of so-called influenza in the fall of that year and it is to be noted that the rate was low all over the state in 1919. The average for the last four years is 115.75 or a reduction of fifteen and five tenths per cent. The rate for 1919 is thirty-five per cent. below that for the period from 1911 to 1915. We feel that these results are largely due to the child welfare work carried on by the Visiting Nurse Association with a small appropriation from the city, since July, 1915.

Watertown is essentially an American city, in which a considerable proportion of the population own their homes. There are, however, several large groups of foreign born, principally Italians. As it is frequently stated that the infant mortality in a community is largely due to deaths among the foreign population I studied the problem with this in view, using the birthplace of the mother as an index of nationality. The result is shown in the following table which is based upon 2,907 births and 362 deaths of infants, a mortality of 124 to the thousand:

TABLE II.

Infant mortality, Watertown, N. Y., from January 1, 1916, to December 31, 1919, by nationality of the mother.

Birthplace of mother	Births	Deaths of Infants	Infant mortality
United States	2,083	224	111
Canada	381	38	99
Italy	242	22	91
Austria - Hungary.	78	8	102
England, Wales, Scotland	46	6	130
Russia	24	0	0
Other countries....	54	94	

This surely does not show that the foreign element is in any way responsible for the conditions which are found in this city. We recognize that in some instances the number of births are so few that the statistics may be influenced thereby. It is not assuring to find that the highest rates are among the English speaking people and that the lowest is among the Italians.

A further study of this question is shown in the following table where are collected the percentages of the deaths by causes for each group of inhabitants of the city:

The Americans and Canadians show practically identical conditions. While it appears that premature birth is a more frequent cause of death amongst the Italians, they also seem to suffer more from communicable diseases. The comparatively low figures for diseases of the digestive system among the Italians is, in all probability, due to the fact that most of these children are breast fed.

TABLE III.

Percentage of deaths by nations

Nationality of mother	Premature birth	Diseases of the digestive system	Diseases of the respiratory system	Congenital malformations and debility	Communicable diseases	Accidents of birth	Other diseases
United States..	26	22	16	15	10	4	7
Canada	26	26	26	5	5	5	3
Italy	32	14	23	5	16	5	5
All other countries	19	28	14	23	10	0	5
Average for all countries	26	23	16	15	10	4	6

For all of the infant deaths during the period we find that twenty-six per cent. were due to premature birth, twenty-three per cent. to diseases of the digestive system, sixteen per cent. to diseases of the respiratory system, fifteen per cent. to congenital malformations and debility, ten per cent. to communicable disease, and four per cent. to accidents of birth. Following the first tabulation of these data the Visiting Nurse Association opened a prenatal clinic.

A further study of the problem is shown in Table IV, which presents the causes of death among children who lived less than a month, the neonatal infant mortality.

TABLE IV.

Cause of death	Percentage of deaths
Premature birth	47
Congenital malformations and debility....	20
Accidents of birth, including difficult labor..	9
Diseases of the digestive system.....	8
Diseases of the respiratory system.....	7
Communicable diseases	1
All other diseases.....	8
	100

This table is based upon 180 deaths and shows the seriousness of the problem. It shows that seventy-six per cent. of the deaths in this group are due to causes over which the health officials can exercise but little direct control. It is probable that a few of the premature children might be saved by an incubator room and it is hoped to have such a room in the near future. It is also probable that in a few cases prenatal care may reduce the number of premature births, especially among those who are syphilitic. However, prenatal clinics are new and in small communities are not very popular.

To aid the nurses who are engaged in infant welfare work the percentage of infant mortality for each month from 1916 to 1919 was studied, and is shown in the following table:

Month	Percentage of mortality
January	8.4
February	6.6
March	9.2

Month	Percentage of mortality
April	9.2
May	8.7
June	8.9
July	8.9
August	10.5
September	9.8
October	7.1
November	6.4
December	7.6

This shows two peaks, the highest in the summer and early fall, due to diseases of the digestive system. Of seventy-eight deaths from such diseases, forty-eight occurred during July, August, September, and October. The second peak occurs in the spring, and is due to diseases of the respiratory system, the highest number of deaths from this cause occurring in May. As a solution of the problem we have adopted the following measures:

1. Extending the infant welfare work.
2. Having a nurse visit all new babies in sections where it is believed her services will be of value.
3. A prenatal clinic.
4. A campaign against the fly.
5. Abolishing as many outside toilets as possible, and rendering others flyproof.
6. Campaign of education, consisting of frequent articles in the local papers regarding infant mortality, and the publishing of the monthly statistics regarding infant mortality.

UNAPPRECIATED AGENCIES IN THE DEFECTIVE DEVELOPMENT OF CHILDREN.*

BY CHARLES GILMORE KERLEY, M. D.,
New York.

All those individuals who had taken no interest in children or young people, other than in their immediate family or in those of their friends, sustained a decided shock when the reports of the various examining boards for recruits in the late international war were made public. From forty-five to sixty-five per cent. were rejected, with poverty having little to do with the case in many instances. It was for the first time realized how sadly remiss we had been in our care of children. That the greatest national asset is a strong, vigorous race no one can deny. At the age of seven years the boy is seven tenths the man and the girl seven tenths the woman. If errors in development from whatever cause exist at this age they will never be entirely eradicated. Evidences of this is apparent in the physical condition of those who have grown up on the continent during the war.

Miss Julie Lathrop reports of her recent investigation in Europe as follows: "In Prague, the capital of Bohemia, I went one day to a paper box factory whose workers there, as in the United States, are chiefly young girls. All of the party noted the small stature but mature faces of the girls. Most of them were in the middle teens, but they looked younger until you saw their faces. The manager said: 'Yes, it is so; we always had some girls who were small, but now they all appear to be small.'" Had these individuals been investigated

further, it would have been found that not only were they physically smaller but that they were generally inferior individuals. It would have been found that they lack resistance and have a diminished capacity for sustained effort, both mental and physical, all of which means that their labor output would be below that of a normal individual of corresponding age.

I shall make no attempt to cover all that relates to proper development. It is my hope to call your attention to certain factors that have an important bearing on this subject, generally unappreciated.

DEFECTIVE BREAST FEEDING.

It is a usual error to believe that breast feeding is always efficient and the best means of nourishment. Breast feeding may supply a substance entirely inadequate to the demands of the infant. Because good breast milk is superior to all other forms of food for the infant, it does not mean that inferior breast milk may be much less desirable than suitable substitute foods. Breast milk is a commodity, and there are varieties of breast milk as well as all other commodities. Every year I see a goodly number of cases of malnutrition in infants aged from six months to a year of age fed exclusively on the breast. We find these infants under weight in some instances, but the most usual evidence of defective nutrition will show itself in flabby muscles, secondary anemia, and beginning rachitis.

In spite of the best intention on the part of mother and physician, the child has been given a poor start. A considerable number of nursing women can supply the child adequately until the completion of the fifth month. Fewer can supply the baby adequately until the completion of the seventh month. After this period practically all babies in this country should have the advantage of additional feeding. Breast milk should be repeatedly examined as to quantity and quality during the nursing period, and the child kept under at least monthly supervision. A frequent error in breast feeding is to assume that the nourishment must be adequate. Kindly understand I am criticising defective breast feeding only. I have helped thousands of infants to better breast milk and for a longer period than they otherwise would have had. I appreciate also that there are exceptions to what I have already stated relating to the limitations of the nursing period. A mother, a former patient at the outpatient department of the Babies' Hospital, nursed five children almost continuously over a period of eight years, the nursing being interrupted but about six months during this time. The longest period of continuous nursing to come under my observation was in an Italian woman who nursed a boy three and a half years. She informed me that her milk had nearly failed after eighteen months, when she had a miscarriage, and the flow returned, when the nursing was continued much more satisfactorily than before.

COW'S MILK FOR OLDER CHILDREN.

After the eighteenth month in the average well child better growth will result with a reduction of the daily milk allowance to approximately twenty

*Read before the Southern Medical Society, November, 1920.

ounces daily, providing adequate nourishment can otherwise be furnished. Under conditions when other foods cannot be given and in suitable amounts a larger daily milk content in the diet may be of advantage to balance up a defective dietary. In such instances cod liver oil and iron should be given. I have seen a vast number of children with varying degrees of malnutrition who were taking from one to two quarts or more of milk daily. Almost invariably such children have a capricious appetite, they dislike other articles of diet largely because they are never given an opportunity to become real hungry and get acquainted with a wider range of foods.

Physically these children show poor muscle development, are pot bellied, constipated, underweight, and flabby. They are subject to frequent so-called bilious attacks. Blood examination seldom fails to show a secondary anemia because of the poor iron content in their milk food. Mentally they are irritable and difficult of management. Nature has fashioned a child for other foods than milk after and even before the cessation of the normal nursing period. Cow's milk never entered into the calculation. Advocating a quart of milk is bad teaching.

PERSISTENT ANEMIA IN INFANTS AND YOUNG CHILDREN.

I refer to those who show a hemoglobin content under thirty per cent. with red cells varying from 1,500,000 to 2,500,000, a condition which is not unusual. The child is pale, weakly, with very faulty development. Treated along the usual lines of feeding changes and drugs, the child makes little or no progress. These cases are not simple malnutrition, with anemia; they are cases of anemia with secondary malnutrition, and are most frequently seen in quite young infants. The treatment that has been most successful in my cases has been intravenous blood transfusion. The cause of the anemia is obscure. There is some radical defect in the blood making processes. The introduction of 120 to 150 c. c. of human blood into the circulation supplies the required stimulating agency. Food which before had only a sustaining value is now well assimilated and a satisfactory growth follows. In some young infants an astonishingly rapid increase in weight resulted. The following is my most recent case of this nature:

CASE I.—A boy four months old, weighing ten pounds, was brought to me because of anemia and marked malnutrition. Blood examination showed a hemoglobin content of thirty per cent. and red cells 2,005,000. Before any attempts at feeding were made, he was given 120 c. c. of the mother's blood intravenously by Dr. P. W. Bevans at the Babies' Hospital. The following day the hemoglobin content was fifty-five per cent. and the red cells 4,100,000. Sixteen days later a blood examination showed hemoglobin fifty-five per cent. and red cells 4,000,000. He was then put on a formula of fat, two per cent.; protein, one and a half per cent., and sugar, six per cent. He immediately began to gain, and six weeks after the transfusion he weighed thirteen pounds, with the blood conditions unchanged.

WASTED ENERGY.

Excessive activity, which means overwork, contributes its quota to the hordes of poorly developed children. The young child who awakens early and is busy all day in childish activities until seven or eight o'clock at night will not thrive as well as if there were reasonable restraint and a rest period after the midday meal of an hour or two and who retires at an early hour. I attempt to cultivate indolence in such natures.

Until the completion of the sixth year in all such children, and in many until the completion of the seventh year, there must be the daily midday rest if we are to secure proper growth. This is a rule that is invariably carried out among my patients. We often see the harmful effects of wasted energy in the second or third child whose strength is overtaxed in his efforts to keep the pace set by older brothers or sisters. This feature of wasted energy must always be investigated in children who come to us because of defective development. It is also to be remembered that stress is an important deterrent factor in the child's capacity for food assimilation. The overworked, tired child does not assimilate his food to the best advantage.

LOSS OF TIME.

A considerable number of children come to me because of inadequate growth who have been subject to frequent illness. When a child is ill, development is suspended. Such children are often the members of indulgent families who are not at all careful as regards meal time and the food given. Several illnesses will leave an appreciable mark upon the child. Recurrent attacks of indigestion every few weeks, which occur in not a few children, have a pronounced, deterrent effect on growth.

THE GASTROINTESTINAL TRACT.

I have found it necessary in eighty-three cases of tardy malnutrition to make x ray studies of the gastrointestinal tract. In children with a persistently poor appetite, those who have to be coaxed or forced to eat, we have found the explanation in a pylorospasm, in dilated stomachs, and in ptosed stomachs. We frequently find food residue in the abnormal stomach from six to ten hours after a bismuth meal. A child will not be hungry with food residue in the stomach. In addition to defective food, they are time losers in that they are those who have frequent attacks of recurrent illness in the nature of vomiting and fever.

An explanation of persistent malnutrition in children is sometimes found in the digestive tract. Thus we find the dilated cecum; the ptosed or dilated colon; angulations, and, frequently, enlarged sigmoids. The elongated sigmoid is one of the most frequent causes of obstinate constipation, low degrees of toxemia, and, not infrequently, recurrent vomiting. For the reason that when there is a delay in the intestine there is often a corresponding delay in the emptying time of the stomach. I will not undertake the care of a case of habitual malnutrition in a runabout child without an x ray of the gastrointestinal tract. Children with grave mechanical defects in the gastrointestinal tract are

never fully nourished, even though they may not be made acutely ill; neither will they be as bright and alert mentally as those with a normal digestive equipment.

The twenty lantern slides that were shown represented in each instance a case of malnutrition. The youngest patient was two years of age. They were all under weight from five to fifteen pounds; the majority under height as well. Each case had been referred to me because of defective growth and development. The personal history of all showed persistent gastrointestinal derangement. In some there was simply loss of appetite; in others recurrent vomiting; in others recurrent vomiting with fever, usually very high. In others there was obstinate constipation. Each case showed gastrointestinal symptoms of sufficient severity to call for an x ray study. In each case it was apparent that there was sufficient abnormalities to account for the persistent digestive derangement.

The lantern slides shown demonstrated dilated stomach, ptosed stomach, pylorospasm, gastropnoia, dilated cecum, ptosed colon, massive dilatation of the colon, angulated sigmoid, dilated sigmoid, and elongated sigmoid.

132 WEST EIGHTY-FIRST STREET.

THE MENTAL HEALTH OF THE CHILD.

Some Physical Determinants and a Method of Observation.

BY C. EDGERTON CARTER, M. D.,

Los Angeles, Cal.,

Formerly Instructor in the Pediatric Department, New York Post-Graduate Medical School and Hospital.

In connection with my pediatric work at the Orthopedic Hospital School of Los Angeles, the interdependence of the mental and physical has loomed so large that it has seemed worth while to emphasize this relation as a factor in the mental health of the child. Obviously the general consideration of *mens sana in sano corpore* needs no stressing. In a vague way we are all conscious of that relation. It is to impress the direct causative factor abnormal physical conditions may have specifically upon the child's mental hygiene that the subject is discussed from the physical angle.

The great difference in the treatment of crippled children, who exhibit biased mentality, and the child of normal mentality, with inclinations toward physical defect, is that of conservation. In the chronic cripples marvelous reconstructive work is done, but at best it is reparative. In the mentally normal, the future possibilities are so much greater that eventually we shall have preventive and corrective clinics for the child of preschool age, as we now have medical and surgical clinics for the afflicted. One such clinic under the management of the Federation of the Parent Teachers' Association in Los Angeles has made a modest beginning. Its purpose has been to give the supposedly well child of preschool age, from two to six years, an opportunity to become a superior child. Instead of attempting to restore to possibly normal the ill or defective child, we start with the apparently

normal and endeavor to give him endurance and robustness which are requisite for superior attainment. Incidentally, we find that over three quarters of the children examined reveal varying abnormalities of more or less consequence. Naturally these defects are corrected where possible; so the clinic proves corrective as well as educative.

The importance of our endeavor, however, lies in the attempt that is being made to better the average—to surpass the "fairly well" standard of the present, and to inspire parents and children toward being (and doing) better. The returns noted in this clinic already have vindicated its existence, and furthermore the conviction that correction of chronic physical defects liberates mental force, has caused to materialize the Orthopedic Hospital School in Los Angeles for the explicit purpose of training these resultant mental abilities with treatment; often tedious, which the child's crippled condition demands.

A health status chart (1) in use at the clinic has been adopted as the method of presenting the physical findings to the parents, thus proving its practical adaptation. Children who, upon superficial examination, impress one as being sound physically, are not uncommonly found to reveal a health status from sixty to seventy-five per cent. normal when charted upon the basis of values. These estimated values are arbitrary and may be modified to meet the requirements of individual examiners or special conditions. The one requisite is that of visualizing health or body defects, that progress in condition may be estimated.

So largely is preventive work in children a question of parental education, and so impossible of enforcement are personal health measures, that mental hygiene, to be applied, must have a practical elemental basis easily comprehended by the parents. For this reason, approaching the subject through the medium of the physical defects and disorders, concerning which the parent has an intimate knowledge, one finds a welcome avenue to a fertile field. It matters little whether the parent completely comprehends the reflex processes by which results are obtained upon mind and character through these physical determinants. The vital fact is that this intimate association exists, and that the intangible can be reached through the tangible. Thus the parent comes to realize that improvement upon temperament and ability may be accomplished, specifically through these physical health measures. For instance, tonsils have long been enucleated for the relief of septic absorption, and because of their deleterious effect upon the blood stream and general metabolism—little argument is needed on that score—but that tonsils should be removed to prevent cardiac involvement is a step farther and is usually accomplished because of the parents' confidence in the physician rather than from being convinced of any real danger. The third step in the argument for the removal of pathological conditions, or for the correction of defects, viz., that the child's mental development shall show definite response to such treatment, requires for a convincing presentation not only the enthusiasm of the believer but knowledge of actual experience.

A practical method of physical examination whereby comparisons of conditions may be appreciated at a glance, is thus a necessary corollary, for parents readily bridge the gap between the physical status and its possible effects upon mind and disposition, provided they can be convinced that the child's condition is subnormal. Here graphic charts serve an essential purpose since the physician is thus enabled to translate his findings to the visible scale which represents the condition with reasonable accuracy.

Heredity.—Perhaps upon no other claim has there been laid greater burden of proof than that of heredity. Parents too often are satisfied to let Jimmie be thin because his father is; to permit Mary to refuse vegetables because mother does; to tolerate an irritable nervous child because he is "high strung," etc., while the possible inheritance of value from the parent, the character impressed by daily example, are given little thought. It is so much easier to fall back upon the hackneyed excuse, "He inherits that from his father."

If, as a parent one delves into the study of inherited traits, one finds that acquired characteristics are buffeted about, confused in experimental proof with mutilations, the influence of throwbacks (or primitive reversions), often ignored in the reckoning, the power of environment underestimated until one is in a quandary at each last analysis and uncertain as to what constitutes a working basis. Undoubtedly we reflect our own uncertain attitude when we fail to urge upon the child the acquirement of a taste for all wholesome foods and healthful games. In nourishment for the growing body as well as knowledge for the growing mind, "such stuff as dreams are made of" will not furnish a healthy basis for future expansion. Homely, simple food for body and mind must form the foundation of any stability in health or character. Yet so much in our likes and dislikes is explained upon the basis of heredity that unconsciously we allow our children to form pernicious tastes in the choice of food and in the formation of habits. Instead of the child inheriting a dislike, he acquires a fixed antipathy through the daily imitation of a parent lacking control, and wholly unaware of thus influencing the tastes and, through them, the growth of the child. Often these food impressions are left to the haphazard choice of a nursemaid abetted by the whims of a difficult to please child. It is bad enough to have our children acquire their accent from nursemaids, whose nasal or strident tones leave an indelible stamp upon the speech of their charges, that is unfortunate and a handicap.

The maturing mind in after years seeks to cast off these acquired peculiarities (alas, often unsuccessfully!), but food dislikes and idiosyncrasies in eating are even more vital and may be the direct and only cause of nutritional disturbances resulting in rickets, flat foot, bony deformities, and other developmental defects. Here the psychology of the mother, assuming that she has the intimate charge of the child, affects its physiology and growth; this in turn gives an undeniable twist to the outlook on life of the child and may figure in the distorted philosophy which the resulting adult

so easily acquires. The kingdom that was lost "all for the want of a horseshoe nail" does not compare with the myriads who never glimpse their kingdom because of reasons seemingly as insignificant. An old established and influential religious order is credited with the dogma that, given a religious training until seven years old, the child will never depart therefrom. In no other instance apparently do we find a well recognized and accepted working hypothesis that takes into account this preschool period as a possible determiner of the child's future. It is a period, nevertheless, in which imitation of conduct, temperament, and habits hold supreme sway. Reason and decision not yet formed, imitation and imagination are dominant. The influence that health has upon mentality and habit upon health is not appreciated. If it were, the preschool child in the family of ideals would not be permitted to drift into a haphazard physical condition as he is today. He would receive at least as much routine attention as does the family automobile, toward keeping his combustion perfect and his "machinery" in order.

In other ways than by diet, however, can the child's mental growth be encouraged. Right physical hygiene fosters healthy mental hygiene. The influence of carriage upon conduct, of posture upon principle, is too well known to need more than passing mention. "Poor bodily mechanics," quoted by Fritz Talbot and Lloyd T. Brown, of Boston, are responsible in great measure for at least three abnormal physical conditions. These in turn act as nerve irritants and affect the mental horizon. Concrete illustrations of physical determinants upon mental health are found in the commoner health problems. Among those producing direct effect upon the adolescent outlook, consider first a simple surgical procedure that is best performed during infancy or childhood, e. g., circumcision in the male. This should be universal, not alone as a protection against irritation and possible later infection, but in the nervous child a scientific operation is an effective means of aiding his mental equilibrium. Habitual apprehension of the future, as well as timidity and senseless fears exhibited in the child's daily life, is not infrequently the result of physical reflexes. Eyestrain, phimosis, anemia, and intestinal toxemia are common contributors. Freeing the clitoris in the female often allays irritation and should also be a routine procedure in infancy. Bernard Shaw's satire on specific surgery makes one hesitant to assert that tonsillectomy in the child from three to six years as a practically routine procedure would save countless lives from sporadic and epidemic infections. However, when one conscientiously observes the multitude of adults who, after dragging through half their lives, are finally rejuvenated by parting with a cryptic tonsil, or hidden source of sepsis, he finds it hard to defend any tonsil under the least suspicion. Furthermore, the death rate from heart disease receives its greatest impetus from infected tonsils of preadolescent years. Kerley has data revealing the ages from five to twelve to be the period of greatest susceptibility. This is a consideration against the doubtful tonsil upon which not enough emphasis is given. As

physicians assuming the care of children, we have been caught napping because we have no habitual method of checking up the supposedly well child. Our observations are usually made after the heart damage is done. Adenoid and tonsillar hypertrophy or infection are so commonly noted among school children as a cause of retarded mentality that they need to be merely mentioned as obvious physical determinants in the child's mental health.

Physical defects.—Perhaps the commonest and least considered physical cause for defect in character development is found in the ubiquitous flat foot or broken down arches of the foot. Analyze for a moment the component elements of character and we find application, or stick-to-itiveness a *sine qua non* in all well balanced minds. This is a quality implying the ability for persistent effort. Let the child find that standing tires him, that long tramps over the hills leave him exhausted and without appetite, that tennis makes his back ache, that skating causes his feet to pain, and we soon find that child losing interest in these physical efforts, yet by such physical efforts demanding skill, strength and endurance, are bodies made symmetrical and minds trained to coordinate. In a word, it is true that the boy who doesn't enjoy outdoor contests loses the greatest possible stimulant to clean character building. He is handicapped by this loss of mental training in the perception, comprehension, courage, and coordination which contests give. Weak arches are directly responsible for many mollycoddles in boys and girls.

The condition of constitutional asthenia to which Lewis has applied the term effort syndrome, and which Kerley pertinently says permits of "poor student material, fifty per cent. of which should be scrapped and put to productive occupation," is not always found in mental weaklings. Physical handicaps may be their mental retardants, and in many cases these are conditions which are prevented or effectively counteracted only during the early formative years. Again, while Nature starts us forth physically equipped with heads asymmetrical, legs unequal, ears imperfect, and eyes astigmatic, not all such stigmata have an appreciable effect upon character. In fact, every normal man, like every healthy dog, has several "fleas" of degeneration to keep him humble and to make him hustle. But too many fleas, like too much degeneration in the child, makes training difficult. However, one common anatomical fault leaves its mental mark because of the intimate association that necessarily lies between breathing and effort. Without argument we all agree that courage and control are desirable qualities to cultivate in the budding mind, yet the boy with ineffectively approximating jaws, with teeth failing to function because of malocclusion, is barred by reason of this defect from a fair chance in the game of life. His utmost physical efforts are made unnecessarily difficult. Observe him whose teeth do not effectively approximate and you will find that he does not excel in feats which demand the clenched jaw of determination "to do or die." However, malocclusion receives attention only because of its influence upon mastication or for cosmetic effect. It deserves a more serious con-

sideration, for an "Andy Gump" type of facial contour is not to be chosen as winner in any endurance contest, physical or mental, while a man with the viselike jaws of Roosevelt carries no handicap during the formative years of childhood as he clicks them together in friendly rivalry or determined effort to overcome. Children with the undeveloped lower jaw have been needlessly handicapped by adenoids or dental malocclusion, and their mental training is made easier if these physical deformities are corrected.

Opportunity for giving a national uplift to the health of the future is apparently at hand. Statistics of the draft examinations in the United States, revealing the now well known rejection for physical defect of every third young man under thirty-one years of age, have proved most unexpected food for thought. Permit the briefest possible reference. Our athletes have beaten the world, mortality and morbidity rates have shown amazing decreases in diphtheria and typhoid, resources have seemed exhaustless, until we have taken it for granted that to be "a young American" was equivalent to winning the threescore and ten lease on life. Cold statistics convince us there is on the contrary a lien on the lease, which will either seriously embarrass the life activities, or stop them altogether, in a million men supposedly of the nation's strength. How does this directly relate to the child's mental hygiene? Physical handicaps are to be prevented only by educational influences wisely and constructively utilized among our children. The five groups of defects or diseases, constituting over three fourths of the million rejected, fall within the limits of diseases preventable, or possibly correctable, if seen early. These same conditions are incurable if advanced. It is to the effect upon the reconstructed lives which children so afflicted must form, to the influence these abnormalities have upon mentality, that present emphasis is laid.

Heart disease heads the list. It is often incurable, and so ranks first as a physical determinant on future efficiency. To treat this as a physical problem merely, without a consideration of the mental warp and fear psychoses the confirmed cardiac exhibits, is to beg the question. The prevention of heart disease is emphatically a physical problem of childhood, but the burden of its weight is distributed throughout the years that remain, be they few or many; and the physical limitations of chronic cardiac patients are the least of their burdens, as everyone familiar with the fear psychoses of these unfortunates will attest.

Tuberculosis, with its roster claiming distinguished and brilliant minds the world over, shows its prevalence in the war data, where every tenth man, or over 100,000 of the flower of our youth, was afflicted with the disease in active process. The point in preventive work is that infection begins in childhood, that it has already decimated the health ranks of our young men, and even though the mental impress may be exhilarating and stimulating instead of depressing and fear inspiring, as in chronic heart disease, both diseases are factors in the mental outlook and the preschool age should be the time for their consideration and prevention.

Nutritional disorders *per se*, with their sequelæ of bony distortions and developmental defects, claimed another third of our rejected young men. A third of a million youths, whose fundamental nutrition was defective, proves we have much to teach (perhaps to learn) about elemental body requirements and food balance. These deficiencies in nutrition are from ignorance, not poverty, and Hindehede's observations upon the blockade in Denmark, during which the mortality decreased thirty-four per cent., are revolutionary. He says: "It would seem, then, that the principal cause of death lies in food and drink. The people must first have bread, potatoes, and cabbage, in sufficient quantity, and then some milk." He further says: "If central Europe had adopted this plan there would have been no starvation or malnutrition." Chapin (2) points the way to the pediatricist's possible influence upon the national welfare. Children with chronic indigestion or constipation or with faulty bodily hygiene are not the ones who radiate happiness. It is, furthermore, impossible for a child to have a happy outlook upon life, who doesn't habitually feel well, and the habit of being well carries with it the possible habit effects upon mental and moral qualities. It is not at all uncommon for the pediatricist to encounter children of six or seven years who complain of "the hardness of life," whose brows are already wrinkled in habitual brooding, and whose mental attitude is habitually apprehensive. These children are not defectives nor are they normal children suffering from the occasional upset which is part of childhood, but are already "chronics" and as surely growing up into social agitators and fault finders, disgruntled with themselves and their associates, as are the borderline cases and degenerates, productive of morons and criminals. The latter classes are congenital and a problem set apart, but the embryo pessimist is not one decreed by fate, nor does he become that from choice but rather because of a wrong habit hygiene, moulding his psychology, his habitual attitude toward the world.

It is unnecessary to note further correlations. Progress in glandular therapy is daily making therapeutic history. It is not inconceivable that blood analysis eventually will enable us to estimate what hormone is out of balance. Undoubtedly in certain groups great strides have been made, and in glandular dyscrasia a physiological basis is commonly found for the mental aberrations. Indeed, so great is this factor in the correlation of the child mind and body function that I hope to present some of these practical applications at a later date. If in this present discussion there is suggested a means whereby the supposedly well child may be "dry docked" every three or six months during the pre-school period from two to seven years and freed from the barnacles that retard his mental progress, ultimate good will come in far greater measure than mere physical findings at first glance would indicate.

LUMBAR PUNCTURE IN DISEASES OF CHILDREN.*

Its Indications and Technic.

BY H. APFEL, M. D.,

Brooklyn, N. Y.

Instructor in Pediatrics, New York Post-Graduate Medical School and Hospital; Assistant Attendant in Kingston Avenue Hospital, Brooklyn, Attending Pediatricist, Brownsville and East New York Hospitals.

Lumbar puncture was first employed by Quinke, in 1890, for the relief of intracranial pressure symptoms in cases of tuberculous meningitis. Furbringer followed in 1895 and employed this means for diagnostic purposes (1).

As an aid in making a diagnosis, lumbar puncture is recognized by clinicians the world over. Every obscure case deserves it; some cases cannot be correctly diagnosed otherwise, while others cannot be successfully treated without it. Its diagnostic value is the more important one; as one author states, "The diagnostic value of lumbar puncture far exceeds any therapeutic value yet described." While most conditions having their pathological basis in the cerebrospinal nervous system can fairly well be diagnosed by clinical observations alone, it remains for the lumbar puncture to corroborate or disprove such a diagnosis. It is not at all rare that the symptom complex of a given case closely fit the diagnosis, we will say, of purulent meningitis, but after a lumbar puncture has been done and the spinal fluid examined the verdict is changed to that of poliomyelitis, or vice versa. While no one today questions the value or practicability of a blood count or urine examination, there still remain a goodly number of practising physicians who deny their little patients the benefit which may be derived from an early lumbar puncture, carefully performed.

Dr. Neal (2), of the laboratory of the Department of Health, of the City of New York, says: "Spinal puncture and the examination of the contents are our most reliable aid in the recognition of poliomyelitis." La Fetra (3) wrote as follows: "Lumbar puncture may show bloody fluid where intracranial hemorrhage is diagnosed." Holt (4) in his book states that lumbar puncture "is the most important means of diagnosis we possess," and further says "I believe it to be absolutely free from danger if properly performed." Koplik (5) may be quoted as follows: "Lumbar puncture is devoid of danger and should be performed without delay in all cases in which we have reason to suspect meningitis. The aim should be to puncture early, for delay means spread of the inflammation and the rapid advance of the disease." Heiman (6) says: "The procedure itself is harmless and is of the greatest diagnostic value."

I believe that quoting the conclusions gained from experience by these clinicians will help convince those who are still skeptical, as to both the value and the safety of this procedure. There is another group of men who are fairly well convinced of the value of lumbar puncture, but who constantly harbor fears of infecting the spinal canal and its meninges in making a lumbar puncture.

*Read before the East New York Medical Society, May 20, 1920.

It is not at all rare for one to hear that a lumbar puncture might have been resorted to, but the fear of a fatality as a result was held out. In fact, the case which suggested to me the topic of this paper as being timely for discussion was that of a newborn baby seen by me with Dr. A. Koplowitz, where we made the diagnosis of intracranial hemorrhage and a lumbar puncture was quite naturally suggested. The parents readily consented, but a relative of the family from New England, who unfortunately happened to be a physician, strenuously objected to the procedure as being a dangerous operation, and no reasoning could convert him to the contrary. That patient died, in accordance with the prognosis, within twenty-four hours, having been denied the probable benefit of a lumbar puncture with the consequent relief of pressure. Having established the exactness of the diagnosis by the presence of bloody fluid, an immediate operation might have saved that child's life. Even though the number of patients who recover are few, the fear of infection should not deter anyone from doing a lumbar puncture, for the same reason that no surgeon would hesitate to do a laparotomy for fear that he may infect the peritoneum. Michael, of Chicago (7), states: "The meninges are very difficult to infect by lumbar puncture." It is understood that the most stringent rules of asepsis should be observed in the preparation as well as throughout the course of the operation. Of all the numerous lumbar punctures which I have done, both in the wards, in the outpatient clinic, as well as in my private practice, not one case resulted in infection.

Pfaundler (8) reported two hundred cases of lumbar puncture without a single bad result, except in one case, where there was collapse due to the removal of too much fluid. Northrup (8) reported no ill effects in fifty cases. Gumprecht (8), in 1900, collected fifteen cases of sudden death and added two cases of his own, following lumbar puncture, but in not one of these cases could it be proved with satisfaction that death was due to the lumbar puncture itself. McDonald (9) reports no bad results except in one case where the patient suffered from headache and syncope, following the removal of fluid. Here also it is possible an excessive amount of fluid was removed. Weinlander (10) reports a fatal outcome in a boy of twelve, but his patient suffered from acute nephritis and uremia at the time of puncture, a sufficient cause for the end result even without his having done a lumbar puncture.

During the last epidemic of poliomyelitis, a thousand punctures (4) were performed at the Kingston Avenue Hospital with no ill effects in any case. It is perhaps timely to repeat the admonition made by many observers never to perform a lumbar puncture when the patient is moribund, if one fears the possible blame to be laid to the lumbar puncture, instead of to the disease which indicated the puncture. What are some of the indications of a lumbar puncture in a child? The indications might for practical purposes be divided into three general groups:

1. For the relief of pressure symptoms.

2. For the purpose of differential diagnosis.

3. For the purpose of administering therapeutic aid intraspinally.

Under the first group come a large number of conditions, both in infancy and childhood.

A. It is a well recognized fact that some cases of hydrocephalus are greatly improved by repeated lumbar punctures, according to Quincke (12). This is true both of the congenital type as well as of the one secondary to meningitis. This statement will bear modification, namely, that experience has taught us that a goodly number of cases of hydrocephalus only refill much more rapidly after they have been tapped once or twice. I recall one case which refilled within a week after the first puncture when the head assumed such large proportions that the patient could not be recognized on the next visit to the clinic. On the other hand, I recall two other cases where the head circumference measured about twenty-three inches on the first visit and by the help of weekly punctures, both spinal and also of the lateral ventricles according to Kausch (13), I succeeded in arresting the abnormal growth of their heads and they are now able to walk around and are happy.

B. In types of meningitis due to some type of organism against which we have no specific antidote, the simple drawing off of the fluid accomplishes drainage as well as relieves pressure symptoms, temporarily perhaps, as in tuberculous meningitis. Convulsions may subside and the patient may get a temporary rest. In fact, there are on record some fourteen cases of tuberculous meningitis reported cured by repeated lumbar puncture, and while we question the authenticity of the diagnosis, we must still bear in mind that it happened in the realm of medicine; hence why doubt it?

C. In acute infectious diseases, pneumonia for example, complicated with serous meningitis or so-called meningismus, the headache, convulsions and opisthotonus are relieved almost immediately after puncture is done.

Considering the second group, every time one is called upon to make a differential diagnosis between an acute disease complicated with meningismus and purulent meningitis, or when one is confronted with the problem, is it a case of tuberculous meningitis or of poliomyelitis; or a given case may present some symptoms of cerebral lues and colloidal gold and Wassermann tests on the spinal fluid have to be done, then our mind immediately reverts to the name Quincke. We send the patient's spinal fluid to the laboratory for a cell count and for the determination of the predominating type of cells and type of organism. A lumbar puncture not only helps us in suggesting the proper management of the case, but it also directs us with regard to the prognosis, from the viewpoint of the family, which must be taken into consideration.

What may be learned from a careful examination of the spinal fluid may be answered by briefly quoting Dunn, as quoted by Rachford, who sums up the diagnostic importance of a carefully examined cerebrospinal fluid specimen in the following manner: "If the fluid is cloudy, some form of meningitis is present. If the fluid is clear, no form of

meningitis can be present except tuberculous." If the cell count is normal (under ten to the c.mm.), no meningitis is present. If the cell count is over ten to the c.mm., some form of meningitis is present. In tuberculous meningitis, the mononuclear leucocytes predominate and the fluid is clear. If the predominating cell is of the polynuclear type, that points to a suppurative form of meningitis. In poliomyelitis or encephalitis the fluid is clear, no bacteria are found, and there is a preponderance of large mononuclear cells. In meningismus, while the fluid is increased in quantity it is normal in character." (2).

As for the third group of indications, one need only refer to the difference in the mortality rate of cerebrospinal meningitis previous to 1890, and the present time to convince the most sceptical as to its benefits as a therapeutic measure.

With the advance in therapeutics the administration of the Flexner's antimeningococcic serum is only one type of intraspinal treatment, and already there are other remedies for different diseases being utilized, for example, in severe cases of cerebrospinal lues, neosalvarsan is used intraspinally with marked success. In 1916, Goodman (15), of the Jacobi clinic, introduced the autoserum treatment for cases of chorea, and while the results are not uniform at the hands of all observers, it nevertheless merits a trial, especially in the cerebral type of chorea. Gemma (12), in 1914, two years before Goodman, advised lumbar puncture for severe cases of chorea, also for whooping cough, etc.

Perhaps the most important part of this paper should be the paragraph dealing with the technic of the subject in question. The procedure need never be limited to the environs of an operating room of a modern hospital. In fact, any fairly clean home is well fitted for the carrying out of lumbar puncture. The kitchen table forms a desirable operating table and the fear of infection is a good prophylactic measure for one to carry in his mind and, therefore, take every aseptic precaution to avoid such an accident.

Necessary articles.—A clean sheet for the table and another to cover the child's body, a few sterile towels, a sterile gown, rubber, several sterile test tubes, and a pus basin, all of which are indispensable.

Instruments employed.—One twenty c. c. Luer syringe, and two needles. (The usual Quincke needle is found to be too large and is not recommended for children. Strauss has devised a needle for lumbar puncture (20), but is rarely used for children.) The operator should always examine these instruments himself. A glass funnel and proper tubing attachment to fit the needles should be provided, all sterile and in working order. This preparation can be carried out in any private residence within short notice. Occasionally members of the family must take the place of nurse and assistant.

The position of the patient.—Much has been written by various authors on this question. Campbell and Kerr (16) advise against the sitting posture, because of the danger of breaking the needle. Fischer (17) in his textbook recommends the right or left side. Norman Williamson (18)

describes a special chair for lumbar puncture, but this chair calls for cooperation on the part of the patient, hence its impracticability in children. This question may be settled by compromising and recommending both the sitting and the recumbent posture. At times it serves the interests of the patient to combine the two postures at a single puncture. As a result of eight years of experience the sitting posture can be recommended for the inexperienced and the recumbent posture for the man who is well trained. Any discussion as to which side is preferable, right or left, when employing the recumbent posture, only occupies unnecessary time and is of no importance from the practical point of view. One has to be a well trained acrobat to do a lumbar puncture with the patient on his left side, unless the operator is left handed. The body should be well flexed, regardless of the posture employed. The parts having been made aseptic with tincture of iodine and alcohol, one chooses the third or fourth lumbar interspace; a line drawn between the crests of the ilia across the back, where the line intersects the spine at the level of the fourth lumbar vertebra; you can therefore choose the interspace above or below. The forefinger of the left hand is used as a guide. Holding the needle in the right hand, it is inserted perpendicularly to the spine, and the needle is firmly forced in the median line into the spinal canal.

The next question that usually arises is how deep the needle should be inserted. This question is answered differently by different authors. Kerley (19) recommends an inch. Other authors recommend an inch and a quarter. I feel that such advice only tends to confusion. The answer we usually give is, go ahead until you get fluid, for the depth varies greatly with the age as well as with the degree of development and the weight of the patient. In some cases you may feel, by the diminished resistance, that you entered the spinal canal. But not in older and well developed children.

Dry tap.—A good deal of criticism has been aroused against the technic which results in a dry tap. One prominent New York pediatricist, when asked what he would do if he got a dry tap, replied sharply: "Get somebody that knows how to do a lumbar puncture." And still it must be conceded that occasionally one will get a dry tap. Dunn makes the following statement: "Peculiar anatomical conditions or certain pathological conditions at the base of the brain may prevent one from reaching the lumbar portion of the spinal canal, hence a dry tap." Again, one may also get a dry tap as a result of adhesions around a point of a previous puncture (17). It is, therefore, advisable, in the treatment of a case of meningitis, where you expect to give serum injections, to begin at the lowest point possible in order to avoid such occurrence. Whenever such adhesions have taken place we must utilize the lateral ventricles. Holt (4) reports a dry tap in four out of thirty-nine cases. In a case of cerebral hemorrhage in a newborn baby admitted to the Post-Graduate Hospital, in May, 1918, on which several attempts to obtain some spinal fluid made by myself as well as by two men of the house staff, were unsuccessful. The necropsy findings by Dr.

McNeal justified the dry tap by disclosing a large blood clot extending from the brain into the spinal canal. These facts are sufficient to prove that a dry tap is not always explained by an inefficient technic.

A word concerning possible accidents in the course of or following lumbar puncture. Breaking of the needle happens occasionally, and should not frighten one. If you are careful and avoid using a long pointed needle, and if you do not bend the needle while introducing it, you may save yourself that accident. If the needle should break, unless the broken end can be easily extracted, it is best to defer its removal to a future time when the patient has recovered from the acute stage of his illness, and even then you may decide to leave it alone.

Koplik (21) reports two cases of apnea from shock more alarming than a broken needle, but he does not tell us the state of health of the patients at the time of the puncture. In such an occurrence one should stop the operation immediately, lower the patient's head, resort to artificial respiration, administer adrenaline, and apply external heat to the body.

In cases of chronic hydrocephalus, where one expects to remove large quantities of fluid, the patient should always be kept on his side during puncture, in order to avoid undue shock. The wound should always be properly dressed, with cotton and collodion, or with adhesive plaster. It is not advisable to use collodion when repeated punctures are planned. Occasionally a bloody fluid complicates the procedure. By using a short pointed needle this may be avoided. This is not a dangerous accident, but a bloody specimen is useless for the purpose of examination. Occasionally only the first few drops are bloody, when a fresh test tube will collect a desirable specimen.

CONCLUSIONS.

The operation is simple, with practically no danger to the patient. Its usefulness for diagnostic purposes is indispensable, and should be done early in the course of the illness. The technic should be learned by all physicians.

327 PENNSYLVANIA AVENUE.

MIDDLE EAR DISEASE IN CHILDREN.

By JOSEPH FRIEDMAN, M. D.,

Brooklyn, N. Y.,

Instructor, Department of Nose and Throat, Post-Graduate Medical School and Hospital; Associate to the Beth Moses and Bikur Cholim Hospitals; Assistant to the Williamsburgh and Coney Island Hospitals.

AND SAMUEL D. GREENFIELD, M. D.,

Brooklyn, N. Y.,

Assistant Attending Ophthalmologist, Beth Moses Hospital; Assistant Otolaryngologist Williamsburgh Hospital; Clinical Assistant, Nose and Throat Department, Manhattan Eye, Ear, Nose and Throat Hospital, New York.

Of all conditions that prove an enigma to the average general practitioner, none can quite equal the case of a young child with an unexplained hyperpyrexia. Being fairly well satisfied that the respiratory tract is clear, and if, after the routine laboratory aids, the physician comes to the conclusion that a pyelitis does not serve to explain the temperature, his case becomes infinitely more complicated. After a day or two of observation, without the appearance of those manifestations which point to a possible exanthem, he often finds himself confronted with that familiar interrogation: "Well, doctor, what do you think is the trouble with my child?" We do not think we are taking too much for granted when we say that at this stage of the game the attending physician is at a loss to explain the child's condition, and if he is possessed of a conscience, would almost wish that, through some good fortune, Providence might rid him of the case. Unfortunately, many men find themselves in a predicament similar to the one we have just depicted, and we are certain, if one will take the trouble to recall those cases which have baffled him most in his practice, a large percentage of them will find a place in this category.

It is unquestionably true that, from the viewpoint of holding his patient, the practitioner finds it a most difficult task to perform. Although knowing that he has failed to account for the child's condition, he will persist in procrastination and defer that assistance which, in addition to solving the problem for him, would afford him an unusual opportunity to crown himself with glory and establish himself most firmly with many a family, and also bring to his weary and much concerned mind a feeling of peace and satisfaction.

It is only upon the appearance of an aural discharge—and this most often discovered by the mother—supplemented by the usual history that the child slept soundly last night for the first time in seventy-two hours or more, that the unsuspecting physician's attention is first directed to the existing and undoubtedly causative aural condition. There is no question in our minds—and many men will bear out our statement, that of all conditions met with in children, middle ear affections rank first among those most frequently overlooked. Very often the early detection of an otitis, although not yet fully established, will frequently lead to a satisfactory explanation of these temperatures and will, in addition, insure early operative intervention, should such measures become necessary. Furthermore, it will assure the patient that the attending physician is alert and on the job and the physician

himself will not overlook a condition for which, in the majority of cases, one can hardly find a just vindication.

We are indeed well aware of the many difficulties with which the general physician is confronted, and especially those obstacles with which he must contend when attempting to induce his patient to consent to a consultation with the aurist, and we are certain no one can appreciate this more than we do. It is with this understanding that we feel most keenly for the general practitioner, and although we may appear somewhat censorious in our statements, we assure you there is not the slightest intention on our part to reproach him. He has far too many cares and worries, and with this in mind, the specialist must not be unreasonably severe in his criticism. But we do feel we are not overstepping bounds, no matter how emphatic and exacting we may seem, when our efforts and endeavors are directed toward awakening in the mind of the general practitioner a sense of the colossal importance of ear examinations in children. Too much stress cannot be laid upon this subject, and the general practitioner must constantly bear in mind that a physical examination in a child is never complete without paying adequate time and attention to the ears.

The external auditory canals in infants are narrow and, in younger children, it is often no easy matter to obtain a good view of the drumhead, but we believe that in many of the cases we have seen there was no reason whatsoever for error, or apparent neglect to examine the ears. We will grant you that the general practitioner is not to determine whether the child is suffering from a catarrhal or a suppurative form of otitis media, or whether there is bulging here or retraction there; but we do feel that he should at least suspect the ear condition when his patient presents an unexplained temperature, and when in doubt he should seek advice so that his suspicions may be either confirmed or dispelled.

We have here in mind a case we saw only recently in which both the attending physician and the consulting pediatricist failed to recognize the aural condition. For twelve days the child had a temperature ranging from 101° to 104° F. Although not established by the laboratory, the consulting pediatricist made a diagnosis of pyelitis, "as a result of exclusion," he termed it, having taken into consideration the child's age and the fact that he failed to find any other cause to which to attribute the temperature. When we saw the child, we found a subperiosteal abscess had already formed. It should be remembered that the pediatricist had seen the child only forty-eight hours previously, and apparently neglected to examine the ears, or failed to recognize the existing ear condition.

We sometimes fail to understand why general practitioners will permit cases similar to the one we have cited, to go on for days without seeking advice, and even when the diagnosis of purulent otitis has been established by the presence of a discharge, will permit these cases to go unseen for weeks, with more or less indifference, giving little thought to the dangerous sequelæ that might follow. The at-

tending physician is then suddenly overwhelmed when his attention is called to swelling and edema over the mastoid, obliteration of the postauricular fold, and an auricle standing away from the child's head. It is only upon the recognition of these dangerous complications that the practitioner is aroused from his lethargy to seek aid. The presence of a subperiosteal abscess is very often the only pathognomonic sign of mastoid disease known to some practitioners, and we have had occasion to come in contact with men who believed this was the only indication for operative intervention in children. Whether, in view of our modern knowledge of handling these conditions, this belief should still be prevalent, we leave it to your own judgment. True, many cases of middle ear disease clear up without operation and, as a matter of fact, most of them have such a happy termination; but if, after a reasonable length of time, one fails to clear up, investigation should not be delayed too long in ascertaining the cause.

If discharging ears are associated with evening rises in temperature, namely, 101° to 103° F., whether this temperature is the result of the otitis must be decided. In other words, if an ear has been discharging for one or two weeks, associated with evening elevations of temperature, our examination must determine whether there is evidence of insufficient drainage facilities, as indicated by the size and location of the perforation or incision. If there is a good sized opening, without a bulging drum, with little or no sagging of the posterior superior canal wall, in the absence of a profuse discharge, we can rest assured that the cause for the temperature should be sought for elsewhere. If, on the other hand, we note a nipple shaped projection, at the apex of which we find a pinpoint perforation, through which a drop of pus can be seen exuding—which picture is good evidence of insufficient drainage—we may justly attribute all or at least part of the temperature to pus retention. There is essentially no difference in pus retention here from that in any other part of the body.

Sagging of the posterior superior canal wall is of great importance when taken together with all the other signs and symptoms. In itself, in early cases and in very young children, as far as being an operative indication, its value, we believe, has been overestimated. We have seen cases in which there was sagging with a vengeance, so to speak, which cleared up most rapidly and completely, and on the other hand, we have seen cases which exhibited very little sagging and upon operation disclosed extensive erosion of the sinus and dural plates and even destruction of these structures, with exposure and disease of sinus and dura.

The amount of discharge itself is often a most important operative indication. A so-called waterfall discharge, one which reappears abundantly immediately upon wiping away, even if unattended by marked rises in temperature, and, if of any duration, is strong evidence that the infection is not limited to the middle ear spaces, but the attic and antrum and possibly more important structures are also involved. The diseased mucous membrane in the middle ear when alone involved cannot pro-

duce so profuse a discharge. Hence it is gross neglect to permit these children to go on for weeks and months with profusely discharging ears. It is only later in life that the bad effects of this neglect are made apparent. At this time is laid the foundation for cholesteatoma cases, for semicircular canal fistulæ, and for labyrinthine and intracranial complications, not mentioning the concomitant impairment of hearing which follows, even if these patients escape the more serious complications.

In passing, it is well to mention that the middle ear conditions occurring with little or no elevation of temperature and few constitutional symptoms, such as are seen in undernourished, debilitated and marantic children, and those seen in the tuberculous, are not included in this category. These children very often present serious effusions and even purulent secretions in the middle ear, with practically no constitutional reaction that might serve to call our attention to the existing otitis. During the routine examination of these children the ear condition is accidentally discovered. We make mention here only of aural affections occurring in the young and healthy infant.

It is, therefore, the duty of every general practitioner to whom is entrusted the care of children, especially those in the early years of life, never to fail to examine the ears. This is particularly true in children suffering from measles, diphtheria or scarlatina. Ear complications are most prone to develop in these children, and the usual symptoms which direct our attention to the ears are often absent or masked by the symptoms of the initial disease. We cannot impress upon you too strongly the rapid and extensive destruction that takes place, especially in the last mentioned disease. It is of the greatest importance to bear this fact in mind. One examination of the ears in such cases is entirely inadequate, but an examination conducted at regular intervals during the course of the disease is of paramount importance.

If the attending physician has not had sufficient experience in examining ears, so that he may arrive at a satisfactory conclusion, he should not hesitate, in justice to the patient and to himself, to seek advice, especially in those cases in which he cannot satisfy himself as to the cause of an abnormal temperature. If the patient comes to him with a running ear, he should not be content with merely prescribing an irrigation, but should be sufficiently interested to ascertain the exact state of affairs behind the discharge. Above all, he should not be guilty of sitting aside, idly waiting for the more serious complications to stir him.

We feel assured that if the proper precautions are taken in determining these cases at the outset; if the general practitioner will exhibit the interest becoming such conditions; if he will always bear in mind the great frequency of aural affections in infants and will endeavor to bring them under the care of the otologist, who can do most for these cases in the early stages of the disease, he will be going a long way toward averting and offsetting those serious complications which the aurist is so often called to treat.

691 LAFAYETTE AVENUE.

THE WEAK FOOT IN THE CHILD.

Flexible Flat Foot.

BY H. SCHEIMBERG,

Brooklyn,

Lecturer on Mechanical Orthopedics, The First Institute of Podiatry, New York.

(Concluded from page 993.)

It is peculiarly unfortunate that persistent pain in the young children is often lacking. I say unfortunate, because if direct pain were more marked, parents would, of course, give the condition early attention. Where pain is present, the tendency is to regard it as growing pains. The absence of persistent pain is easily explained. Pain itself can only occur with or be consequent to such factors as overstrain, actual injury, or in disease as, for example, a tuberculous arthritis of the ankle or neighboring joints. In the common weak foot, however, we have no history of direct injury or disease, while the element of overstrain cannot operate to produce persistent pain because of the relatively lighter weight of the child's body and the frequent rest periods to which the child resorts. It is only when the child gets older and heavier, or where we have an unusual rapid growth or increase of weight, or where employment necessitates foot work without a choice of rest periods, that the element of overstrain enters and painful disability and often nervous exhaustion become the dominating symptoms.

We can thus realize the intimate relationship between the weak foot and the body mechanism. It becomes clear that in attempting to correct faulty posture in any part of the body, the feet should not be overlooked as a possible direct or contributing factor in creating lack of body balance. Where the abdomen projects excessively or round shoulders exist, where there is clumsiness in action and frequent falling, we may also find that the child is suffering consciously or unconsciously from a weak foot which may require prime consideration. The general practitioner might do well, therefore, to include the feet in a routine examination of the child, particularly after acute illnesses that may have weakened the general musculature.

In the treatment of the ordinary weak feet in children the use of operative surgery is not a logical expedient because as we have seen the problem is not one of a fixed and localized deformity as much as a functional weakness on the part of several structures and restoration of functional ability on the part of the weakened structures is of prime importance, not the correction of the deformity. When functional tonicity on the part of the weakened fleshy structures has occurred, the deformity automatically disappears. Operative methods are contraindicated also, because of the danger to ultimate bone growth from interference with rapidly developing bone; but primarily because the prognosis by the use of simple measures and the co-operation of the patient, is both excellent and fairly immediate.

The use of plaster of paris or adhesive plaster dressings for the purpose of maintaining the foot in an overcorrected (inverted and adducted) posi-

tion is contraindicated here. Such measures are appropriate to overcome spasm, or fixed shortening of the peronei muscles, or where immobilization is sought, as in an acute inflammatory condition. Here, however, none of these conditions obtain while the element of continued immobilization, more so with the plaster of paris, incident to these methods contradicts the prime essential for the cure of the condition, namely, the restoration of functional ability which can only be secured by function. With adhesive plaster, we have less immobilization, but the continuance of adhesive on the skin over a period of time as required in the majority of these cases cannot long be tolerated. In some cases, however, I have found that several adhesive plaster strapings so adjusted as to throw back the heel bone, when used in conjunction with due attention to other elements of treatment, has resulted in an unusually rapid correction in a few weeks and in some rare cases in about a week. This is not typical, but where it has occurred the child seemed to be unusually intelligent, and this intelligence may have operated reflexly to, effect an instinctively enforced assumption of the correct position during the time that the adhesive plaster dressings prevented the assumption of the incorrect posture. The objection of immobilization holds also with leg braces that are intended to hold the foot in an overcorrected position.

The successful treatment of the majority of these cases demands specific attention to the following essentials: 1, Attitude; 2, footgear; 3, exercise to restore functional tonicity to the relaxed muscles and ligaments; 4, preventing the feet from assuming the attitude of deformity, but without functional interference.

Attitude.—This needs no further comment except that care should be taken that improper standing or walking is not secondary to other postural or structural causes.

Footgear.—As already stated, correct fitting should be understood and checked by the practitioner treating the patient. In the shoe itself, the fore part should adduct slightly toward the median line of the body so as to help preserve a normal relationship of the longitudinal segments of the arch. Excessive adduction, however, of the front of the shoe, may by pressure induce an irritation at the region of the fifth metatarsophalangeal joint, and thus affect gait. It is absolutely necessary to avoid impingement against the large toe—a caution which cannot be too strongly emphasized. Pressure against the large toe is the forerunner of the hallux valgus and the unsightly bunion or the two conditions combined. Primarily such pressure by abducting the large toe from the median line of the body diverts direct action of the exterior longus hallucis and the flexor longus hallucis, which muscles attach to the large toe, from the leg and are important adjuncts to the maintenance of the arch. Counter and waist should be snug. From the viewpoint of prevention in a normal foot, such factors as the softness of growing bone combined with the unyielding street pavements and the normal tendency of the os calcis to rotate inward, seem sufficient argument against sandals, sneakers, and flexible

shank shoes generally, and these, therefore, are certainly barred as therapeutic considerations. Though, perhaps, the subject in hand does not warrant an unduly prolonged discussion on the shoe question, two interesting items warrant reference. One relates to the so-called problem of making a proper shoe for the child. My observation of the children's shoes on the market show me that no problem would exist if an attempt were actually made to simply follow the contour of activity of a normal child's foot—something that has not yet been done from the viewpoint of manufacturing a standard shoe. Of course, the fitting problem for a particular case still exists. The other item of interest on the shoe question is the favorite argument resorted to by the exponents of the flexible shank shoes that nature intended perfect freedom of function for the delicate plantar structures of the foot in order to attain perfect development. But was it Nature or man who evolved city walks—hard, unyielding surfaces, and which are themselves so artificial that even the horse must be shod for protection against the jar? Besides, proof is lacking that, given a rigid shank shoe in a particular case, the shoe to be well fitted, interference with foot function actually exists.

Nor should we overlook the directly contributing influence of stockings in producing mechanical foot disorders, particularly the weak foot. It has always been a matter of surprise to me to find that in written or oral discussions on foot ailments, too little consideration has been given to the stocking. It should pass as too plain for discussion that even with proper shoes, much damage can be effected through stockings that are too short, of unyielding texture, and which, therefore, by cramping the toes, interfere with circulation and function.

But with the weak foot in particular, the stocking has an intimate relationship. This can only be appreciated by observing the peculiar changes that take place in and about the large toe when off the ground at rest and when bearing weight in activity. When weight bearing its function distinct from that of the smaller toes is that of a weight bearing base from which the body is thrust forward while at the same time the smaller toes grip the ground by a flexion or bending at their first interphalangeal joints: To bear the body weight, the great toe remains straight through its length while the gripping action of the other four toes is manifest in the flexion mentioned. But this is not all. With the foot off the ground in the rest attitude, the tendons attaching to the great toe are relaxed, permitting that toe to lean up against and come in contact with the second toe (Fig. 6), and a straight line if extended on the inner margin of the foot from heel to toe would not come in contact with the entire inner margin of the great toe. Under weight bearing, however, the large toe swings in toward the median line of the body (Fig. 7) so that a straight line extended on the inner side of the foot from heel to toe would touch the large toe along its length and a space now exists between the large toe and its neighbor. As the large toe swings toward the other foot in the upright position to take the weight of the body, it does so by the tightening of the tendons of the muscles attaching

to it, the extensor longus hallucis and particularly the flexor longus hallucis. The tautness of the flexor longus hallucis tendon, which runs across the entire sole forward to the extremity of the large toe, results also in a bracing of the segments of the longitudinal arch so that the concavity under the arch becomes visibly increased, particularly in the tip toe position at the end of the step, when, through the tightening of this tendon, the concavity of the longitudinal arch is at its greatest. The ordinary stocking is, however, median pointed as if both sides of the foot were symmetrical and terminated in a tip with its farthest extremity at the third toe instead of at the first. Thus ordinary stockings by compression maintain the large toe against the second even when the foot is bearing weight and when the large toe should adduct inward. Besides the stocking is put on with the foot off the ground, which is the position in which the large toe leans against the second. Thus there exists a combination of factors that tend to make inevitable the inefficient operation of the large toe as a weight bearing and locomotive factor, and with this, therefore, a consequent weakening of the long muscles attaching to it and to all the toes which brace up the arch. Almost invariably, therefore, in cases of hallux valgus do we find an associated weak foot or flat foot, or symptoms of arch strain. A fuller realization of the special function of the large toe and its essential shifting toward the other foot in weight bearing, may some day result in stockings with separate stalls for the large toes and shoes with straight inner lines becoming more universal items of dress. When that day arrives, a great proportion of weak and flat foot cases will simultaneously begin to disappear.

Exercises.—The anatomical pathological condition is a varying degree of relaxation of the adducting muscles and of the ligaments of the legs and feet, thus resulting in abduction and eversion. The exercises should be suited to the particular case and are such as invert the entire foot, adduct the forefoot, throw the ankle outward, besides training in normal posture and locomotion with the child barefooted. As structural shortening of muscles is rare, manipulation seems hardly necessary.

In general, exercise in the child's case can be easily effected by converting an otherwise dull proceeding into a session of play. This can be done by having the seated child rotate its feet around the fingers held at certain heights and angles, or catching and tagging a finger that is actually guiding the foot in active overcorrection.

It is perhaps unnecessary to state that in the treatment of the weak foot or any other condition, if an accompanying active destructive process is present, such as tuberculosis of bone or joint, rachitis, or an infectious arthritis, rest and the maintenance of the foot in an attitude that will prevent permanent subsequent deformity are indicated instead of exercises.

As prevention is always of prime interest, it is proper to here allude to an element of care which may prevent weak feet consequent to prolonged confinement to bed. Aside from the direct weakening effects on the tissues of the foot due to the

disease itself which has occasioned confinement, a change often occurs in the legs and feet which may affect the weak feet. This occurs because, in the attitude of rest as in bed, the foot tends to lie in extension, that is, at an angle of over ninety degrees between it and the leg. This angulation is illustrated in the rest attitude that has been assumed by the child in Fig. 6. When this attitude is maintained over a period of time as with continued confinement, structural shortening of the calf muscles takes place with a corresponding relaxation and weakening of the anterior muscles—a sort of mild, nonparalytic talipes equinus. With walking resumed after confinement, such structural shortening of posterior and relaxation of anterior muscles of the leg interferes with normal flexion and extension of the foot on the leg which is required in locomotion and may occasion a secondary flexion or lateral displacement of the midtarsal joints just as occurs in the weak foot and as more fully detailed in a previous article on the high heeled shoe (1). To prevent these structural changes in the leg muscles, it is advisable during confinement and where a local condition does not contraindicate to daily manipulate both feet in flexion, extension and circumflexion, or to have the patient engage actively in these movements if possible.

Preventing the foot from assuming the attitude of deformity without interference with function.—We have seen that, in weak foot, the heel bone enhanced by normal anatomic peculiarities and a weakened musculature falls inward, and that with this the forefoot abducts and the arch thus angulates with an inward lateral convexity. Where in the normal foot, the entire force of the body weight was directed vertically through the tibia and astragalus on to the heel bone and eventually over the longitudinal axis of the foot, it is now to a great extent diverted toward the inner margins of both feet. By bringing a sufficient pressure to bear in a reverse direction to the inclination of the heel bone, that is, both at the upper inner and lower outer surfaces of this bone, we automatically restore the normal alignment of the longitudinal arch and correct whatever secondary misalignment exists in the knee, hip and spinal articulations. Our problem then concerns itself with forcing and holding this bone in place. In the very mild cases this bone may be ultimately thrown back and the condition cured by attention to attitude, footgear, exercises, and the elevation of the inner margin of the shoe heel, a requisite height depending on the particular case. In the more advanced cases, however, this is insufficient, and experience has demonstrated the final expediency in even a majority of these cases for the unyielding and corrective pressure that only metal can give.

The necessary lateral pressure to counteract the force of the body weight concentrated at and below the ankle joint cannot be secured by stiff counter shoes, commercial supports and the like, as these cannot prevent the ankle bulging and their rigidity is lost through softening by body heat. The suggestion of metal, however, raises the natural question of how to utilize it to the best advantage without immobilization of the foot. This, in turn, calls

for a little inquiry into the commercial appliances now on the market, with particular relation to their value in treatment.

In referring to the arch support, it should be borne in mind that promiscuous application of foot plates has been justly condemned by many eminent orthopedists, unless made over a specially corrected plaster positive of the foot to secure the proper indications in a particular case, and then used as an adjunct in treatment which aims to discard them when their use is no longer necessary. This is all in perfect accord with the experience of those who have successfully treated many cases of weak foot in the child. But in the general sale of commercial appliances, the noncompliance with the essentials of scientific treatment has led to an unmerited condemnation of supports as a whole.

The specific objections against market appliances are easily evident so far as the treatment of the common weak foot is concerned. In the first place, their construction is based upon a few fixed patterns that cannot meet the indications as to fit and correction in the varieties of weak feet. With teeth by way of illustration, the community would deride the idea of patronizing an establishment that professed to sell well fitting stock teeth, realizing that each case requires specific preparation. The public is not yet aware that the variations in the case of the feet are just as numerous. Again, it is assumed in these stock supports that the arch has broken down, and that it needs to be lifted up. No provision is made for the exact and powerful lateral pressure essential for correction. Merely pressing upward cannot correct a laterally displaced arch, and only furnishes relief to the ligaments while the arch remains tilted. Between the ligamentous strain which where present is temporarily relieved, and the assurances of the salesman of perfect cure, further neglect ensues with a loss of time and money.

One excellent adjunct in complying with the requirements of correction without immobilization is the Whitman plate with a higher inner flange and a smaller and lower outer flange, the flanges being devised to exert the necessary lateral pressure to counteract the tilting of the os calcis. This brace, of course, is to be made over a plaster positive of the foot. The cast should be taken with the foot at right angles to the leg and slightly inverted. The element of overcorrection, often essential for cure, is secured by careful deepening of certain points on the positive to obtain extra pressure where desired and before the final construction of the plate over this positive. When viewed plantarwise, the plate should terminate behind the head of the first metatarsal, run thence diagonally across foot to the outer flange situate at the posterior lateral surface of the foot, and the rear margin running transversely across the bottom of the foot a little in front of the back curve of the heel. When thus constructed and properly adjusted, it may be safely worn without any interference to function. At the same time it acts as an effective reminder to the child to maintain the correct attitude by making the assumption of the weak foot pose painful. Proper accompanying treatment now facilitates cure because the relaxed structures are prevented from lengthen-

ing in standing and walking and thus given an opportunity to shorten structurally. The assumption of the normal foot attitude is also materially enhanced and made habitual because the improper pose cannot be assumed. The support should be discarded when the correct attitude is assured, but care to be continued for a while to attitude, exercises and footgear.

Though appreciating the seeming logic of those who argue for physiological treatment solely in preference to any arch supports, there are considerations with respect to weak feet often overlooked that often justify support by braces as a measure of prime value. Weak feet by referred misalignment often occasion stumbling and falling, together with general mechanical strain. This stumbling and strain exist as omnipresent mediums for a possible tuberculosis of bone or joint which in childhood is commonly consequent to trauma. But stumbling, falling or strain are immediately checked and normal balance and locomotion promptly effected by proper bracing. On the other hand, physiological treatment cannot always check this faulty balance and strain, but must await actual correction. Besides, by a scientific preparation of the positive before making the support, overcorrection of the condition through extra pressure against the heel bone can be obtained and the value of overcorrection in treating any deformity so as to secure perfect correction is axiomatic in orthopedic practice. As with the pro and con of many other questions, the actual truth exists between both sides of the argument, and to my mind there has been as much of too little use when warranted of supports as well as an excessive dependence upon such appliances.

The cure of the weak foot is almost invariably assured by the proper application of the foregoing principles of treatment. Where it is apparent that the weak feet are associated with a general lack of tone, treatment of the general weakness is naturally indicated, but never without attention to the local condition which too often survives. The length of time required for a cure varies from a few weeks to several years. Such factors as excessive weight, general weakness due to disease or otherwise, lack of cooperation on the part of patient or even child, are examples of causes that may delay ultimate cure.

CONCLUSIONS.

1. The feet of children should be examined when walking begins, to determine whether abnormalities exist that require attention.
2. Routine examinations of children by physicians or pediatricists should include observation of the feet as a possible source of contributing factor to disability or ailment.
3. The feet of children in public schools should be examined periodically by duly qualified specialists as is now done with the other organs.
4. A greater number of clinics for the particular observation of children's feet should be established.
5. The diagnosis of foot ailments in the shoe store should be prohibited by legislation.

CONGENITAL MEGACOLON (HIRSCHSPRUNG'S DISEASE).

*With a Report of a Case in Twins.**

BY JOSEPH POPPER, M. D.,
New York,

Attending Physician, Infant Welfare Department, Lebanon Hospital; Attending Physician, Israel Orphan Asylum.

The cases I am about to report are true cases of congenital megacolon of the type often referred to as Hirschsprung's disease. In 1880 Hirschsprung first called attention to this condition and published his complete exposition of the subject in 1896. Cases were reported in this country before 1880, but the first authoritative study of the subject in this country was made by Finney in 1908. The literature abounds in reports of so-called Hirschsprung's disease and the condition is now so well recognized as to be treated in most textbooks on pediatrics.

However, lest it be imagined that the disease is fairly common, I should like to state that of the abundance of reports and studies on the subject many of them concern another condition which is probably acquired and not congenital in the same sense as the cases described by Hirschsprung, and which form the basis of this report. Thus in speaking of the condition congenital megacolon one should distinguish between the two types.

The first or Hirschsprung's type of congenital megacolon is characterized by the following symptoms and signs beginning at birth or shortly after birth: Obstinate constipation, marked distention, active and visible peristalsis, and finally accompanied by symptoms of intestinal toxemia. This type, according to recent investigators, begins as a definite pathological entity from birth, the large intestine being both dilated and hypertrophied from the beginning. This type is extremely rare and is usually fatal in a short time in most cases. As evidence of the infrequency of this condition I may state that in a personal communication Dr. Rongy and Dr. Aranow, attending obstetricians to the Lebanon Hospital of this city, assured me that they had never seen a case in their many years of service in the hospital, and that there was no record of any case having occurred in the hospital during its entire existence, a matter of over a quarter of a century and covering many thousands of births. That it is more common than the published reports of authentic cases would indicate is very likely, for undoubtedly many deaths from this disease are reported as due to intestinal obstruction, as was the case with one of the twins reported below.

The other type, and one which is by far much more commonly met with, is that which begins late in infancy or in early childhood, characterized by abdominal enlargement and severe constipation with its associated symptoms. It probably has a different pathology in that it is probably acquired and not congenital and is secondary to some spastic condition of some part of the colon with resulting dilatation and hypertrophy of the gut immediately above it. It is analogous to the hypertrophy and

dilatation of the stomach secondary to pylorospasm. For the same reason it differs from Hirschsprung's disease in its amenability to treatment. Thus Meyers (1) succeeded in relieving the patients in a series of cases by proper diet and the administration of atropine just as Haas (2) has successfully treated pylorospasm. Other measures have likewise succeeded, such as exercise and posture and local treatment. Thus far only operative interference has offered any hope in the treatment of Hirschsprung's disease, but as yet the mortality from such treatment is extremely high.

HISTORY.

This history practically concerns only one of the twins, for the other had died shortly before I arrived at the patient's home. However, from the previous history and from a superficial inspection of the dead twin, I am convinced that death was due to the same malady from which the live twin is now suffering.

The twins were females who came under my observation on the fourth day of life. This was the mother's fourth pregnancy, and birth took place at full term, delivery being normal. Birth weight of the patient, five pounds eight ounces; that of the dead twin, three pounds eight ounces. The family history was negative. From birth on the history was one of progressive intestinal obstruction, the symptoms and signs being identical in both up to the fourth day. Neither infant had passed meconium nor expelled flatus since birth, in spite of cathartics, enemata, and various other measures. After the first day attempts at nursing were unsuccessful, and even water was not retained. Vomiting steadily increased and on the third day the vomitus consisted of black stained fluid. Weakness, loss of weight and distention soon became quite marked. On the fourth day the distention had assumed such proportions as to interfere with the cardiac action, with resulting cyanosis and, in the case of one of the twins, death.

I arrived on the scene shortly after the death of one twin, and inspection of the live one revealed an infant practically in a moribund state. This child was markedly cyanosed, the abdomen was tremendously enlarged, the breathing was shallow, the extremities cold, the radial pulse imperceptible, the heart rapid and feeble. The diagnosis occurred to

FIG. 1.—Case of Hirschsprung's disease in one of twins, at five months.

me after taking the patient's temperature, which was 96° F. I experienced a slight difficulty in passing the anal sphincter, and after the thermometer was within the bowel it seemed to me that the gut was unusually roomy. I then withdrew the thermometer and in its place inserted a glass test

*Read before The Bronx County Medical Society, December 16,

tube about four and a half inches long and three eighths of an inch in diameter. This tube also had to be forced through the anal sphincter, and when in the bowel I was able to make wide excursions with the free end of the tube within the gut. Holding the tube in place with my right hand, I

FIG. 2.—X ray photograph showing markedly dilated colon.

proceeded to exert considerable pressure with my left palm on the distended abdomen. Presently a large amount of fluid mixed with meconium and gas was expelled past the tube. I continued this treatment until the abdominal distention was almost completely reduced. The relief experienced by the infant was immediately apparent, the heart action improved, the cyanosis cleared up, the breathing became deeper, and within less than an hour water was retained by mouth and the baby even made an attempt to take the breast.

Inspection of the abdomen after the distention was reduced revealed the presence of active peristalsis throughout, a large wave extending from the right iliac region up and across and down the left side, seeming to follow the course of the colon and several smaller waves going across the centre of the abdomen from left to right. At the same time on palpation through the thin abdominal wall and especially in the centre of the abdomen, which was the seat of diastasis recti, one could grasp the thickened and enlarged coils of intestine. There was no doubt of the fact that the gut was hypertrophied to the touch. The diagnosis was verified by fluoroscopic examination as well as radiograph made when the baby was sixteen days old. (Fig. 2.) A complete physical examination made on the fifth day of life revealed only one other abnormality, viz., a distinct but not very loud systolic murmur at left pulmonic area transmitted to the back.

SUBSEQUENT HISTORY.

At the time of writing my little patient is twenty-eight weeks old. During that short period she has led a very eventful and precarious existence. On several occasions she was at the point of death. Her bowels have never moved completely without assistance. Occasionally she would have a spontaneous movement. At three different times as a result of intestinal toxemia she has had severe convulsions, vomiting, fever, distention, and generalized edema. Her stools at this time would contain a considerable amount of mucus and blood. On the other hand, on two occasions such severe diarrhea developed that in about twenty-four hours her body became practically dehydrated. When four weeks old she contracted a pneumonia involving the right upper lobe and lasting about two weeks. At eight weeks an abscess developed in the lower central abdominal wall which discharged through the umbilicus, probably an infection of the patent urachus.

Most of her severe ailments occurred during the first three months. Following that she seemed to be getting along fairly well until when five months old a severe eczema developed, involving the scalp, face, and elbows, and resulting from the addition of fruit juices to the diet. This has improved considerably since correcting the diet.

Her weight curve with many interruptions has continued to ascend, so that today she weighs eleven pounds three ounces. With gain in weight her abdominal muscles have lost their thinness, so that one can no longer grasp the hypertrophied coils of intestine, but peristalsis is still visible and distinct. The cardiac murmur also has persisted.

The treatment of this case has been and still is beset with great difficulty. In the feeding of this baby I have tried breast feeding, mixed feeding, dry milk and whole milk dilutions. For the past five months she has been doing best on whole-milk diluted with very thin barley water and with the addition of very little sugar in the form of lactose. Other sugars have been tried, but they always produced a great deal of fermentation with resulting increase of distention. She has also been getting lately zwiebach or toast with milk and water and stewed fruits. In attempting to treat the local condition I have used without success atropine, pituitary and suprarenal extracts. The only measures that have succeeded in keeping this baby comfortable thus far are a proper diet, an abdominal binder, and the daily use of saline or sodium bicarbonate irrigations assisted by abdominal massage.

The Malnourished Child in the Public School.—William R. P. Emerson (*Boston Medical and Surgical Journal*, June 24, 1920) names in order as the five principal causes of malnutrition, physical defects, lack of home control, overfatigue, improper food habits, and improper health habits.

THE PHYSICAL SIGNS OF PNEUMONIA IN CHILDREN.

BY SAMUEL A. BLAUNER, M. D.,

New York,

Adjunct Pediatricist, Lebanon Hospital; Medical Director, Israel
Orphan Asylum.

The diagnosis of pneumonia in infancy and in early childhood is distinctly by physical signs. We cannot conceive of a pneumonia without some form of consolidation, and consolidation means a change in the physical notes from those of the normal chest. Of course, pneumonia being a severe acute illness involving the lungs, we may feel that from the subsidiary symptoms, especially the external respiratory changes and the severe toxemia that usually accompany this illness, a diagnosis can be suspected without awaiting the physical signs. That may be true to a considerable degree in adults, but in children these symptoms are too variable to be dependable, and frequently an error in diagnosis creeps in if relied upon, for rise of temperature, rapid pulse, rapid respiration, are not unusual in other febrile conditions of childhood, and even dilatation of the *alæ nasæ* is frequently encountered, especially in affections of the upper respiratory tract. Toxemia, an accompaniment of pneumonia in adults, giving an early clue to the probable affection of the patient, is also a most varying symptom of pneumonia in children, and in fact is just as frequently absent as present, and even in the apical types of pneumonia where it is usually expected it is not infrequently absent.

In the diagnosis of the various febrile conditions temperature plays its important rôle. In adults especially the temperature curve is often of great assistance in particular diseases, and long before other symptoms are elicited this curve will suggest the most likely diagnosis. This is particularly true in the pneumonias and even in differentiation of the lobar and bronchopneumonic types—the temperature will often be sufficiently characteristic to be of assistance in the separate diagnosis. However true this may be in adults, the same cannot be said of the pneumonias in children. It is true that the temperature curve frequently follows the typical course of the pneumonias in adults, but as a general rule other febrile conditions in childhood may act similarly, and we therefore cannot definitely determine the diagnosis in the absence of physical signs. Who has not seen in a case of ordinary grippe the temperature run high for several days and then suddenly drop to normal? For example, a child eight months old has a sore throat, with fever. The temperature rises quickly to 103° and 104°, remains that way for five days, and then falls to normal within twelve hours, the closest examination not revealing the slightest sign of pneumonia. Who has not seen in similar conditions in childhood, the temperature run high and then come down to normal, either slowly or suddenly? It may be argued, of course, that such temperature may be indicative of consolidation, although we are unable to elicit the signs, but whatever the reasons a diagnosis of pneumonia under such conditions is made on hypothesis only and not on positive data; for in institutions with radiographic facilities it can be shown

that many of these so-called pneumonias are not pneumonias at all.

My observation has been, however, that the characteristic feature of temperature in febrile conditions in childhood is its extreme irregularity and our thorough inability to read symptoms into the curve the same as we do in adults, this holding true even in the pneumonias in children; for instance, a lobar pneumonia, contrary to our expectations, may run wide variations, and either suddenly or gradually reach normal, while often in a case of bronchopneumonia, with all the typical signs of this disease, the temperature may remain high with slight remissions for several days, and then suddenly or slowly reach normal.

In Case No. 7764, a child, aged eight years, typical signs of bronchopneumonia developed; for eight days the temperature curve remained typically lobar in type, for five days variations became wider, and then the temperature suddenly reached normal. There was an uneventful convalescence. If there is any similarity between the temperatures of lobar and bronchopneumonia it is the fact that, although variations in temperature may be wide in both instances, in bronchopneumonia they may touch normal or even subnormal, while in lobar pneumonia they usually do not reach normal, although at times they do. In fact, it is not always an easy matter to differentiate between lobar and bronchopneumonia, for only too frequently bronchopneumonia is limited to one lobe and is massive in character. From the physical signs and the variations in temperatures that may be present in either form, it is utterly impossible to differentiate the two conditions, although when the temperature is normal we may suspect a bronchopneumonia. In other words, from the subsidiary and subjective symptoms alone it is unwarranted to make a positive diagnosis of any form of pneumonia. This is as it should be, for, in justice both to ourselves and to our patients, we should not make a positive diagnosis on impressions alone. Changes in the lung produce sufficient acoustic changes for us to recognize them, and our failure to do so lies rather in our inability to recognize these changes than in their absence, and also because of the false acoustic principles which we have been taught and which have been retained by many of us.

It will be appropriate here, before I consider the physical signs of pneumonia in its different stages and varying forms, to say that central lobar pneumonia does not exist and we are only besetting ourselves with difficulties when we reach such a conclusion. If a pneumonia is present we can find it, and it is only the varying and finer acoustic changes that occur that make it difficult for the busy practitioner to recognize them. We must recognize, too, the great acoustic principle that pitch remains unchanged only if it travels through a uniform medium and that it will promptly change if the medium changes. In other words, a note traveling through an air containing lung will not change its pitch by striking a consolidated area, for the consolidated area cannot act the part of a condenser and rechange the vesicular note to a bronchial note.

We must remember that the bronchial breathing we hear in pneumonia is really the tracheal tubular breathing produced in the larynx and trachea transmitted unchanged, as far as pitch is concerned, through a consolidated area of uniform medium, but to produce this physical possibility the consolidation must extend down to the hilum of the lung or be at least in connection with a fair sized bronchus so that the tubular breathing can go through unchanged. If the note first enters the lung and becomes vesicular, it remains vesicular even though it may later impinge upon a consolidated area, for the consolidated area has no physical means of re-changing the pitch. This law of sound explains the many varying physical signs of pneumonia, and also explains why the bronchial breathing is delayed or even absent in some cases. Another point it is well to emphasize is that pneumonia begins with a wedgeshaped triangular patch with base at surface of lung and apex pointing inward, and whether bronchial breathing will or will not be heard depends upon whether the consolidated area is in communication with a bronchus or has reached the hilum of the lung. These assertions are not merely theoretical; they are very practical, and our success in finding a pneumonia patch will depend on our knowledge of these two facts, for otherwise, expecting some change in the auscultatory note, we will overlook a slight grade of dullness indicating a pneumonic area.

As an instance of the difficulty of diagnosis we may cite the case of a child treated by Dr. H., who for three weeks had had a cough and a temperature with wide variations. Several consultants expressed various opinions, and it was finally thought that the case was one of malaria, as the child came from a malarial district and the blood examination revealed suspicious bodies. I was asked to see the child. I discovered a dull patch in the left subclavicular region, but normal vesicular breathing was present. Diagnosis of pneumonia was confirmed by radiographic findings. Similarly in Dr. A's case a right apical dullness developed, lasting ten weeks, but at no time was bronchial breathing to be heard. This was also confirmed by radiographic findings.

With these facts in mind I may say that in the diagnosis of early pneumonia the percussion note is the most important sign to be depended on. We must remember, too, that a child's chest is very resilient and its lungs highly elastic, and a slight change in percussion note will often be overlooked unless we use the lightest stroke so as to throw as little of the surrounding chest into vibration as possible. The child must be placed in a position, preferably supine, so as to relax the entire musculature of the chest thoroughly, otherwise tension of the muscles on one side will give a higher note, with the possibility of a mistake in diagnosis. In the early diagnosis we must not depend on any auscultatory assistance for even râles in the pneumonias of childhood are as often absent as present. A child may go through a pneumonia without a râle and even in the stage of resolution none or very few râles may be heard. Because of this marked variation of the presence of râles I teach

my interns not to place too much interpretative value on râles in a chest. They indicate a pathological process, but the exact nature of this process it would be difficult to state because of this variation. As the process continues the auscultatory changes begin to come to the fore. The breathing becomes high pitched, bronchovesicular, and then bronchial, with or without râles.

All that has been said above holds true for the lobar type of pneumonia and not for the bronchopneumonia type. Because of its different pathology and the usually accompanying bronchitis the patches are frequently too small to be detected by percussion note, and, for that matter, even for the radiograph. Frequently, with otherwise positive signs of bronchopneumonia, a radiograph will often be negative, and we, therefore, have learned to expect little confirmation from the x ray findings, and unless the patches become confluent and more or less massive we can find few signs except those of a fine bronchitis. Because of this bronchitis with tenacious mucus in the finer bronchioles, unaffected lung vesicles about the bronchopneumonic patches may be put in a state of atelectasis or high tension and, therefore, either apparently extending the consolidated area, enabling us to obtain a dull note, or overshadowing the bronchopneumonic patch, giving a hyperresonant note. Aside from these slight percussion changes in nonconfluent bronchopneumonia we have little to expect in the way of physical signs except those of a bronchitis. As far as bronchial breathing is concerned it is most frequently absent for the very reasons I have explained that the patches are usually noncommunicating with a sufficiently sized bronchus, or have reached the hilum of the lung.

The physical signs of resolution in lobar pneumonia in children are somewhat different from those in adults. As a rule, resolution in adults takes place *en masse*, a quick liquefaction of the consolidated area and the presence of the characteristic râles *redux*. In children the same thing may occur, but just as often the resolution is a slow process extending from three to seven days, the percussion note and bronchial breathing if present slowly diminishing in pitch until normal vesicular sounds are heard. Here, too, râles play an unimportant rôle, for frequently a child will go through the resolution stage with very few râles or none at all.

Z. F., six years old, entered the hospital with a right lower lobar pneumonia. Temperature receded by lysis, but during the entire course of the disease scarcely a râle was to be heard. In other words, aside from the critical descent of the temperature, the physical signs may remain unchanged, but if the descent of temperature is gradual we have no means of telling from the physical signs alone whether the patient has entered the crisis or not. Another variation from the adult I have noticed is that after complete resolution has taken place in lobar pneumonia without any demonstrable concomitant pleurisy, there often persists a certain degree of dullness which lasts for a varying time and which may be wrongly interpreted as of some pathological significance, as I shall point out later.

The great bugbear of pneumonia in children is

the complication of fluid, either serous or purulent, usually the latter. According to our textbooks with the description of the so-called classical signs nothing should be simpler than a diagnosis of empyema. Aside from the falsity of some of these so-called cardinal symptoms, I know of no more perplexing situation than a diagnosis of empyema, and often even in spite of radiographic examination, an exploratory puncture must be made to settle the question, and that even is often not conclusive.

Patient, M. B., a boy, nine years old, went through a typical lobar pneumonia of the right lower lobe; crisis occurred at the end of seven days, but physical signs persisted. Despite fourteen negative punctures, negative radiographic findings, and consultations aplenty, it was finally decided that the boy is suffering from tuberculous pneumonia and should be sent away. Having followed the case very closely, I maintained that the child had the physical signs of fluid despite our negative findings. The fifteenth puncture finally revealed pus, and an operation by Dr. R. showed an ordinary empyema, and that not even of the encapsulated type.

PHYSICAL DIAGNOSIS.

The physical diagnosis of empyema should be considered from two angles, first, ordinary empyema with the ordinary amount of fluid, and secondly, the type with considerable fluid of long standing, for both have distinctive symptoms. In the first place it should be remembered that the child's lung is very resilient and that it takes considerable and continuous pressure to compress it. This is of prime importance for, because of this physiological fact, the signs at least of moderate empyema have not the auscultatory note (bronchial breathing) we are taught to believe. Secondly, for the same reason empyema fluid spreads out over the affected side like a sheet on the posterior surface and does not collect underneath the lung to form the so-called spiral line. With this in view we can see why there is little compression of the lung and slight displacement of the abutting organs, especially the heart. Again the upper edge of the empyema fluid has a tendency to form adhesions, making the condition an enclosed sac and abolishing, therefore, the tendency to a change of percussion note with change of position. However, I have noticed that this tendency to fibrin formation shutting off the fluid is absent along the spine, thus giving the fluid a chance, with change of position, to flow into the reflected portion of the pleura along the spine (mediastinum), with a corresponding change of the percussion note. This I have called the "ribbon sign" because its width is about that of ordinary baby ribbon. I have been able to demonstrate this in about ten cases, but the number is far too few to be of positive value. I believe, however, from the experience already obtained, that the sign will be of value in recent cases of empyema, but in old standing cases with fibrin formation even along the inner edge of the fluid it will not aid us.

In the ordinary type of empyema the percussion note is of prime importance. The note is dull but more often flat, and the flat note in itself is suspicious of fluid. Unless we are dealing with a localized encapsulated or intralobar empyema a dull

note becoming progressively deeper as we reach the base is always suspicious in postpneumonic conditions. If the pneumonia has been thoroughly resolved, the auscultatory note, though somewhat diminished in intensity, will be vesicular in type or only a slight variation from the normal in pitch. We should not expect bronchial breathing, as the textbooks tell us, for the fluid overlies the lung and the lung is too resilient to be compressed in order to obtain the bronchial breathing. For the pneumonic process having resolved we will need a compressed or nearly compressed lung to obtain the uniform medium for the transmission of the bronchial breathing, as I have explained above. For the same reason we do not get a displaced heart or one so slightly displaced that for ordinary percussion it would be difficult to appreciate. Therefore a dull or flat note following an otherwise frank lobar pneumonia with no or but slight vesicular changes, with little or no displacement of the heart, and with a possible ribbon sign, is justifiably a procedure for chest puncture.

EMPHYEMA WITH FLUID

In types of empyema with considerable fluid, or in those of long standing with distinct fibrin formation, along the edges of the fluid and where the lung is finally compressed, the signs are all those of a frank lobar pneumonia with the exception that in this type the heart is usually displaced. Here we have the dull or flat note, bronchial breathing, bronchial voice, etc., but here too we are assisted by a little pathological anomaly which is frequently forgotten. This was pointed out to us by the late Dr. Hodenpyl, and consists of the fact that the very apex of the lung is as a rule uninvolved in lobar pneumonia, and when a dull or flat note is present there we are dealing with some other condition, such as bronchopneumonia, tuberculosis, or with a compressed lung, so that with a previous history of a lobar pneumonia, with signs still simulating a lobar pneumonia, a dull or flat apex displaced heart, we can only diagnose empyema but an empyema of long standing or of considerable fluid.

In differential diagnosis between empyema and other conditions we have to consider the possibility of bronchopneumonia of lower lobe of more or less massive involvement where bronchial breathing was absent, or even the possibility of a lobar pneumonia where the consolidated area about the hilum has resolved more quickly than the rest of the affected lung and eliminating the pure bronchial breathing. Under such conditions the previous history with the physical signs will be of great assistance.

In conclusion, let me say that the diagnosis of either pneumonia or empyema is as a rule not difficult. It is only necessary to unlearn some of the false teachings of our textbooks and to remember that to obtain bronchial breathing we must have a uniform consolidated area extending to the hilum of the lung or in communication with a bronchus, and that the apparent variation in the physical signs results from the failure of the original tracheal breathing to reach a uniform consolidated area and be transmitted unchanged.

1323 MADISON AVENUE.

A NEW SITE FOR SMALLPOX VACCINATION.

BY I. H. GOLDBERGER, M. D.,
New York.

The ugly looking, hideous and disfiguring scars that result from vaccinations against smallpox prompted me, many years ago, to discontinue the use of the outer side of the arm as a site for the inoculation against this disease. Others, too, realizing that visible scars on the outer side of the arm were objectionable esthetically, especially in girls and women, found that by vaccinating on the lower extremity (thigh, calf, etc.) the objection was partially overcome. The selection of this latter site overcomes, partially, the objection to the visible scar, but, on the other hand, in infants the danger of local infections resulting from wet and soiled diapers is frequent and serious enough to make the lower extremity objectionable, also as a routine site for vaccinations. Then, too, infants and young children are in the habit of being bathed daily, and if they are vaccinated on the lower extremity, this hygienic measure has to be interrupted for at least a period of fourteen to twenty-one days. This feature alone, aside from the possibility of local infections, contraindicates the selection of the lower extremity as a routine site for vaccinations.

For the past seven years I have used the inner and back side of the arm as the ideal site for vaccination against smallpox. In this manner I have overcome the objection against a visible scar. I have vaccinated over five hundred children, and in spite of the fact that the vaccination was made near the lymphatics of the arm, in not a single case did enlarged glands develop in the axillæ. Possibly this has been because the vaccinations have been free from secondary infections and because the vaccination is not performed over muscle fibres, the frequent contractions of which are apt to cause irritation and deep induration involving skin, fascia and groups of muscles. Vaccinating over the loose, fleshy portion of the arm, not directly over bone or muscle, has resulted in less inflammation, induration and infection than that which follows vaccinations over muscle and bone areas.

The vaccination scars in my cases are so small and so superficial that in a hurried examination of the arm the scar is apt to be overlooked entirely. This fact was emphasized recently when, during a survey of the public schools of the City of New York by medical inspectors of the Department of Health, many of my little patients were informed that they would have to be vaccinated because, on baring the arm, the scar was overlooked.

The method I employ is as follows: After the arm has been properly cleansed, the forearm is flexed at right angles to the arm and the vaccine is applied below a line midway between the internal condyle of the humerus and the anterior axillary line. A Von Pirquet platinum borer is turned once or twice through the vaccine virus. The virus is permitted to dry thoroughly before placing over the abrasion a sterile pad of gauze, held in place by two wide strips of adhesive plaster.

In my opinion, the inner and back side of the

arm is the ideal location for the inoculation of smallpox virus, for the following reasons:

1. It leaves no visible scar.
2. It does not keep children from having their daily tub bath while the vaccination is passing through its various stages.
3. There is little or no exposure to infection from outside sources of infection.
4. It minimizes possibilities of trauma.
5. There are no infiltrations, extensive indurations, sloughings, or extensive scars.

2562 GRAND CONCOURSE.

Public School Clinics in Connection with State School for the Feeble-minded.—Edith E. Woodhill (*Mental Hygiene*, October, 1920) presents a report of the public school clinics established in Massachusetts, in connection with the weekly outpatient clinics at the Massachusetts School for the Feeble-minded, at Waverly. The cases seen at the clinics are mostly children of school age, without special character defect, selected for examination because of backwardness in the grades or truancy, while a large number of those presented at the institution clinics are borderline cases that have become problems on account of social or moral delinquencies. The organization and method of conducting these school clinics are similar to those used at the clinic at Waverly, and the methods of diagnosis are the same. The staff of examiners, consisting of a psychiatrist, a psychologist, a teacher, and a school nurse, visits the various schools monthly. These school clinics benefit the child by helping the teacher to understand the mentality of the feeble-minded pupil and the kind of training needed. They serve the school by selecting children for special classes and taking out feeble-minded children who are incapable of making more progress. They serve the community by advising and instructing parents as to home care and supervision, and by helping to take out of the community the feeble-minded who need institution protection and training and who may become a menace to the community. With the exception of a few idiots, all feeble-minded children pass the public schools at some time. If systematic examination of all the retarded children in the public schools could be made, in time there would be a complete registration and census of all the feeble-minded.

Massachusetts has passed a law requiring a mental examination of all children three years retarded. Partly on this account, the need for more school clinics has become so pressing that the work has been broadened and a traveling clinic is now being organized by the Department of Mental Diseases. A staff of experienced examiners will spend their entire time in this work. They will visit various sections of the state, in turn, making surveys of the schools in these sections. This is part of a constructive program for better care of the feeble-minded of the entire state. The benefit of a school clinic is not all on the side of the schools and the community. It is a distinct advantage to an institution staff to come in contact with these school problems and this number of undiagnosed cases.

LATENT SINUSITIS IN CHILDREN.

While infective sinusitis in adults, associated, as is usually the case, with symptoms suggestive of a sinus infection, is commonly suspected and diagnosed, similar conditions arise in children of all ages, but are more prone to remain undiagnosed unless attended with acute or manifest symptoms. Acute sinusitis in infants is rarely localized, but involves the nasal mucosa and the relatively undeveloped sinuses as a whole, usually with symptoms of purulent rhinitis, which may become chronic or subside into a recurring nonpurulent nasal catarrh, or eventuate in recovery; or, on the other hand, the process may finally produce a large area of external suppuration, as described by Skillern. In children between the ages of five or six and fifteen years, a nasal sinus infection is more likely to be localized and occasionally present symptoms such as lead one to suspect nasal sinusitis in adults. A chronic or recurring nasal catarrh in a child is usually attributed correctly to adenoids or to infected tonsils, and, if the symptoms persist after an operation for the removal of the offending organs, the child is sometimes supposed to have a recurrence of enlarged tonsils and adenoids, so that a second, not to say a third, operation is sometimes performed.

The symptoms of chronic latent sinusitis are essentially similar to those of infected tonsils and adenoids, namely, a recurrent nasal catarrh, buccal respiration, catarrhal deafness, aprosexia, mental backwardness and chronic sepsis. In the sphenoidal sinus cases especially, other manifesta-

tions may arise, such as restriction of visual and color fields, as has recently been pointed out by Watson-Williams, but if they are not suspected and sought for, these symptoms will be overlooked. More serious results of chronic sinus infection are those of infecting bacteria passing continually, on the one hand, into the gastrointestinal tract, and sometimes infecting the appendix; on the other hand, the bronchi and lungs may become involved.

A persistent anterior unilateral nasal discharge is highly suggestive of sinus infection, provided the presence of a foreign body can be eliminated. A posterior rhinoscopic view showing pus or mucus in one choana is similarly strong evidence of a nasal sinusitis. It is necessary to make examinations on more than one occasion to eliminate the possibility of an adventitious collection being mistaken for a persistent secretion. According to Watson-Williams, the most useful methods of examination are endorhinoscopy and exploration of the sinuses by the suction syringe. Endorhinoscopy in children over seven years of age is often possible with local anesthesia, but, on the other hand, it is often impossible without general narcosis. When a definite streak of pus is seen coming from the sphenoidal region or from the middle meatus of one or both sides, the evidence of the corresponding sphenoidal or antral cavities being the source of the purulent discharge is almost conclusive.

Exploration of the maxillary antra or sphenoidal sinuses by means of the suction syringe is most valuable, but necessitates a general narcosis in children. Unfortunately, the exploration of the sphenoidal sinuses in young children is far less easy than the exploration of the maxillary antra, and is not so free from risk. Nevertheless, the exploration of the sphenoidal sinuses in children is usually a fairly easy and safe procedure, provided one is accustomed to such investigations in adults.

DRIED MILK AS A FOOD.

When the great number of women in America who do not nurse their babies and who rely on substitutes for mother's milk to feed them is taken into consideration, it is obvious that the greatest care should be taken in the selection of a substitute. Upon the proper rearing of a child during the first few years of life depends largely its future health. Also upon the proper rearing of children in the mass depends the health and therefore the prosperity of a nation. Of course, the most common substitute for an infant's natural food is cow's milk modified

in the manner which the medical attendant, as a rule, prescribes. But even when the most careful attention is paid to obtaining a milk as uncontaminated as possible, there is no certain guarantee that this end is always achieved. Sterilization and pasteurization both have their drawbacks, and therefore any substitute for mother's which possesses the nutritive properties of cow's milk and which, in addition, can be guaranteed as absolutely clean and free from hurtful germs, would be hailed with acclamation by all those who have the health of the people at heart. By some it is asserted that dried milk possesses these attributes, which are absent in many instances from milk transported considerable distances and probably subject to contamination or perhaps infection before it is used as a food.

Among those who have recently spoken in favor of dried milk as a food is Col. R. J. Blackham, M. D., who gave an address on the matter before the British Sanitary Congress, held in Birmingham in August last. Blackham has had much experience in the use of dried milk in the British army and in civil life, and his conclusions are valuable. His address was somewhat lengthy, as he dealt with the question from all aspects and minutely, so only the outstanding points will be discussed briefly. Fats are no longer in emulsion, but in a condition resembling butter and quite granular. When mixed with water the fat globules are considerably fewer and much larger than in fresh milk. Albumin and globulin are coagulated, but caseinogen is not coagulated. All observers are agreed that the protein content is more digestible than in fresh milk. The milk sugar is unchanged. The ferments are all destroyed, but Lane-Clayton has shown that this loss is of no importance as regards the value of dried milk for hand feeding of infants.

As for the vitamins, according to existing views an essential part of the infant's diet, Blackham points out that until Professor Halliburton found that some vitamins will stand high temperatures, it was generally thought that the milk vitamins were destroyed by the heat used in the process of manufacture. Funk, however, demonstrated the presence of vitamins in dried milk, and showed that there was sufficient of the antiscorbutic substance in boiled milk to supply the needs of infants, although some was destroyed by heating. Leonard Hill goes further, and states that the antiscorbutic food accessory is not destroyed in boiled milk. Blackham draws attention to the fact that confusion seems to have arisen over failure to differentiate the three accessory growth substances all grouped together as vitamins, and goes on to show that fat soluble A is the antirachitic factor and it is present in all animal

fats, but absent from most vegetable oils. It is not affected by heat, and is therefore present in dried milk. Water soluble B is the antineuritic factor. It stands desiccation and is therefore present in dried milk. Water soluble C is the antiscorbutic factor, and here the very crux of the question is reached. Experiments at the Lister Institute show that the antiscorbutic property, which is poor even in fresh cow's milk, is largely diminished in the preparation of dried milk, whereas the results of American investigators—Hess, Fisk, Unger, and others—demonstrate that there is no diminution of this factor, and that they have actually cured cases of scurvy by the use of dried milk. It may be added that Dr. Eric Pritchard, the well known English authority on children's disease, has reported favorably on the use of dried milk as an infant's food, and that Blackham himself states that he has never seen infantile scurvy in a child fed on dried milk. Compared with fresh milk, numerous French and Belgian doctors consider it superior to sterilized cow's milk or even humanized cow's milk. Others regard it as a temporary diet to be given for a short time when other foods disagree.

The following is Blackham's opinion of this product: 1. In dried milk we have a valuable food which has a wide sphere of usefulness, not only in the feeding of infants and invalids, but in domestic and commercial cookery. 2. For use with tea or coffee it cannot be claimed that reconstituted dried milk is likely to be popular, and up to the present it has not been placed on the market at a price sufficiently attractive to induce the public to put up with the difference between the fresh and reconstituted article. 3. For use in the tropics and in places such as Malta, where cow's milk is unobtainable, and goat's milk dangerous, it has a large range of application, and on long voyages it presents many advantages over condensed milk. 4. For military purposes it will probably entirely displace condensed milk in future campaigns. It must be understood that milk should be scrupulously clean at the time of drying, for no process will make dirty milk into clean milk, and also the process should be carried on under the best sanitary conditions.

It seems that dried milk may be used to advantage as an infant's food mainly, perhaps, on account of its greater digestibility. It is difficult, often impossible, to so modify fresh cow's milk as to render it digestible to some infants. This is certainly a point in favor of dried milk. As for the other advantages claimed for this product as an infant's food, it may be said that while a good case has been made out for it, no decided verdict can be given. It must be tested further and on a wider scale.

MEN OF SCIENCE IN RUSSIA.

From time to time news filters through from Russia. Hysterical observers have given us their impressions and created a sentiment among the reading public. Countless reports, unauthentic and biased, have contributed to this feeling. We have come to believe that Russia is a savage country, inhabited by a barbarous horde bent on the extermination of themselves and all others with whom they may come in contact. Nothing is further from truth. The Russians are a peaceful, kindly people, and their men of culture have done much to enrich the world of science. At present the Russian people are suffering from privation and hunger. Their transport system has broken down. At best the country was not in a state of high development from the industrial point of view, and it is easy to see how seven years of warfare and an internal upheaval would cause the breakdown. But it is not our purpose to discuss the reasons. We shall only consider some of the actual conditions as reported by Wells, Brailsford, Lansbury, and other unbiased observers, and shall consider these conditions only as they pertain to the medical and scientific field, with perhaps a word of inquiry in regard to Red Cross activities.

First of all, let us consider an editorial in *The Freeman* of November 24, 1920, which emphasizes the horrible situation among men of science, including the medical profession in Russia. The following statement and appeal is made:

"Science is universal, like art, music, literature, or any other purely spiritual activity of mankind. There is no such thing, except for pure convenience of designation, as Russian science or American science; there is only science. The obstacles put by political government against the progress of science in Russia is primarily not a crime against Russia but against science; and it seems to us that men of science in the United States should not be backward about so declaring it. By all means supply the Russians with the literature they need; but let our men of science get out a manifesto, saying what they think about the unconscionable effrontery of the United States Government in the premises, and why they think it. That is what would help more than anything to set people thinking about the rightful place of science in the world."

This statement is made in response to the report presented by H. G. Wells, of which the following is an extract:

"If St. Petersburg starves this winter, the House of Science, unless meantime some special effort is made on its behalf, will starve too. But these scientific men said very little to me about the possibility of sending them supplies. The House of Literature and Art talked a little of want and miseries, but not the scientific men. What they

were keen about was the possibility of getting scientific publications. They value knowledge more than bread. Upon that matter I hope I may be of some help to them. I got them to form a committee to make me out a list of all books and publications of which they stood in need, and I have brought this list back to the Secretary of the Royal Society of London, which had already been stirring in this matter. Funds will be needed, three or four thousand pounds perhaps—the address of the Secretary of the Royal Society is Burlington House, W.—but assent of the Bolshevik Government and our own to this mental provisioning of Russia has been secured, and in a little time I hope the first parcels of books will be going through to these men who have been cut off for so long from the general mental life of the world."

As seen from the foregoing, steps have been taken by the British Government to feed, mentally, these men of science who are laboring for the good of all mankind. By the progress they make their results will one day be of service to us; it will save lives—our own, perhaps. So it behooves us, from a purely selfish point of view, to do all we can to enable them to continue their labors. We surely should not allow them to be segregated from the rest of the world. We should make an effort to get in touch with them; find out what they are doing, and supply their immediate needs—books, periodicals, and supplies to carry on their work. Perhaps our readers will have some suggestions to offer in this matter. We will welcome any that you may send.

Now a word in regard to the activities of the Red Cross. Here again we cannot do better than to quote George Lansbury (*What I Saw in Russia*, Boni and Liveright): ". . . for instance, Allied soldiers, in common with Russian, who have fallen into the hands of the Soviet Government, have had to suffer for months from neglected wounds, and undergo major operations without anesthetics because there were none in the country. Furthermore, without medical and sanitary supplies, diseases have become endemic in Russia, the public health of the entire nation being in jeopardy, and tens of thousands of preventable deaths occurring."

The following is taken from the introduction to Lansbury's book:

"Mr. Lansbury raises a question concerning the Red Cross. As an international organization, founded to administer relief and afford medical aid impartially wherever its services can be utilized, it has been supported by voluntary contributions from the people of the whole world. It is non-national, nonpolitical, and purely humanitarian in its origin, its organization and profession. But according to Lansbury it has given all aid to the Army Medical Corps in Poland; it has refused to give any aid to Russia."

As medical men we are not interested in politics. Our business is to prevent suffering and not to inquire into what form of government suffering men and women are obliged to live under. Here again we ask our readers to express themselves freely by writing to the editor of the *NEW YORK MEDICAL JOURNAL*, stating what they think should be done in the matter.

PHYSICIAN AUTHORS: DR. BERNARD
DE MANDEVILLE

History was repeating itself when, a few years ago, a flurry of interest was created by discovery of the fact that Joseph Conrad's incomparable sea stories were the work of a man who had had to learn the English language after he had grown up. That a man should attain such rare mastery of style and expression in English under such conditions was indeed unusual, but not unprecedented. Something over two hundred years ago Dr. Bernard de Mandeville, a Dutch physician, went to London when he was twenty-one years old to learn English. In a few years he was talking it so well that Londoners who did not know him refused to believe he was a foreigner. Moreover, in a few years he was writing English with the brilliancy of a genius. Dr. de Mandeville was born about 1670 at Dordrecht (Dort), Holland, where his father practised as a physician. He went to London shortly after his graduation from the University of Leyden on March 30, 1691, intending to remain there only a year or two. Instead, he spent the rest of his days there and became the most talked of writer in England. He amazed all men of learning by the boldness of his thought and the richness of his literary style. His *Fable of The Bees* was the literary sensation of the hour and became the storm centre of a controversy that was about as furious as any rumpus of its kind that ever raged in merrie England.

This controversy arose over the audacious doctrines that de Mandeville propounded with such vigor and lucidity. The moot point in *The Fable of The Bees* was that individual virtues are detrimental to the welfare of the state in its commercial and intellectual progress and that private vices are public benefits. This hypothesis at once set in motion a flood of attack and defense. Some said it was truth and others said it was twaddle. In the main, however, British intellectuals stigmatized this bizarre philosophy as false, cynical and degrading. The matter even reached the stage of a grand jury investigation, but nothing much ever came of that except that it stimulated de Mandeville, his supporters and his opponents, to fresh

onslaughts of debate. The jury investigation hinged largely on the charge that de Mandeville's book was oversalacious, and it must be admitted that even for that free-spoken day and age it was, to say the least, a trifle immodest and gross, particularly in those erotic stanzas wherein the genial Dutch doctor sought to fortify his paradoxical arguments by examples.

The *Fable of The Bees* was a satire in the Hudibrastic vein showing a society possessed of all the virtues and devoid of all vices falling into apathy and utterly paralyzed. It was a humdrum, sluggish world, this supervirtuous world that de Mandeville depicted—stagnant from lack of luxuries, miserable from absence of self-love and indulgence. In such a world, he contended, civilization marks time, comes to a standstill because there is nothing to stimulate society into action and progress, to arouse inventive ambition and keep up the proper circulation of capital. In teaching that men who restrain their selfish appetites and sacrifice their own interests for the public good are fools and dupes, de Mandeville anticipated a good part of the teachings of Nietzsche, the self-styled immoralist, who contended that all the conventional morality and traditional ethics of the human race are absurd.

As Chamber's *Encyclopedia of English Literature* points out, de Mandeville was at his best and nearer to modern views in his account of the origin of modern society. There is, in fact, a lot of sound reasoning in de Mandeville's fable outside his main thesis concerning virtue and vice. Contemporaries who attacked him condemned him throughout, but as has been pointed out by several critics in more recent times, it is mere prejudice to deny that he had considerable philosophic insight. Not all of his ideas were buncombe. Samuel Johnson says "de Mandeville opened my views into real life very much" and Macaulay was exceptionally loud in his praise of the ability of de Mandeville to trace the motives of human actions. Other defenders of de Mandeville point out that his antimoral speculations were not written with an immoral object but were rather the outcome of a playful desire to shock and divert his contemporaries. In one respect it may be said that de Mandeville was somewhat like George Bernard Shaw. It was well nigh impossible to tell at times when he was in jest and when in earnest. It is reasonable to suppose, however, that he more than half believed most of the things he advocated. There was, for instance, never any doubt as to his attitude toward free schools for the poor. He was absolutely against them. They were his pet aversion and he never tired of railing at them. When the first was founded in 1699 he con-

tended that if parents were too poor to afford their children the elements of learning the children should remain ignorant and the money could better be spent on the higher and professional education.

De Mandeville's first work was *Typhoon: A Burlesque Poem*, followed, in 1704, by *Aesop Dressed, or Fables in Familiar Verse*. Then came *The Grumbling Hive, or Knaves Turned Honest*. This was enlarged into *The Fable of The Bees* in 1714, and still further enlarged in 1723, at which time the Middlesex jury investigated it as a nuisance. There were two other editions of it during his lifetime. His other works include *A Treatise on the Hypochondriac and Hysteric Passions*, highly commended by Johnson; *The Planter's Charity* and *The Virgin Unmasked*, a work in which the coarser side of his nature is prominent; *Free Thoughts on Religion*, equally unpleasant in tone; *The Origin of Honor and Usefulness of Christianity in War*, and some disquisitions on the social evil.

De Mandeville practised medicine in London until his death, but his practice was, much of the time, secondary to his writing, from which he gained a large income. He was, incidentally, one of the first of the tribe of press agents. Even in those days the drys were active and King Gambrinus felt the need of an able pleader before the bar of public opinion. Dr. de Mandeville was that pleader and was well remunerated for his work by the brewery interests of London. The genial old doctor spent much of his time in their tap rooms. It was in one of these that Benjamin Franklin met him and found him to be "a most entertaining, facetious companion."

News Items.

Anthrax.—During October, 1920, one case of anthrax was reported in Washington, one in Maine, and two in Pennsylvania. During November two cases were reported in Massachusetts. During the week ending November 20, 1920, one case was reported in Lowell, Mass., and one in Bloomfield, N. J.

Hospital for Women to Be Opened in Pittsburgh.—The Elizabeth Steel Magee Hospital will be opened in Pittsburgh early next year as a general hospital for women. The construction and endowment of this hospital were made possible by a bequest of \$3,000,000 by the late Christopher Magee.

Borough Park Residents Object to Hospital.—An injunction has been asked by a number of residents of the Borough Park section of Brooklyn to restrain Dr. Philip Mininberg from building and maintaining a maternity hospital on his property at Forty-fifth street and Fifteenth avenue. They assert that the hospital is undesirable and would lower property values.

A Nutrition Clinic in the Far West.—The Anti-tuberculosis League of King County, Wash., has established a nutrition clinic in Seattle, which is said to be the first of its kind established in the Far West by an antituberculosis organization.

National Tuberculosis Association.—The seventeenth annual meeting of this association will be held in New York, June 13th to 17th, with headquarters at the Waldorf-Astoria. Mr. Homer Folks is chairman of the committee of arrangements.

New York Neurological Society.—A stated meeting of the society will be held on Tuesday, January 4th. Dr. E. David Friedman will present a case of Dyspituitarism with Hypertension, and papers will be read by Dr. Charles Rosenheck, Dr. George H. Kirby, Dr. L. Pierce Clark, and Dr. Philip R. Lehrman.

Diphtheria in New York.—During the four weeks beginning October 23rd and ending November 20th, 1,354 cases of diphtheria were reported to the Department of Health of the City of New York, with sixty-seven deaths. The average number of cases and deaths during the corresponding period of the five preceding years was 855 cases and sixty deaths.

Brooklyn M. E. Hospital Plans Maternity Hospital.—On December 15th, the thirty-third anniversary of the Methodist Episcopal Hospital, of Brooklyn, announcement was made that the establishment of a Maternity Hospital was being seriously considered by the board of managers, and that an anonymous gift of \$30,000 had been received to launch the enterprise, which it is estimated will cost \$200,000. No immediate action will be taken, but a committee of five has been appointed to study modern methods of construction and equipment of maternity hospitals.

St. Louis University Establishes a Department of Pharmacology.—Announcement has been made by the president of St. Louis University that Dr. John Auer, pharmacologist of the Rockefeller Institute of New York, has been secured to institute and conduct a department of pharmacology in the College of Medicine of the University. It is the hope of the faculty of the university to be able, through the Centennial Endowment Fund of \$3,000,000 now being raised by the friends and alumni of the institution, to establish complete departments in every line of medical instruction and research.

Vital Statistics in New York.—During the week ending December 11th there were 1,144 deaths from all causes reported to the Department of Health of the City of New York, corresponding to an annual death rate of 9.72 in a thousand of population, compared with a rate of 11.18 for the corresponding period in 1919. Of these deaths, 44 were due to acute infectious diseases, 86 to pulmonary tuberculosis, 9 to influenza, 64 to lobar pneumonia, 56 to bronchopneumonia, and 66 were violent deaths. The violent deaths do not include suicides, of which there were 18. The deaths under one year numbered 160; under five years, 221; between five and sixty-five, 659; sixty-five years and over, 264. The births during the week numbered 2,302; stillbirths, 123, and marriages, 1,368.

American Association for the Advancement of Science.—The seventy-third meeting of the American Association for the Advancement of Science will be held in Chicago, December 27th to January 1st, under the presidency of Dr. L. O. Howard, of Washington, D. C. The retiring president, Dr. Simon Flexner, of New York, will deliver an address on Twenty-five Years of Bacteriological Research.

Personal.—Dr. Edward A. Park, associate professor of pediatrics at Johns Hopkins University, has accepted the chair of pediatrics in the Yale Medical School.

Surgeon General Ireland, of the United States Army, has been awarded the silver medal of the Serbian Red Cross.

Dr. E. Ellis Owen has been appointed health officer of Louisville, Ky., to succeed Dr. Thomas H. Baker, deceased.

Rockefeller Foundation to Aid Medical Schools of Central Europe.—To assist medical schools in Central Europe, the Rockefeller Foundation announces a cooperative program covering the following points: 1. Aid in the rehabilitation of scientific equipment for medical teaching and research. 2. Aid in furnishing medical journals to universities throughout Europe. 3. An invitation to the authorities of Belgrade University Medical School to study medical education in America and England, as guests of the Foundation. Colonel F. F. Russell, who has been in Prague since August, serving as technical adviser in public health laboratory organization to the Czech Ministry of Hygiene, will arrange the details of the plan.

Brooklyn Cardiological Society.—The next meeting of the Brooklyn Cardiological Society will be held Monday evening, January 31st, at 8:30 o'clock, at the office of the president, Dr. William J. Cruikshank, 102 Fort Greene Place, Brooklyn. The paper of the evening will be read by Dr. Harold E. B. Pardee, of Manhattan, on the Field of Usefulness of Polygraph and Electrocardiograph Diagnosis of Cardiac Disease.

In a previous item concerning this society, published in our December 11th issue, page 954, the name of Dr. Richard C. Cabot, of Boston, was inadvertently omitted from the list of honorary members of this society, and through a typographical error the name of one of the speakers, the Rev. Dr. Kraeling, was spelled incorrectly.

Resolutions on the Death of Dr. Hyman Climenko.—Resolutions on the death of Dr. Hyman Climenko, which occurred in New York on December 16th, were adopted by the Neurological Staff of Mount Sinai Hospital, as follows:

WHEREAS, The untimely death of Dr. Hyman Climenko has deprived the Neurological Staff of Mount Sinai Hospital of a beloved colleague; and

WHEREAS, We, his associates, wish to recognize his great attainments as a true physician, his nobility of character, the simplicity of his life, his devotion to ethical conduct and his love of social justice; and

WHEREAS, We, his intimate friends, feel keenly the irreplaceable loss which his death has caused, therefore be it

Resolved, That we express our sympathy with his widow in her sorrow over the loss of so devoted a husband, and with the children who have been prematurely deprived of the tender guidance of their father.

Meetings of Local Medical Societies.—The following medical societies will meet in New York during the coming week:

TUESDAY, December 28th.—New York Academy of Medicine (Section in Obstetrics and Gynecology); New York Dermatological Society; New York Medical Union; Metropolitan Society of New York City (annual); New York Psychoanalytic Society; Riverside Practitioners' Society; Therapeutic Club; Valentine Mott Society; Washington Heights Medical Society; Woman's Hospital Society; Clinical Society of the Hospital and Dispensary for Deformities and Joint Diseases.

FRIDAY, December 31st.—Hospital Graduates' Club of Brooklyn.

Legal Status of the Public Health Service.—Surgeon General Hugh S. Cumming, of the United States Public Health Service, in his annual report, said that in his opinion it was of the utmost importance that the legal status of the Public Health Service in its war risk work should be firmly established by placing an administrative head over the three major agencies involved, namely, the War Risk Insurance Bureau, the Federal Board for Vocational Education, and the Public Health Service, and that these three bureaus should operate thereunder as coordinate and independent bureaus in close cooperation.

Died.

BACKMAN.—In Philadelphia, Pa., on Monday, December 6th, Dr. Edward F. Backman, aged sixty years.

BISHOP.—In Edensburg, Pa., on Saturday, November 27th, Dr. William T. Bishop, aged eighty years.

BROWN.—In Boston, Mass., on Thursday, December 9th, Dr. Louis Sumner Brown.

BUECHNER.—In Youngstown, Ohio, on Wednesday, December 15th, Dr. William H. Buechner, aged fifty-six years.

CLIMENKO.—In New York City, on Thursday, December 16th, Dr. Hyman Climenko, aged forty-five years.

CORNWELL.—In Buffalo, N. Y., on Saturday, November 27th, Dr. Benjamin W. Cornwell, aged fifty-eight years.

DAVIS.—In Ellicott City, Md., on Tuesday, December 14th, Dr. John W. Davis.

DOUGLASS.—In Philadelphia, Pa., on Tuesday, December 7th, Dr. John S. Douglass, of Cape May Court House, N. J., aged forty-five years.

KINSMAN.—In Saginaw, Mich., on Sunday, December 5th, Dr. Enos C. Kinsman, aged fifty-six years.

MARTIN.—In Baltimore, Md., on Wednesday, December 8th, Dr. Frank Martin, aged fifty-eight years.

MERRILL.—In Dozier, Ala., on Sunday, November 28th, Dr. J. P. Merrill, aged forty-six years.

MILLER.—In Somers, Mont., on Tuesday, November 30th, Dr. Charles E. Miller, aged seventy-seven years.

MILLETT.—In Belfast, Me., on Wednesday, November 16th, Dr. Adelbert Millett, aged sixty-two years.

PADIERA.—In Rochester, N. Y., on Thursday, December 2nd, Dr. G. W. Padiera, aged eighty-three years.

PHILIPS.—In Linesville, Pa., on Friday, December 3rd, Dr. David A. Philips, aged eighty years.

PLUMMER.—In Boston, Mass., on Thursday, December 2nd, Dr. Frank J. Plummer, of Malden, Mass., aged sixty-six years.

PYLES.—In Washington, D. C., on Sunday, December 5th, Dr. Richard Pyles, aged fifty-eight years.

SMITH.—In New York City, on Thursday, December 16th, Dr. Edwin Fayette Smith.

STEWART.—In Memphis, Tenn., on Monday, December 6th, Dr. C. M. Stewart, aged eighty-nine years.

WEED.—In Cleveland, Ohio, on Saturday, November 30th, Dr. Theodore A. Weed, aged sixty-four years.

WOEHNERT.—In Buffalo, N. Y., on Friday, December 10th, Dr. Albert E. Woehnert, aged fifty-two years.

Book Reviews

OCCUPATIONAL SKIN DISEASES.

Occupational Affections of the Skin. Their Prevention and Treatment. With an Account of the Trade Processes and Agents Which Give Rise to Them. By R. PROSSER WHITE, M.D., Ed., M.R.C.S., Lond. Life Vice-President, Dermatologist, Senior Physician and Ethetic Officer, Royal Edward Infirmary, Wigan; Vice-President Association Factory Surgeons, etc. Second Edition. With Twenty-four Plates (Comprising Twenty-eight Figures). New York: Paul B. Hoeber, 1920. Pp. xiv-360.

There was a tremendous outcry during the war whenever it was found that the men were running some unnecessary risk or living under bad, preventable circumstances, the outcry promptly bringing about a change, particularly when human lives became costly and scarce.

And that many millioned army which each morning sets forth in the dawning! It must gain a livelihood for itself, also comfort and luxury for non-combatants. It has to face, and is facing, hundreds of foes, silent, hidden, unsuspected, lurking even in flowers and trees, attendant on every new invention, every discovery, from a new dye for a lady's scarf to the potent, little known radium.

So great the risks, so woeful their wreckage, that scientists for philanthropy's sake, and trade economists for very shame, have set to work and found many evils preventable and all amenable to early treatment. Everyone should read the results, for, in reading, they would shoulder the responsibility of knowledge and, if honest, would not enjoy their food, clothes, books, carriages, and luxuries until the preventable had become prevented.

Mere reading of the index of this book will rouse one to activity. Foes there are to electric workers, to the washer woman, the fish packer, the photographer, the spinner, the dyer, the woodworker, the tanner, the chemist, the farmer, and danger is not over when the various things pass from gross manufacture to individual workers using additional things in finishing. Dermatitis venenata—what is that? The chapters so headed describe the skin diseases which may arise from some plant, dye or drug with which the worker comes in contact. The lacquer tree of Japan (*Rhus vernicifera*) is a bad enemy, so is the tomato and the beautiful *primula obconica*, which affects the skin of those who gather it for florists. Gardeners also suffer from handling the Virginia creeper, which causes great skin irritation, and the *Vanilla plantifolia*, so much used in flavoring, is a source of skin disease to the cleansers and packers of the pods, and to those who put up the packets of powder. Even the aircraft factory has revealed two enemies. The splinters of the silver spruce are one, producing small, gradually enlarging blebs, and the Indian satinwood, even in the transporting, gives rise to a kind of erysipelas among the dockers.

Most people have heard of the dangers which skin dressers and those who work on wool and hair are liable; butchers also contract an acute febrile pemphigus through handling diseased animal tissues, which often ends fatally. Then, too, the streptococcus is lurking in the sausage skins which employment of cleansing is generally done by

women. From tree top to ocean depths dangers lurk. A parasite of the sponge, much dreaded by divers, is the *Sargasia rosea*. Blisters form all over the part stung; multiple abscesses and skin sloughing follows.

Not only workers, as generally understood, are in danger. There is the *Verruca necrogenica*, or anatomical tubercle, found most frequently in the human cadaver, which attacks doctors, veterinarians, bacteriologists, postmortem attendants, nurses, and undertakers.

The list of enemies is enough to scare any fighter, yet, curiously, until recently the workers regarded them as a necessary accompaniment and, disabled, received no compensation. The great difficulty now is to make employers fully alive to the crime of nonprevention and the employees to the necessity of it. Rich women who wept as the troops marched warwards cannot yet pocket their handkerchiefs if their sorrow was sincere, for every morning the great army of toil stained, toil stunted, patient people go marching out to meet invisible foes, and women's tears and women's protests would speedily stay the hardships and force Dr. Prosser White to bring out a third edition to report jubilant victories.

PHYSICAL CULTURE.

Massage and Exercises Combined. A Permanent Physical Culture Course for Men, Women, and Children. Health Giving, Vitalizing, Prophylactic, Beautifying. A New System of the Characteristic Essentials of Gymnastic and Indian Yogis Concentration Exercises Combined with Scientific Massage Movements. With Eighty-six Illustrations and Deep Breathing Exercises. By ALBRECHT JENSEN, Formerly in Charge of Medical Massage Clinics at Polyclinic Hospital and Other Hospitals, New York. New York: Published by the Author, 1920. Pp. xiii-93.

Many writers on nervous diseases are averse to massage for some patients because they are already selfconcentrated and lazy, and massage, being an exterior aid, makes no demands on the patient in the way of exertion. Many hysterics will have a thorough course of treatment and, though acknowledging an improvement to themselves, will tell others it hasn't helped them much as it was not suited to their particular malady. Such are really not worth the trouble of massaging, but if they can be coaxed or compelled to do the exercises themselves the feeling of dependence is removed and introduces other good habits, useful to the patient, and a blessing to the tired family. The great thing with all patients is to induce them to persevere when the novelty is over. Who does not know the dusty chart of exercises nailed up in the bathroom, now hardly looked at, or the book with curled corners and full of passages scored approbatively with whose contents we bored our friends until we ourselves were bored and the book became hidden under piles of others. The exercises detailed in this book are easy to follow because shown in good illustrations. The chapter on special and general deep breathing exercises gives easily followed directions. How faulty our breathing we disrealize until we try to do it properly. When the Maori football team came over to play against England,

the English were easily beaten. Asking a Maori how this came about, he said: "You English, no air inside; we breathe all over from mouth to toes." That was at a time when soldiers were thought beautiful when the chest protruded and was rigid, the shoulders well set back. Whereas the natural, healthy man has his chest walls relaxed, his shoulders fall comfortably, yet he does not stoop. The humped up shoulder is indicative of faulty breathing, of tension, of selfconsciousness.

Eastern cities abound with masseurs, but they live in bathing places, not in parlors; they are stalwart negroes who, after the steam bath, seize you and pound you and knuckelize you with strong oils until you expect to be carried away defunct; instead, you are lithe and happy and long for the next time. This book of selfmassage will keep many from the foolish ladies and inept men who open massage establishments without any knowledge of anatomy and less of disease. It will give a pleasant feeling of cooperation even when the massage is not selfdone; diseased conditions are improved, even chronic ones.

EVOLUTION OF THE DRAGON.

The Evolution of the Dragon. By G. ELLIOT SMITH, M.A., M.D., F.R.S. Illustrated. London, New York, Chicago, Bombay, Calcutta, Madras: Longmans, Green and Company, 1919. Pp. xx-234.

The writer of this book is hardly just to its value. He designates it as "little more than a collection of data and tags of comment." One feels this in certain places and accepts the author's apology for it. In much of the book any such criticism is forgotten in interest in its vivid facts. The data it presents have this vividness, for they are the strange facts not of material reality but the products of man's fertile ability for phantasy creation. They are vivid also with Smith's own interest in searching them out and presenting them. Even more are they alive with the keen interpretation with which he views them as expressions of man's basic strivings.

He has been fearless in carrying them back to an expression of the ever active reproductive need. This has always sought varying expression. So there are ample discussions of some of these large features which form great psychic way stations where desires stop, start out again, and again return. The study of the Great Mother, typified in Aphrodite but symbolized over and over again, in part and in whole, is one of these. The Dragon is a picture of the same and of more besides. One could ask for an even deeper penetration of the symbolism, a profounder comprehension of the striving dreams of man.

Then we are confronted with the again raised question of spontaneous arising of all this symbolic matter in different parts of the world, or its diffusion from one cradled origin would fade into insignificance. Migrations preserve and carry forward the past, but everywhere this past meets fertile growths like itself and is reimpregnated by them. Together they form new products, the origins of which can as little exclude one another as either parent can with egotism exclusively assume the production of a child.

MEDICAL LECTURES TO NURSES.

A Course of Lectures on Medicine to Nurses. By HERBERT E. CURFF, M.D., F.R.C.S., Principal Medical Officer to the Metropolitan Asylums Board; Late Medical Superintendent, North Eastern Fever Hospital, Tottenham, London. Seventh Edition. With Twenty-nine Illustrations. Philadelphia: P. Blakiston's Son & Co., 1920. Pp. vii-257.

The tired nurse with ragged nerves and aching feet does not always respond cheerfully to the invitation to improve her mind, but there are some, wearied with routine and hard work, who will resolve to make themselves fit for something better, out of pure desperation. When the lectures are given by a man interested in the nursing world and is a clear expositor, he rarely lacks an audience. To fortify the little knowledge possessed by the nurse of anatomy and pathology, and to prevent discouragement, the author has fully explained enough to launch her safely on the sea of medical knowledge. The fact that a seventh edition has been called for is sufficient recommendation of the teacher. In it a lecture on pulmonary tuberculosis and sanatoria treatment has been added. He deals with many forms of disease not usually given in nursing manuals, having noted the anxiety of the nurse to understand what he is saying to students in his clinical rounds, and knows she often falls into despair when trying to find out for herself in textbooks. The chapter on Children's Diseases is good, as these inarticulate patients who cannot explain their pain often sorely puzzle the nurse. Hemorrhage, too, especially when internal, often makes for alarm. The book is small and pocketable. We are safe in predicting an eighth edition.

A MEDIEVAL ROMANCE.

The Revels of Orsera. A Medieval Romance. By RONALD ROSS. New York: E. P. Dutton & Co., 1920. Pp. vi-393.

With one or two exceptions, doctors as story writers are as big a failure as a layman attempting a surgical treatise. They are so accustomed to condensation in case writing that they cannot put in enough frills and thrills and scenery to expand and beautify stern facts. Their characters are often only animated megaphones. It was therefore with a melancholy sniffiness that the reviewer took up this book, only consoled by the fact that a Scotsman might be dry but would never be foolish. Hope is realized. Curiosity is awakened as the reader travels back to the Swiss mountains in 1495 and encounters Morova Neroni and her deformed son, Zozimo, with his twin sister, the marvelously beautiful Astrella. She, with Count Reichenfel's daughter, Lelita, move the hearts of and influence the Prince of Astra, Trullo, the Count's nephew, Bran, his captain of arms, a crowd of knights, guards, priests, a deformed jester, and a witch. There is an uneasy mystery hanging heavily on the story, for there is a Voice, the supernatural Astrella, the rapidly appearing and disappearing Count Azrimar, who becomes the chosen suitor for Lelita, he winning her by adventure in joust and tourney, and recovering after blows so hard that the author must be supposed to have been attacked by the dime novel germ at an early age, for his career as a doctor could hardly have included such cases.

Irrespective of the fine storm drenched pictures of the mountains, there are good descriptions of the emotions. One is on the weapon of silence, where the witch, Brunde, is being tried:

"What is your name?" thundered the Cardinal again.

"Brunde's eyes remained fixed on vacancy. Only retort of the wretched against the world arrayed in judgment before them—silence! 'What is your condition?'—rags. 'What is your crime?'—misery. 'What is your name?'—no answer.

"The world rises, puts both his fists on the table, and shouts at her. Or he flings himself backward, smiles deprecatingly, and loosens his waistcoat buttons, or his doublet or his tunic, as the case may be. The law, in the shape of policeman, halberdier, or beadle, looks ferociously at her, squints down his red nose or shakes her arm. No answer. The whole court is insulted. The judges turn round their heads like parroquets and look at each other, while their tongues click in their mouths with amazement. Are we, God's vicegerents of justice, to be insulted by you, God forgotten? They leap up and roar at her, they smile at the ceiling, scratching their chins with their pens; they grow apoplectically crimson; they nod their heads gravely seven times; they lift their hands and call Heaven to witness. 'What is your name?'—no answer."

The Revels were begun thirty years ago. In them the author has "tried to analyze character into its constituent elements and to set forth each element by itself in apposition."

But, with the author's permission, we will not try to find his second meaning. Let it be strong enough to strike us or it shall go unheeded. The book is one of great interest right away to the end. Why does he require wearied men, armed only with papercutters, to halt during the reading and dig for his hidden meanings? The story shall be enjoyed for its own sake first, and readers can wait for the solution until some learned psychologist finds out exactly what the author meant and tells us.

SATAN'S DIARY.

Satan's Diary. By LEONID ANDREYEV. Authorized Translation Never Before Published in Any Language. With a Preface by Herman Bernstein. New York: Boni and Liveright, 1920. Pp. xvii-263.

In reading *Satan's Diary* one is strongly tempted to contrast it with some of Andreyev's earlier works—his realistic *Red Laugh*, for instance, one of the most powerful stories that has ever been written on war, or *The Black Maskers*, a play rich in its wealth of symbolisms. But here we have the man in another mood, no longer the weaver of mystic drama, no longer the bold propagandist, flinging aside the curtain on abominable scenes he wished to have abolished from the history of man. He has attempted to combine realism and fantasy, the conflict of Wondergood, American millionaire, and Satan. The workmanship is crude, the fusion has been incomplete, and the result is far from convincing, as a work of art. He has attempted what, under ordinary circumstances, would have turned out a masterly thing from the pen of Andreyev—something akin to his *Judas*—which was a finished

piece of work. Can it be that he was fatigued or that he was unable to polish the product as he would have liked to? Can it be that the bleak Finnish wastes only reflected the barren phases of the Russian upheaval? These questions are difficult to answer. At any rate, admirers of Andreyev will read this, his last book, and wonder where the skill and warmth of the old Andreyev have vanished; they will read and compare the old Andreyev with the new, and they will feel that the new Andreyev had grown old too soon.

MOONS AND MISSIONARIES.

The Crescent Moon. By F. BRETT YOUNG. Third Edition. New York: E. P. Dutton & Co., 1920. Pp. 284.

Africa has meant many things to many men. To Francis Brett Young, author of *The Young Physician*, it is "the land above all others which men of European race have never conquered," a land of lush beauty, of mystery and of a sinister horror, a land where the clerical virtues of the Anglo-Saxon go down to defeat before the untamed things in the swamps. *The Crescent Moon* has all these qualities. It recreates with unflinching fidelity the terror and unwilling fascination with which an unsophisticated English girl finds herself for the first time thrown face to face with the primitive things of the forest. More than that, it is a pitying and ironic study of that temperament which, essentially artistic, expresses itself in religion through the pressure of generations of puritanism and ignorance.

As an adventure story *The Crescent Moon* can give points to many of the current mystery tales. It details the life of Eva Burwarton, a girl from a tiny, shut in English town, who, on the death of her father, goes to Africa with her brother, a young missionary. Their mission is situated on a hillside above the "dark forest" wherein seethes the life, human and subhuman, which is so far outside of their limited experience. James, the evangelical brother, is thus epitomized:

"I suppose in the class from which he came there are any number of young men of this kind, born mystics with a thirst for beauty which might be slaked in any glorious way, yet finds its satisfaction in the only revelation that comes their way in a religion from which even the Reformation has not banished all beauty whatsoever. They find what they seek in religion, in music (such music! . . . but I suppose it's better than nothing), in the ardours of lovemaking; and they go out, the poor, uncultured children that they are, into the 'foreign mission field,' and for sheer want of education and breadth of outlook die there . . . the most glorious, the most pitiful of failures. That, I suppose, is where Christianity comes in. They don't mind being the failures that they are. Oh, yes, James was sufficiently consistent. . . ."

By contrast with their only neighbor, Godovius, a German Jew with a smattering of culture and a whip hand over the ladies, James is sufficiently inadequate, and all through Eva's struggle against the power of Godovius he grows more so. He is consistently drawn. "To him religion was such a simple thing." And in the uprising, fomented by Godovius

and suddenly grown beyond his control, he dies, pitifully and consistently.

It is James's inadequacy that nourishes the friendship between Eva and Hare, the keen and self-reliant refugee whom she finds in the forest one night with a broken arm. Hare is everything that James is not, and the two of them, he and Eva, are drawn together as the web of hostile circumstance tightens about James. The ending to this story, too, is inevitable.

This book should appeal to a divergent public—probably has so appealed since this is the third edition. It contains thrills, color, and an unexpected irony. Above all, it is Africa as seen through several differing temperaments.

ANATOLE FRANCE.

The Bride of Corinth and Other Poems and Plays. By ANATOLE FRANCE. A Translation by WILFRED JACKSON and EMILIE JACKSON. London and New York: John Lane Company, 1920. Pp. xv-285.

The Seven Wives of Bluebeard and Other Marvelous Tales. By ANATOLE FRANCE. A Translation by D. B. STEWART. London and New York: John Lane Company, 1920. Pp. vi-216.

In *The Bride of Corinth* we find France at work on the conflicts which touched him the most deeply. Here we find him contending with restraint in the portrayal of an old struggle, the soul and the heart of woman, and the bivalent pull that is exerted, the old fixations on home and mother, and again expressed by church and a complete heterosexual creative call; neither of these is answered and it is only by the skill of France that the dominant note is not one of black despair. In the end, neither object is attained and we witness the emotional distress which is not allowed to become too profound. The story is worth reading, if only for the skill with which it has been handled.

In the same volume we find *Crainquebille* and *The Man Who Married a Dumb Wife* in addition to a third play. The first two plays have been presented and well appreciated in America, the first in French and the second a satirical farce in English. Crainquebille portrays failure through weakness; weakness on the part of a sympathetic old character and the weakness of a social order which reflects an all too frequent condition in many countries and during many crises. The reactions he shows of the small social group could well be applied to the majority of the hysterical French press of today. Anatole France has made Crainquebille a national character in France. He was aided in this by the masterly interpretation of the character by Lucien Guitry, to whom he has inscribed the play.

* * *

In *The Seven Wives of Bluebeard* we find France in his most clever mood. In this group of charming stories he shows the errors of history and how famous characters, Macbeth, Bluebeard, Jean d'Arc, and many others have been grossly maligned. He attributes these misconceptions to the inaccuracy of various writers and historians. He thinks it just as well that we have his interpretation of these various characters, and it must be acknowledged that his is the more human concept of the lives and doings of these people. If France had the time he

would rewrite all history, mythology, and folklore, and give us a new history, mythology, and folklore, not more nearly accurate but more as he would like to have it, and it seems fairly certain we would appreciate his concepts more than the older ones. His myths are more plausible and less monotonous, for it must be admitted that he has great versatility. These stories should furnish deep pleasure to his readers.

New Publications Received.

[We publish full lists of books received, but we acknowledge no obligation to review them all. Nevertheless, so far as space permits, we review those in which we think our readers are likely to be interested.]

POTTERISM. By ROSE MACAULAY. New York: Boni and Liveright, 1920. Pp. x-227.

REPPRESSED EMOTIONS. By ISADOR H. CORIAT, M.D., New York: Brentano's, 1920. Pp. 213.

WHAT I SAW IN RUSSIA. By GEORGE LANSBURY. New York: Boni and Liveright, 1920. Pp. 172.

THE "WELCOME" PHOTOGRAPHIC EXPOSURE RECORD AND DIARY. London: Burroughs Wellcome & Co., 1921. Pp. 260.

THE NEW DECAMERON. Volume the Second, Containing the Second Day. New York: Robert M. McBride & Co., 1920. Pp. vi-183.

THE SECRET CORPS. A Tale of Intelligence on All Fronts. By CAPTAIN FERDINAND TUOHY. New York: Thomas Seltzer, 1920. Pp. 289.

ELFTES HEFT. Krankheiten des Rückenmarks und der peripherischen Nerven. Von Professor Dr. R. CASSIRER in Berlin. Mit 1 Abbildung. Leipzig: Verlag von Georg Thieme, 1920. Sehntes Helf, Seiten 72. Elftes Heft, Seiten 157.

DIAGNOSTISCHE UND THERAPEUTISCHE IRRTÜMER UND DEREN VERHÜTUNG. Innere Medizin. Herausgegeben von Prof. Dr. J. SCHWALBE, Geh. San.-Rat in Berlin. Zehntes Heft. Krankheiten des Blutes und der Drüsen mit innerer Sekretion. Von Prof. Dr. O. NAEGELI, Direktor der Medizinischen Poliklinik in Zürich. Mit 4 Abbildungen.

DIAGNOSTISCHE UND THERAPEUTISCHE IRRTÜMER UND DEREN VERHÜTUNG. Chirurgie. Herausgegeben von Prof. Dr. J. SCHWALBE, Geh. San.-Rat in Berlin. Erstes Heft. Chirurgie des Thorax und der Brustdrüse. Von Geh. Med.-Rat Prof. Dr. G. LEDDERHOSE in München. Mit 8 Abbildungen. Leipzig: Verlag von Georg Thieme, 1920. Seiten iv-123.

LABORATORY MANUAL OF THE TECHNIC OF BASAL METABOLIC RATE DETERMINATIONS. By WALTER M. BOOTHBY, A. M., M. D. and IRENE SANDIFORD, Ph.D., Section on Clinical Metabolism, the Mayo Clinic, Rochester, Minnesota, and the Mayo Foundation, University of Minnesota. Illustrated. Philadelphia and London: W. B. Saunders Company, 1920. Pp. 117.

CHEMICAL PATHOLOGY. Being a Discussion of General Pathology from the Standpoint of the Chemical Processes Involved. By H. GIDEON WELLS, Ph.D., M.D. Professor of Pathology in the University of Chicago and in Rush Medical College, Chicago; Director of the Otho S. A. Sprague Memorial Institute. Fourth Edition, Revised and Reset. Philadelphia and London: W. B. Saunders Company, 1920. Pp. 695.

PRACTICAL PREVENTIVE MEDICINE. By MARK F. BOYD, M. D., M. S., C. P. H., Professor of Bacteriology and Preventive Medicine in the Medical Department of the University of Texas; Passed Assistant Surgeon (Reserve), U. S. Public Health Service; Formerly Epidemiologist of the Iowa State Board of Health and Associate Professor of Preventive Medicine in the College of Medicine of the University of Iowa, etc. With 135 Illustrations. Philadelphia and London: W. B. Saunders Company, 1920. Pp. 352.

Practical Therapeutics and Preventive Medicine

A Compendium of Treatment and Prophylaxis, Original and Adapted

Childhood the Period for Mental Hygiene.—William A. White (*Mental Hygiene*, April 1920) says that one of the most important issues in mental hygiene is to correlate the sick adult with the knowledge we have that his illness is traceable in its beginnings to his early life. This must be done by a more developed knowledge of the psychology of childhood, which is reflected in the home, in the school, and in the principles and methods of education. Efforts to improve the environment, even with reference to such obvious features as food, clothes, and ordinary sanitation, are not lacking in their general effect upon the mind of the developing child. Recent observations in the devastated countries of Europe have shown how quickly destitution, which takes all the joy out of life, is reflected in the mental makeup of the children. Such problems as the care of the pregnant woman, child labor, sex education, school sanitation, and more specifically the problems of the atypical child and juvenile delinquency, all can be better dealt with in proportion to our increased knowledge of child psychology. Social problems have a direct bearing. Inasmuch as many of the breaks, perhaps most of them, occur in the adolescent or early adult period, it would be of inestimable value if help could be systematically extended to the youth when the symptoms of final disaster are likely to be discoverable.

Malignant Tumors in Childhood.—Malvern B. Clopton (*Journal of the Missouri State Medical Association*, September, 1920) writes that malignant tumors in children are far from rare, and sarcoma is the type of growth almost always encountered in childhood, just as epithelial cancer is the common type in old age. Sarcoma in children often follows a more rapid course than in adult life, and the most malignant growths are those which appear earliest in life, some of these possibly being congenital. Often there is no change from normal good nourishment of the child until metastasis occurs, when the downward course is most rapid. Febrile reaction may mislead the observer into thinking that the mass is due to an infection. No organ is exempt from these new growths, but it is generally considered that the kidney is the seat of sarcoma more often than any other organ. Two types of eye tumors occur in childhood: sarcoma of the iris or choroid, and glioma of the retina. Brain and spinal tumors are not uncommon, the greatest mortality being in gliomata. Sarcoma or mixed celled growths of the testicle are not common, and a few cases are found in the literature of carcinoma and sarcoma of the ovaries. Carcinoma of the small intestine is practically never found in children; when sarcoma occurs it is in the small intestine. Sarcoma of the long bones occurs rather infrequently in childhood. As to treatment, early operation offers the best chance for recovery, but Clopton is convinced that Coley's toxin should be used in these cases with

great thoroughness. He does not agree that all giant celled growths should have the toxin, because they are benign and should be eradicated if possible; but all other growths, whether operated upon or not, should get the injections and have the benefit of the röntgen ray in massive doses, or be treated with radium.

Differential Diagnosis of Diseases of the Hip Joint in Children.—Arthur T. Legg (*Boston Medical and Surgical Journal*, June 10, 1920) says that at times it is a matter of great difficulty to differentiate between the tuberculous and the non-tuberculous infection of this joint, and impossible until the case has been thoroughly studied. A most careful history should be obtained. A most complete physical examination should be made. A röntgenogram should be taken in every case of suspected bone or joint disease; and every laboratory method at our disposal should be used before making a positive diagnosis.

Complications of Bacillary Dysentery.—P. Manson-Bahr (*British Medical Journal*, June 12, 1920) describes an arthritis which occurs in the course of bacillary dysentery. It was noted twice in cases not treated with serum, but in the majority of cases it appeared subsequent to the injection of serum. There were two types of arthritis observed. The first was a transient polyarthritis appearing on the seventh to the twelfth day after serum injection and ushered in by symptoms of serum sickness. The second type was a prolonged, intractable form accompanied by a sudden effusion into the joint cavity but without signs of local inflammation, such as redness and heat. Of twenty-nine cases treated with serum, the transient type developed in eleven, and in eight the intractable type developed, while in three hundred and thirty-five cases, convalescent or light, not treated with serum, arthritis developed in only one.

Bacillary Dysentery in Children.—Wilburt C. Davison (*Bulletin of the Johns Hopkins Hospital*, July, 1920) used as the basis for this study 134 cases of diarrhea, seventy-one of which were diagnosed clinically as dysentery. More than eighty per cent. of the acute cases if ileocolitis were due to infection with *Bacillus dysenteriae*. In a control series of sixty-three cases of simple diarrhea and one hundred normal children *Bacillus dysenteriae* was not recovered from the stools in any instance. Dysentery was less prevalent among children receiving breast milk or boiled milk and boiled milk mixtures in boiled containers. Assistance in the diagnosis of dysentery can be gained by the agglutination reactions of the patient's serum by standardized technic. *Bacillus morgan* No. 1, *Bacillus welchii*, *Bacillus pyocyaneus*, *Bacillus proteus*, and the *Streptococcus fecalis* are not the cause of dysentery (ileocolitis) or diarrhea. Davison suggests that the name ileocolitis should be changed to dysentery in children and the disease made reportable to the health authorities.

Modification of the Action of Adrenalin by Chloroform.—W. J. R. Heinekamp (*Journal of Pharmacology and Experimental Therapeutics*, November, 1920) describes experiments proving the fact that chloroform is toxic for heart muscle, producing or tending to produce weakening of the organ. Inhibition under chloroform anesthesia after administration of adrenalin is due primarily to the toxic or paralytic dilatation of the heart, ventricular fibrillation supervening. Because of the action of chloroform on the heart, adrenalin is contraindicated wherever chloroform is employed and chloroform wherever adrenalin is used. The blood pressure has no definite reflex relation to the production of the condition of paralytic dilatation, but has a most important direct action by preventing the ventricle from emptying itself. The adrenalin action is peripheral, since it occurs after section of the vagi.

Diagnostic Signs in Tracheobronchial Adenopathy.—García Trivino (*La Medicina Ibero*, March 20, 1920) notes that the tracheobronchial glands are divided into two groups. The first or pretracheobronchial group lies in two parts alongside the trachea and in the superior angle formed by the trachea and the large bronchi. The second or intertracheobronchial group lies in the inferior angle formed by the bifurcation of the trachea. Clinical physical signs of enlargement of these glands are Smith's sign or venous hum over the manubrium of the sternum with the head in forced extension; D'Espine's sign of bronchophony or pectoriloquy below the level of the seventh cervical vertebra; Hochsinger's sign of glandular enlargement in the fourth and fifth intercostal spaces in the median axillary line. This condition of enlargement of the bronchial glands is much more common in children than in adults, and it predisposes to the invasion of the tubercle bacillus although the primary infection may be due to grippe, whooping cough, measles, or syphilis. In a final analysis a radiograph will either prove or disprove the existence of the glandular enlargement.

Tuberculous Myocarditis.—E. Lenoble (*Bulletin de l'Académie de médecine*, October 19, 1920) states that various arrhythmias may be met with in chronic or acute pulmonary tuberculosis. He has personally witnessed one case of sinus arrhythmia with alternating pulse; six cases of auricular fibrillation; two of nodal rhythm; three of premature beats; one of paroxysmal tachycardia with alternating pulse; one of prolongation of the *a-v* interval with alternation of the jugular pulse, and one showing secondary waves during the *a-v* interval. Fluoroscopic studies showed the heart to be sometimes small, as in the average case of tuberculosis; generally, however, it was enlarged as a whole or in one of its parts. The blood pressure ranged from seventy to 190 millimetres of mercury. The prognosis is unfavorable in these cases because the heart disturbances are an expression of a deep seated pathological change in the myocardium, superadded upon the tuberculous disease involving other organs. The existence of paroxysmal tachycardia or of nodal rhythm is particularly ominous. The diagnosis is based partly on the absence of a history

of rheumatism or other major infections. Out of fourteen cases in which a Wassermann test was made, the author obtained only one positive result. The gross pathology of the heart was rather variable, but microscopic study sometimes yielded rather striking changes. Actual angiomas were found at the junction of the superior vena cava with the auricular muscle tissue. Other conditions noted included fibrosis and lime infiltration about the bundle of His; perifascicular fibrous deposition, and changes in the vessel walls. In one of the cases of nodal rhythm the node of Keith and Flack was infiltrated with small primitive connective tissue cells compressing the muscle fibres. In the other case there was in addition thrombosis of the pectineal tissues. Out of nine guineapig inoculations, two were positive. The author recognizes not only an active type of heart muscle disease in tuberculosis, viz., bacillary myocarditis, but also a type attended with cicatricial deposits due to healed tuberculosis, such deposits being responsible for the arrhythmias observed. The connective tissue deposits, as in the case of the kidneys, need not necessarily contain tubercle bacilli. These deposits are due to the sclerosing toxins of the tubercle bacillus.

Determination of the Need of Surgery in Peptic Ulcer.—W. A. Bastedo (*American Journal of the Medical Sciences*, October, 1920) maintains that surgery in a case of peptic ulcer must not be resorted to too lightly. He considers surgery imperative and medical treatment futile in the following conditions: 1, Chronic penetration as shown by radiographs; 2, palpable induration; 3, adhesions which cause distortion of the stomach, interference with peristalsis, or much pain during the digestive period; 4, permanent hourglass; 5, pyloric stenosis not syphilitic; 6, repeated copious hemorrhages; 7, conditions which suggest that an ulcer is becoming carcinomatous. The majority of peptic ulcers can, in his opinion, be definitely said to require surgery only after the failure of thorough and prolonged medical treatment. When the case is medical, the relief of symptoms (not the cure) by treatment is, as a rule, quite prompt. Therefore, on the one hand, the failure of the treatment to relieve the symptoms suggests that the case is probably surgical; whereas, on the other hand, when a case seems in all likelihood surgical, but not certainly so, a course of medical treatment is advisable to prove the point. Furthermore, if the patient shows a positive Wassermann reaction or gives a history or any physical evidence of syphilis, antiluetic treatment should be tried. Given a thorough medical trial by someone competent to supervise the treatment, we should consider those cases surgical which continue to show: 1, persistent or recurrent hemorrhage even small in amount; 2, pain; 3, nausea; 4, pylorospasm of such persistence as to simulate pyloric stenosis; 5, inability to ingest comfortably the ordinary wholesome foods permitted by the circumstances of the patient, this making the poor patient a surgical case earlier than one who is well to do; 6, inability to ingest comfortably enough food to maintain nutrition while living a normally occupied life; 7, recurrence after apparently a cure.

Dry, Wet, and Ointment Dressings for Wounds.—Charles T. Souther (*Ohio State Medical Journal*, May, 1920) advises the use of dry gauze dressings in clean surgical cases. They may be used in cases in which suppuration is already established, especially when the wound is united or connected with a serous lined cavity. When mucous lined cavities are involved some form of ointment dressing is to be preferred. Wet dressings are indicated in the presence of cellulitis or when there is much edema in and about the wound. The use of Dakin's solution should be limited to the wound area and not come in contact with the skin. Wet dressings are contraindicated in outpatient clinical work in cold weather because of the danger of freezing. Bichloride does harm in solutions stronger than one in 10,000. Carbolic acid is extremely dangerous, even in weak solutions. Ointment dressings are of great value because they facilitate drainage, protect the surrounding skin from eczema, prevent albuminous exudate from getting dry and sealing a wound, and prevent infectious material from being absorbed. There is no pain on changing ointment dressings, nor any pull on the stitches. Epithelium grows faster under an ointment dressing. Ointment dressings need not be changed as frequently. Ointments with a mineral fat base are preferable.

Experimental Studies on Effects of Carbohydrate Diets in Diabetes.—Frederick M. Allen (*Journal of Experimental Medicine*, April, 1920) reports that the injurious effects of excessive carbohydrate feeding are demonstrable in partially depancreatized dogs in the same manner as in human patients, and that when a severe diabetes is produced there is a consequent rapid progress of emaciation, weakness, and early death of the animal. When a milder degree of diabetes is produced, the result after the operation frequently depends on the diet, so that if the tolerance is spared for a time recovery may occur to such a degree that it is impossible to produce diabetes by any kind or quantity of feeding, but a second operation, removing a small additional fragment of the pancreatic tissue is necessary. In this early period it is very important to give the proper degree of carbohydrate over-feeding in order to produce the most useful type of diabetic animals, that is, those with good digestion and general health, and with a permanent lowering of assimilative power comparable to the condition of the human diabetic. In the early part of the disease glucose was more powerful in producing glycosuria than starch. Admixtures of glucose given to an animal progressing toward complete recovery on a starch diet were capable of producing a helpless diabetes. This is accounted for by a difference in the rate of absorption, showing that a rapid flood of carbohydrate is more injurious to the pancreatic function than a slow absorption. But when a permanent diabetes is established, with no hope of recovery, starch brings on a glycosuria just as surely as sugar, if more slowly. From such experimental evidence the clinical deduction is drawn that even if a patient becomes free from glycosuria on withdrawal of sugar only, other foods should also be restricted. Experiments on com-

parisons of starches showed no significant difference in their assimilation, nor was there any extreme lowering of the carbohydrate tolerance by proteins, such as has been claimed by some authors in connection with the "oatmeal cure." As the basis for the early tendency to recovery, Allen mentions repair of traumatic inflammation and hypertrophy of the pancreas remnant, and as an accompaniment of the lowering of tolerance by excessive diet, hydropic degeneration of the islands of Langerhans.

A Simple Means of Obviating Anaphylactic Shock.—A. Lumière and J. Chevrotier (*Presse médicale*, November 6, 1920) report experimental work indicating that anaphylactic manifestations are due to the formation in the blood plasma, at the time of the second injection, of a colloidal flocculent precipitate which causes asphyxia by obstructing the capillaries. Seeking to find substances which might prevent such precipitation, they ascertained that among the few compounds effectual in this direction sodium hyposulphite was by far the least toxic. Addition of a considerable proportion of this salt to the animal serum constituting the second injection of protein was observed in experiments to prevent anaphylactic shock, to which, on the other hand, the control animals, unprotected by the salt, invariably succumbed. Similar experiments with antidiphtheritic serum gave the same results. The authors deem addition of sodium hyposulphite in suitable amount to therapeutic serums a simple, practical, and harmless means of obviating anaphylactic manifestations in clinical work.

Aftertreatment in Surgical Cases.—D'Arcy Power (*Practitioner*, July, 1920) gives the following suggestions concerning postanesthetic vomiting: The smell and the vomiting both have to be combated after ether and chloroform anesthesia. The smell of ether can be lessened by equal parts of eau-de-Cologne and water, used on a handkerchief, or sprinkled on the beard or mustache. The taste can be reduced by ordering a mouth wash of carbonate of soda (phenol, eight; caustic soda, three and one half; distilled water, one hundred), diluted ten or twenty times; or by phenol, six grains; citric acid, five grains to an ounce of Cologne water diluted to two ounces with warm water. The degree of vomiting varies with the length of the operation, the previous preparation of the patient, and with his individuality. It is most severe after the removal of enlarged cervical glands. When vomiting is not very severe, sips of hot water may be given. In more persistent cases fifteen grains of bicarbonate of soda may be dissolved in a tumblerful of hot water; the patient vomits it directly, but the sickness afterwards subsides. In very severe cases give nothing by mouth, but administer a sedative enema, consisting of bromide of potassium and chloral hydrate, each twenty grains, and mucilage of starch, two ounces. The author has never had to wash the stomach out to stop the vomiting. When vomiting has been unduly prolonged it is sometimes a good plan to feed the patient solid food rather than to restrict him to slops.

Proceedings of National and Local Societies

AMERICAN PEDIATRIC SOCIETY.

Thirty-second Annual Meeting, Held in Highland Park, Ill., May 31, June 1 and 2, 1920.

The President, Dr. THOMAS S. SOUTHWORTH, of New York, in the Chair.

(Continued from page 1008.)

The Ulcerated Meatus in the Circumcised Child.—Dr. JOSEPH BRENNEMAN, of Chicago, stated that ulceration of the meatus was very common in circumcised children. There was usually ulceration, scab formation, narrowing of the meatus, painful urination, often partial obstruction, and occasionally hemorrhage at the end of urination. The condition seemed always associated with what was known as the ammoniacal diaper, and apparently resulted from direct contact of the meatus with the wet diaper. The treatment consisted in applying vaseline or wet boric acid dressings to the meatus if inflamed and in the prophylaxis of the ammoniacal diaper. The latter was probably due to a metabolic disturbance that was not yet fully understood, but probably commonly due to over-feeding with cows' milk fat, as a result of which there was an excessive excretion of ammonium salts in the urine. Inasmuch as the ammonium salts must be broken down to liberate ammonia, and this was commonly effected by an alkali, it was well in addition to reducing the ammonium content of the urine to rinse the diapers to remove all excess of soap and also to boil them for a long time to eliminate the possible influence of bacterial action.

Treatment of Congenital Syphilis in Infants and Children.—Dr. WALTER R. RAMSEY and Dr. O. A. GROEBNER, of Minneapolis, presented a communication on further progress in the study of the relative efficiency of the different mercurial preparations in the treatment of congenital syphilis in infants and children as determined by a quantitative analysis of the mercury elimination in the urine. The paper was read by Dr. Ramsey who said that the treatment of syphilis with the different mercurial preparations was still a haphazard affair, the rule being to give as much mercury as the patient would tolerate without salivation or diarrhea. Assuming that the amount of mercury eliminated in the urine during a given time would give a fair index of the amount in the circulation, Dr. Ramsey and Dr. Ziegler had made some experiments, the report of which was read before this society in 1918 and had been published. In these experiments it was demonstrated that mercury, whether given by inunction, by mouth or by hypodermic injection, was eliminated in the urine in appreciable amounts. Where only one dose was given by any of these methods mercury continued to be eliminated in the urine for a variable time and in one case as long as ten days.

In this new series of experiments, they had sought to determine with some degree of accuracy the amount and rapidity of absorption and elimination of the common mercurial preparations in common use as determined by quantitative estimate of the

amounts eliminated in the urine. The method was the same as that employed in the previous experiments.

The practical deductions which might be drawn from this series of experiments were as follows: 1. Mercurial ointment fifty per cent. was to be preferred to the less concentrated preparations and should be repeated not more often than twice weekly instead of daily. 2. Calomel ointment was absorbed but less rapidly and to a less extent than mercurial ointment and should therefore be given in greater concentration twice weekly. 3. The salicylate of mercury in oil should be given hypodermically twice weekly instead of once. 4. The mercury chloride administered by hypodermic injection, although the dose was very small, continued to be eliminated for several days, but owing to the fact that its use was frequently followed by the appearance of protein in the urine should exclude it from the treatment of syphilis. 5. Calomel by the mouth was absorbed in small amounts and continued to be eliminated for a considerable time, therefore it was probable that it would be sufficient to give it at intervals of several days without producing diarrhea. 6. Gray powder was absorbed to a small degree and eliminated rapidly so that fairly large doses repeated daily would probably be necessary to maintain mercury in the circulation. Experiments were being continued to determine, if possible, whether the clinical results would bear out the observations made in this paper. In one case of congenital syphilis treated by inunctions, and not repeated oftener than once weekly, the clinical progress was apparently not less satisfactory than in cases in which daily inunctions were given.

A Study of the Incidence of Hereditary Syphilis.—Dr. P. G. JEANS and Dr. J. V. COOKE, of St. Louis, made this study which was aided through a grant from the U. S. Interdepartmental Social Hygiene Board. The material was collected from several sources, being almost equally divided between charity and private patients. The results presented were based on data collected from the first one thousand cases and as many of these as possible were examined at the end of two months. In these, histological examination of the placenta as to the presence or absence of syphilitic changes corresponded to the established diagnosis in 95.5 per cent. of the cases. The lack of correspondence consisted entirely in finding no syphilitic changes in the placenta in cases in which the infants had syphilis. In every instance in which the placenta was noted as having syphilitic changes the infant was found later to have syphilis. In this group of cases in which the diagnosis was established, the Wassermann reaction on the placental cord blood corresponded to the diagnosis in the infant in 96.5 per cent. Here also the discrepancies were entirely due to finding a negative Wassermann reaction in the fetal blood in instances in which the infant was syphilitic. In every instance in which the fetal blood gave a positive Wassermann reaction the

infant was later found to have syphilis. Of the 1,000 cases, 574 were of the dispensary or poorer class, and in this group there was an estimated incidence of syphilis in 9.6 per cent. Classified according to race, the incidence among negroes was 14.4 per cent., and among the whites 5.8 per cent. The observations tended to confirm the reliability of these methods and established the justification of applying either or both methods in making estimations. Among private patients able to pay a physician's fee and private room rates in a hospital, the estimated incidence based on an examination of placentas was 1.4 per cent. Including the doubtful cases the incidence was 1.9 per cent. Estimating the incidence from the Wassermann reaction on the cord blood, it was found to be 1.6 per cent., again showing the close agreement between the two methods. In some instances in which the infant had syphilis the maternal Wassermann alone was positive, in others the placenta alone. Therefore, in order to give a clean bill of health to an infant at birth it was necessary that all three examinations, maternal Wassermann, placenta and cord blood, should be negative. The fact that the treatment of the mother during pregnancy would result in a nonsyphilitic child had been confirmed by these observations. The total incidence of syphilis in the whole group was six per cent. It was their belief that the whole group fairly represented a cross section of the population of St. Louis, and if such was the case the incidence of hereditary syphilis at birth was six per cent.

A Study of Pneumonia in Infants and Children during the Recent Epidemics.—Dr. HENRY HEIMAN, of New York, presented an analysis of 336 cases of pneumonia admitted to the pediatric service of Mt. Sinai Hospital during the pandemic of influenza. Not all of these cases were influenza pneumonias; there were 288 bronchial pneumonias and forty-eight lobar pneumonias. The mortality was 16.6 per cent. With the exception of the two to five year period the mortality varied inversely as the age. A variety of organisms had been found in the sputum, including the influenza bacilli, pneumococci, streptococci, staphylococci, but none in sufficient predominance to justify conclusions. The x ray had been found to be of valuable assistance in the diagnosis of both types of pneumonia. The most frequent complication was otitis media which occurred in seventy-five of the 336 cases. Empyema developed in seventeen cases. When this complication occurred Dr. Heiman had advised against early operation before the acute stage of the pneumonic process had subsided.

Of prime importance in the treatment of pneumonia in children were hygienic care and efficient nursing, a bright sunny room and an abundance of fresh air, quiet surroundings and close supervision. Vigilance should be exercised to protect against infection of the eyes, skin and mouth. A cleansing bath should be given each morning as a routine measure. While fresh air was very necessary, the author did not favor the cold air treatment. It was important that the digestive tract should receive the closest attention. Milk of magnesium as an enema might be given at night. As a stimu-

lant aromatic spirits of ammonia might be given. In the moderately severe cases with high temperature hydrotherapy might be employed in the form of warm packs. In toxic cases atropine and adrenalin might be given. The promiscuous use of dry cupping was to be condemned. Dr. Heiman did not recommend the general use of digitalis in children, since as a rule the pulse was not lowered or the blood pressure raised by this agent. It was to be hoped that there would be a further differentiation of types of pneumonia in infants and children with the hope of securing specific therapy.

Lesions in the Midbrain.—Dr. J. H. M. KNOX, JR., of Baltimore, reviewed the anatomy of the midbrain and referred to the difficulty of distinguishing between symptoms that might be due to the destruction of nerve tissue by disease and those which were produced by alteration in function in the same area because of the involvement of neighboring structures. The syndromes of Weber, Benedict, and Nothnagel were described. In view of the confusing symptomatology often noted in patients suffering from midbrain lesions the case reported, in which the symptoms were comparatively definite and the pathological findings fairly circumscribed, was of interest. The patient was a colored boy, three years of age, brought to the Harriet Lane Home, Johns Hopkins Hospital, on February 3, 1915, because of general weakness, trembling, and drooping of the eyelids. The family and personal history of the patient were negative, the boy appeared perfectly normal until six months before admission, when he stopped crying almost completely. About four months later the tremor was noted and a little later the drooping of the eyelids. The outstanding abnormalities revealed by physical examination were some enlargement of the epitrochlear glands and the eye symptoms. The pupils reacted to light, the left better than the right. There was occasional lateral nystagmus of the right eye, marked bilateral ptosis of the eyelids, apparently equal on both sides, and a definite deviation of the eyeball to the right. Two weeks later the patient returned with the history of having had two attacks of paraplegia, having become very weak and limp after the second one. The symptoms before noted were increased. There was great uncertainty of movement and an examination of the fundi showed a very slight degree of secondary atrophy.

The spinal fluid was under marked pressure, gave a reaction for globulin, and contained an increased number of cells, mostly mononuclears. The x ray examination of the head showed a moderate hydrocephalus and a probable tumor above the sella turcica. About ten days after his admission a slight rigidity of the neck was noted, and from that time on the child grew constantly weaker, and there were slight daily fluctuations of temperature of about two and a half degrees. He died after being under observation for forty-two days. The acquired ptosis, the curious tremor of long standing noted in the extremities, and the gradually developing paralysis of the movements of the eyeballs, except those produced by the external recti with resulting external strabismus, in a child previously well, led one to venture the diagnosis of a tumor of the mid-

brain, interfering with the nuclei of the third and fourth cranial nerves. The ataxia might also be accounted for by lesions in this region, involving the red nucleus or cerebellar tracts. Toward the end there was certainly meningitis, probably of tuberculous origin, associated with hydrocephalus, although the tubercle bacillus was not demonstrated. The positive von Pirquet reaction and the subsequent development of meningitis suggested that the tumor was probably tuberculous in origin.

The postmortem findings were given leading to the anatomical diagnosis of solitary tubercle of the midbrain and right parietal lobe, together with tuberculous meningitis. The anatomical findings confirmed in the main the clinical symptoms described. The writer further discussed the affections produced by midbrain injury, and also the symptomatology of pineal tumor, which was identical with that of primary lesions of the midbrain. The order in which the symptoms developed was of the utmost importance in reaching an accurate diagnosis. When the early symptoms were general and attributable to increased cerebral pressure, such as headache, vomiting, optic atrophy, and hydrocephalus followed, it might be with ptosis and oculomotor palsies, one would be inclined to place the initial lesion outside of the midbrain, such symptoms might result from meningitis or tumor elsewhere, possibly originating in the pineal gland. Whereas, as in the case of the boy here reported, the limitation of the symptoms for months to ptosis and paralysis of the oculomotor nerves and tremor without evidence of intracranial pressure supported the diagnosis of an injury beginning in the midbrain and as far as it went the absence in this case of an increase of growth or of sexual development suggested that neither the pineal nor pituitary glands were involved.

Dyspituitarism, So-called: Absorption of Membranous Bones, Exophthalmos, and Polyuria.—Dr. ALFRED HAND, of Philadelphia, recalled a case which he had reported in the *Transactions of the Pathological Society of Philadelphia*, Vol. XVI, 1891-93, under the heading General Tuberculosis, and also in the *Archives of Pediatrics*, Vol. X, 1893, under the title of Polyuria and Tuberculosis. The patient was a boy three years old, seen December 1, 1892, with a history of great thirst and polyuria of sudden onset eight weeks earlier. He had had enterocolitis at the age of eight months, and croup and measles at the age of two years. The family history was negative. The boy was undersized, with a dry bronzed skin, exophthalmos, corneal opacities in each eye, and anterior synechiæ in the right. The thyroid was not enlarged. There had been rachitis. The urine had a specific gravity of 1,000 and the maximum quantity in twenty-four hours was 150 ounces, containing neither sugar nor albumin. After two months the boy died of bronchopneumonia, the main feature of autopsy being a yellow area of softening in the right parietal bone involving both tables of the skull, with other areas affecting only the outer table. The kidneys were enlarged, the left had three small cysts, and in the pelvis of each was a hard, tuberculous mass; the lungs showed bronchopneumonia, and there was

small round celled infiltration of the liver, spleen and kidneys, with degeneration of the epithelium of the uriniferous tubules.

Dr. Hand quoted the notes of a case shown before the Medical Society of the State of Pennsylvania, in 1906, by Dr. T. W. Kay, and reported by him as a case of acquired hydrocephalus, with atrophic bone changes, exophthalmos and polyuria. In the Osler Memorial Volume there was an article entitled Defects of Membranous Bones, Exophthalmos and Polyuria, an Unusual Syndrome of Dyspituitarism, by Dr. Henry A. Christian, who reported such a case and had found two similar ones described by a German writer, Schüller. The latter said: "We can, therefore, make a presumptive diagnosis of anomaly of the skeleton as a result of disease of the hypophysis." Dr. Christian treated his patient with pituitrin, which, when given under the skin and into a vein, caused great diminution in the amount of fluid ingested and excreted, but, given by mouth or rectum, had no effect. Dr. Christian also concluded that the condition was due to disturbed pituitary function.

Dr. Hand added to the group a sixth case which he had seen recently. This patient was a boy, four years of age, from whom there was removed at the age of two years a tumorlike swelling from the left parietal region; there was absence of bone beneath the tumor down to the dura. Section showed a slight degree of inflammation, but mainly a myxomatous change. Since then other swellings had appeared, and exophthalmos which was greater on the right, but as yet there had been no polyuria.

Analysis of these six cases seemed to render the theory of dyspituitarism insufficient to explain the syndrome, although the polyuria undoubtedly depended on a disturbance of the hypophysis; the bone changes seemed to be the primary condition, causing the exophthalmos mechanically by changes in the orbital plates, and the polyuria by changes in the sella turcica. The cause of the bone changes was not clear, and further observations were needed before this interesting and curious group of symptoms could be satisfactorily explained.

Use of Fresh Vaccines in Whooping Cough.—Dr. ROWLAND G. FREEMAN, of New York, stated that vaccines for the prevention and cure of whooping cough had been used for the past eight years, and, while some enthusiasm had been shown, the general opinion had been that they were of but little service in the treatment of whooping cough, although possibly of some value in its prevention. His own attitude was that they did not modify the course of whooping cough, and he had never seen a case of whooping cough apparently prevented by their use.

Two years ago he saw Dr. Hueneken's paper on the application of the complement fixation test for the detection of antibodies after the injection of whooping cough vaccines, in which he showed that the antibodies were not present unless the vaccines were freshly prepared, and that after a week of storage but little antibody protection resulted from their injection even in large doses. It seemed to him that this fact might explain the contradictory reports from the use of whooping cough vaccines

in the course of their work. He felt that it should be tried out. He was, however, unable to report any institution work, but had brought together all the cases in which he had used it in private practice, hoping to stimulate interest in these fresh vaccines and thus render it easier to obtain them. If we were to have an opportunity to give the vaccines a fair trial we must have a laboratory producing fresh vaccines every week.

The present series of cases, which Dr. Freeman reported, included sixteen children with whooping cough, in whom the vaccines had been used at various periods of the disease. In five cases no results were obtained. In three of these cases the vaccines were used early in the disease, and in the other two, very late. Of the eleven remaining cases, in nine a material improvement took place and in four a practical cure was obtained. His confidence in the vaccines had been somewhat shaken by the results in one family of six children, reported in this paper, who failed to react, but the good results obtained in other cases and the quite remarkable results obtained in certain beginning cases convinced him that these vaccines should have an extended use, particularly in institutions, where control might be used to demonstrate whether we might not have in these vaccines a valuable method of reducing the large mortality from whooping cough.

Some Observations on Rickets.—Dr. JOHN HOWLAND and Dr. EDWARDS A. PARK, of Baltimore, presented a contribution on this subject, which consisted of a lantern slide demonstration showing the alterations at the junction of the shaft and cartilage in rickets, as determined by the x ray. A definite correlation was shown between the x ray signs and the actual pathological conditions. Proof was adduced that the calcium deposits in the cartilage cast well defined shadows. The effectiveness of cod liver oil as a therapeutic agent in rickets was demonstrated by serial x ray pictures. In animal experiments a beginning calcium deposit was demonstrated two days after beginning the administration of cod liver oil. In human beings the calcium deposit in the cartilage was definitely demonstrable at the end of three weeks after beginning the administration of cod liver oil. The probable relation of cod liver oil to the process of repair was discussed.

Hypertrophic Stenosis.—Dr. H. M. McCLANAHAN, of Omaha, stated that since June, 1919, he had had under his care six cases of congenital hypertrophic stenosis complying with the following syndrome: Loss of weight; vomiting several times a day, frequently expulsive in character; stools small, dark, and without any evidence of milk digestion; visible peristaltic wave, and scanty urine. In three or four patients recovering without operation a movable tumor could be palpated. In one of the patients not operated upon the diagnosis was further confirmed by an x ray plate. Four of the six patients recovered under gruel feeding, their ages being five, five; seven, and eleven weeks. These infants were placed on thick gruel in the manner described by Dr. Sauer and later by Dr. Langley Porter. The rate of gain varied, but all made slow

but steady improvement. The fifth baby made fair progress for two weeks, but the parents, seeing the results in the next case reported, demanded operation. This baby was operated on and made a good recovery, but it was Dr. McClanahan's belief that this baby would have recovered without operation. The sixth patient was in desperate condition at the time of operation, the walls of the stomach being dark in color, in striking contrast to that of the intestines. This infant had congenital hypertrophic stenosis, general staphylococcus infection, and acute gastritis. The case would undoubtedly have terminated fatally without operation.

Focal Infections in Children.—Dr. OSCAR M. SCHLOSS stated that this report concerned cases of focal infection of the tonsils which were responsible for two types of disturbances. In one group of cases, the disturbances were cyclic in character, were accompanied by fever and persistent vomiting, with a large elimination of acetone bodies in the urine and an accumulation of acetone bodies in the blood. There were eight cases in this group. The other type of disturbance was evidenced by mild nephritis. The urine contained albumin in moderate amounts, red blood cells, hyaline and granular casts, and some leucocytes. These children were not especially ill. The symptoms were traced to a tonsillar infection and subsided promptly when the infected tonsils were removed. Two such cases were observed. In most of the cases in both groups the tonsils were not large. In several instances the tonsils had been previously removed and there remained only a small amount of tonsillar tissue between the faucal pillars.

Sarcoma of the Kidney.—Dr. ROWLAND G. FREEMAN, of New York, stated that this case was of interest because of the rapid production of metastases after operation, and also because of the type of tumor. The child was two and a half years of age and weighed twenty-six and a half pounds. When she came under observation she had been failing in health for two months. X ray examination confirmed the diagnosis of tumor of the kidney on the left side. Six weeks after operation she was brought back to the hospital in a desperate condition, with a temperature of 102° F., dyspnea, and râles over the entire chest. The x ray showed numerous metastases in the lungs.

A Case of Portal Thrombosis.—Dr. RICHARD M. SMITH, of Boston, stated that portal thrombosis was a rare condition in children. This patient, a child three years old, gave a history of acute rise in temperature with a cough of seven days' duration at the time of admission. The striking points in this case were the persistent fever, the enlarged liver and spleen, engorgement of the superficial abdominal veins, severe anemia, and intestinal hemorrhage. No diagnosis was reached during life. At autopsy thrombosis of the portal vein and its great radicles was found, with passive congestion of the spleen, ascites, hypertrophy and dilatation of the heart, edema of the lungs, and anemia. Undoubtedly the thrombosis was of infectious origin arising in connection with the initial infection of the respiratory tract.

(To be continued.)
